The expanded structure of ice plays a crucial ecological role in temperate and polar climates. The lower density of ice means that lakes, rivers, and polar oceans freeze from the top down, allowing fish and other aquatic life to survive in the liquid water below. Each fall, surface water cools first, and its density increases until its temperature reaches 4°C, the peak of the graph in Figure 10.30. This maximum-density water at 4°C sinks to the bottom, bringing warmer water to the surface, which in turn cools to 4°C and sinks, pushing the next layer of warm water to the surface in a continuing cycle (**Figure 10.32**). This autumnal turnover stirs up dissolved nutrients, making them available for life in the sunlit surface during the next growing season. When all the water has reached 4°C and the surface water cools further, it becomes less dense and ice may eventually form. The layer of ice insulates the 4°C water beneath it, allowing aquatic life to survive.

In spring, the ice melts and the surface water warms to 4°C. At this temperature, the entire column of water has nearly the same temperature and density; dissolved nutrients for plant growth are evenly distributed, and the stage is set for a burst of photosynthesis and biological activity called the spring bloom.

Further warming of the surface water creates a warm upper layer separated from colder, denser water by a *thermocline*, which is a sharp change in temperature between the two layers. Biological activity depletes the pool of nutrients above the thermocline as decaying biomass settles to the bottom. Consequently, photosynthetic activity drops from its spring maximum during the summer, even though there is much more energy available from the Sun. The thermocline persists until the autumn turnover mixes the water column and the cycle begins anew.

Glossary

surface tension

the energy needed to separate the molecules at the surface of a liquid.

meniscus

the concave or convex surface of a liquid in a small-diameter tube.

capillary action

the rise of a liquid in a narrow tube because of adhesive forces between the liquid and the tube and cohesive forces within the liquid.

viscosity

the resistance to flow of a liquid.

10.7 Polarity and Solubility

In Section 10.3 we explained the importance of ion–dipole interaction in the process by which ionic compounds dissolve in water. These interactions allow ionic compounds to dissolve in other polar solvents. Similarly, polar molecular compounds, such as sugars and low-molar-mass alcohols and ethers, dissolve in water and other polar solvents because of dipole–dipole interactions (and sometimes hydrogen bond formation) between molecules of solute and solvent. On the other hand, nonpolar compounds have limited solubility in water and other polar solvents, because the dissolution process relies on dipole–induced dipole interactions, which are much weaker than dipole–dipole interactions (see Table 10.3). These solute–solvent interactions are too weak to overcome the stronger interactions that attract molecules of solvent to other molecules of solvent and that attract molecules of solute to one another. The key point is that the solubility of a particular solute in a particular solvent results from a competition between the strengths of solvent–solvent and solute–solute interactions that inhibit the dissolving process and the solute–solvent interactions that promote it.

Figure 10.33 illustrates this key point. Figure 10.33a shows that molecules of methanol form hydrogen bonds with one another as do molecules of water, which means that molecules of methanol and water can form hydrogen bonds with each other. It is reasonable to assume that the strengths of the water–methanol hydrogen bonds are like those that form in pure water and pure methanol. The validity of this assumption is supported by the observation that methanol dissolves in water in all proportions, that is, these two liquids are *miscible* in each other.

CONNECTION *Miscible* was introduced in Section 5.1 to describe the homogeneous mixtures that gases form in all proportions.

On the other hand, Figure 10.33b shows that the hydrocarbon octane, C_8H_{18}, does not dissolve in water. Apparently, solute–solvent interactions based on relatively weak dipole–induced dipole interactions (see Table 10.3) between polar molecules of water and nonpolar octane molecules are no match for the strong hydrogen bonds between water molecules that would have to be disrupted to accommodate molecules of octane in an aqueous solution, plus the dispersion forces between the long hydrocarbon chains of octane molecules that would need to be disrupted if they were to dissolve in water. Thus, strong solute–solute and solvent–solvent interactions and a lack of strong solute–solvent interactions limit the solubility of octane in water (it is only about 7 μg of octane per liter of water at 20°C).

SAMPLE EXERCISE 10.5 Predicting Solubility in Water LO6

The compounds (a) carbon tetrachloride (CCl_4), (b) ammonia (NH_3), (c) hydrogen fluoride (HF), and (d) oxygen (O_2) are shown in **Figure 10.34**. Which ones are very soluble in water, and which ones have limited solubility in water?

Collect and Organize We are asked to predict the relative solubilities of four substances in water. Water is polar, which means compounds that are polar are more likely to dissolve in it than nonpolar compounds.

Analyze To judge which of the four substances is polar, we need to draw their Lewis structures and determine (1) which of them have polar bonds and (2) whether the arrangement of these bonds gives these molecules permanent dipoles, as described in Chapter 9.

Solve The Lewis structures of the four compounds are shown in Figure 10.34. An analysis of their bond dipoles and the three-dimensional orientation of their bonds reveals that the tetrahedral molecular symmetry of CCl_4 makes it a nonpolar compound (as is O_2), but the asymmetry of the trigonal pyramidal molecular shape of NH_3 makes it a polar compound (as is HF). The polar compounds (NH_3 and HF) should be soluble in water, but the nonpolar ones (CCl_4 and O_2) should have only limited solubility in water. Also, NH_3 and HF form hydrogen bonds, another property they share with water, making them even more likely to be water soluble.

Think About It Our conclusion that the two nonpolar compounds should have limited solubility in water is supported by an analysis of the intermolecular forces involved, particularly the relatively high strength of the hydrogen bonds in water that must be disrupted to accommodate the molecules of these solutes and the relatively low strength of the dipole–induced dipole interactions between these solutes and water that promote the dissolution process.

Practice Exercise In Chapter 5 we mentioned that some deep-sea divers breathe a mixture of gases rich in helium because the solubility of helium gas in blood is lower than the solubility of nitrogen gas in blood. Assuming these gases dissolve in blood plasma as they do in water, why should helium be less soluble in water than nitrogen is?

The unlimited solubility of methanol in water and very limited solubility of octane in water illustrate an important solubility principle: polar solutes tend to dissolve in polar solvents, but nonpolar solutes tend not to dissolve in polar solvents. This principle may lead you to wonder whether nonpolar solutes tend to dissolve in *non*polar solvents. Indeed, they do. In fact, the ability of polar solvents to dissolve polar solutes and nonpolar solvents to dissolve nonpolar solutes leads to a simple, widely used description of solubility: *like dissolves like*. Among the common nonpolar solvents is the principal ingredient in some household cleaners (**Figure 10.35**) that remove grease, crayon wax, adhesives, and other nonpolar materials from surfaces and fabrics. It is often labeled *petroleum distillate*, which means a mixture of hydrocarbons derived from crude oil. These hydrocarbons are effective in dissolving nonpolar substances because they are also nonpolar.

Surfactants are organic compounds that are the principal cleaning agents in the detergents used to wash laundry and dirty dishes and, when needed, to clean the oiled feathers and fur of marine birds and mammals that encounter petroleum spills (see this chapter's opening photo). Surfactants are composed of long hydrocarbon chains bonded to ionic groups (**Figure 10.36**). The ionic group helps make these compounds soluble in water, but once they dissolve in water their molecules collect on the surface with their ionic *heads* in the water and the nonpolar hydrocarbon *tails* sticking above the surface. This orientation makes it possible for clusters of the tails to interact with and dissolve grease and oil spots on clothes, fatty food residues on dishes, and the oiled feathers and fur of marine birds and mammals.

Let's consider a medical application of "like dissolves like." For more than 150 years diethyl ether, $CH_3CH_2OCH_2CH_3$, was widely used in medicine as an anesthetic. As we have seen in this chapter, ethers have the general formula R—O—R′, where R and R′ are straight-chain or branched hydrocarbons or aromatic rings (R and R ′ may be the same or different organic groups). Because the C—O—C bond angle is close to the tetrahedral bond angle of 109.5°, the dipole moments of the two C—O bonds in an ether do not cancel, which means that ethers are polar molecules. This structural feature means that the solubilities of ethers in water are comparable to those of alcohols of similar molar mass. However, their boiling points are much lower than those of similar alcohols (see Figure 10.20) because molecules of ethers do not form hydrogen bonds with one another as molecules of alcohols do.

This combination of volatility and solubility helped make diethyl ether an effective anesthetic. Patients inhaled its vapor, which readily dissolved in blood passing through their lungs and was transported throughout the body. The presence of short hydrocarbon chains helped make diethyl ether soluble in nonpolar cell membranes where it blocked nerve stimuli and made the patients lose consciousness. Ether has the unfortunate effect of inducing nausea and headaches and it is flammable, which contributed to its being replaced by volatile, nonflammable halogenated hydrocarbons, such as CHClBrF, which are used for general anesthesia today.

Combinations of Intermolecular Forces

The surfactants used in detergents are an example of substances whose molecules are composed of functional groups (ionic or polar) that promote their solubility in water *and* nonpolar regions that inhibit aqueous solubility. Those that promote the molecule’s solubility in water are called hydrophilic (“water-loving”) interactions, and the nonpolar regions that inhibit it are called hydrophobic (literally, “water-fearing”) regions. The solubility of a compound whose molecules contain both polar and nonpolar or ionizable groups is a balancing act between hydrophilic and hydrophobic interactions. As the hydrophobic portion of the molecule increases in size, the entire molecule becomes more hydrophobic and solubility in water decreases. At the same time, solubility of these molecules in nonpolar solvent increases.

One way that scientists determine the relative affinities of compounds for polar versus nonpolar solvents is to try dissolving them in a mixture of both types at the same time. A common combination of polar and nonpolar solvents that is used for such tests is water and 1-octanol, $CH_3(CH_2)_7OH$ (**Figure 10.37**). When a compound is added to a mixture of these two immiscible liquids and the mixture is vigorously shaken, some of the compound may dissolve in the water layer and some in the 1-octanol layer. After the compound has completely dissolved, its concentration is determined in each layer and the ratio of the concentrations is calculated. **Figure 10.38** shows the results of a set of these experiments in which the test compounds were alcohols with the generic formula $CH_3(CH_2)_nOH$, where n ranges from 0 to 9, that is, from methanol, CH_3OH, to 1-decanol, $CH_3(CH_2)_9OH$.

The data plotted in Figure 10.38 show a steady increase in the ratio of 1-octanol to water as the length of the hydrocarbon chains of the alcohols increases from one carbon atom to ten. This trend makes sense because the longer hydrophobic chains increase their affinity for a nonpolar solvent and decrease their solubility in water. Also note that the *y*-axis is not linear. Each tick mark represents a factor of 10 change in the concentration ratio: the highest value (1-decanol, 3.7×10^4) is over 10^5 times that of the lowest (methanol, 0.17). The very small ratios for methanol and ethanol are consistent with the fact that both are miscible in water.

You may be wondering why scientists are interested in ratios such as those in Figure 10.38. One reason is the need to predict the impact of water pollution on aquatic organisms. Many of the cells in these organisms are surrounded by nonpolar membranes. Pollutants with high ratios of 1-octanol to water are likely to be composed of molecules that can penetrate these nonpolar cell membranes and disrupt cell function once inside.

SAMPLE EXERCISE 10.6 Predicting Miscibility of Liquids LO6

Predict which pairs of liquids are miscible. Explain your predictions. (a) Ethylene glycol ($HOCH_2CH_2OH$) and water; (b) benzene (C_6H_6) and pentane ($CH_3CH_2CH_2CH_2CH_3$); (c) octanol

($CH_3CH_2CH_2CH_2CH_2CH_2CH_2CH_2OH$) and octane ($CH_3CH_2CH_2CH_2CH_2CH_2CH_2CH_3$)

Collect and Organize We are given the formulas of different liquids and we want to determine their miscibility. We discussed the cyclic molecular structure of benzene in Section 8.4. We can apply a molecular-level understanding of the common phrase "like dissolves like" to predict miscibility.

Analyze To predict miscibility, we need to consider the composition of and molecular structure of each pair of compounds —particularly the presence of polar functional groups, and especially those capable of hydrogen bonding—and the length of nonpolar hydrocarbon chains.

Solve

1. Ethylene glycol is an organic liquid with two –OH groups per molecule that can form as many as six hydrogen bonds to nearby water molecules. Prediction: the two liquids are miscible.
2. Benzene and pentane are both nonpolar hydrocarbons. Given the "like dissolves like" mantra, the two should be miscible.
3. Octanol has a polar –OH group capable of forming hydrogen bonds, whereas octane does not and is completely nonpolar. However, octanol and octane both have hydrocarbon chains of the same length. The dispersion forces associated with these chains interacting should lead to their miscibility.

Think About It "Like dissolves like" was the guiding principle in all three predictions: in (a) both compounds form hydrogen bonds; in (b) and (c) the principal mode of interaction in the pure liquids and their miscible mixtures is dispersion forces. The fact that octanol molecules also form hydrogen bonds was overwhelmed by the length of their hydrocarbon chains, demonstrating the strength-in-numbers aspect of dispersion forces.

Practice Exercise Predict whether methanol (CH_3OH) or hexanol ($CH_3CH_2CH_2CH_2CH_2CH_2OH$) would be more soluble in acetone (Figure 10.7). Explain your answer.

Glossary

ether

an organic compound whose molecules have an R—O—R′ structure.

hydrophilic

a “water-loving,” or attractive, interaction between a solute and water that promotes water solubility.

hydrophobic

a “water-fearing,” or repulsive, interaction between a solute and water that diminishes water solubility.

$$0.112 = \frac{0.100 - x}{x}$$

$$0.112x = 0.100 - x$$

$$x + 0.112x = 0.100$$

$$x = 0.0899 \text{ g}$$

10.8 Solubility of Gases in Water

Even though the solubility of oxygen in water is only about 10 mg/L at atmospheric pressure and room temperature, that is usually enough to sustain aquatic life in marine and freshwater ecosystems. However, the solubility of O_2 and of most other gases in water decreases with increasing temperature, and fish suffering from a lack of oxygen may be observed at the surface gasping for air in very warm weather. The solubility of gases in water also decreases with decreasing pressure, as demonstrated by the audible rush of escaping gas when a bottle containing a carbonated beverage is opened.

CONNECTION The kinetic molecular theory of gases (Section 5.8) is a model that explains the behavior of ideal gases. Partial pressure (Section 5.7) is the contribution to the total pressure made by one gas in a mixture of gases.

Figure 10.39 shows a particulate view of the influence of temperature on the solubility of O_2 (or any nonpolar gas). At low temperatures there is an equilibrium between O_2 in the air and dissolved O_2 in the water. At a higher temperature, O_2 molecules have more kinetic energy, which allows them to overcome the dipole–induced dipole interactions that keep them in solution. As a result, a greater fraction of the molecules escapes into the gas phase, decreasing their concentration in solution (Figure 10.39b).

The solubility of an atmospheric gas in a liquid such as water also depends on the partial pressure of the gas in the air above the surface of the liquid. For example, the partial pressure of O_2 at sea level is a steady 0.21 atm, but the lower partial pressure of oxygen at higher altitudes reduces O_2 concentrations in rivers and lakes and in other liquids, including the blood and tissues of humans and animals. When people travel to regions of low atmospheric pressure, such as the tops of mountains, they may need supplemental oxygen to function normally because of the decreased partial pressure of oxygen. Climbers of Earth's highest mountains may become weak and unable to think clearly from a lack of oxygen in the brain, a condition known as *hypoxia.*

To visualize this pressure dependence of gas solubility on a particulate level, consider the populations of gas molecules above the liquid surfaces in **Figure 10.40**. The gas in the container on the left is air in which $P_{O_2} = 0.21$ atm. The gas in the container on the right is pure O_2 at a pressure of 1.00 atm. The amount of O_2 that dissolves in either liquid depends on the frequency at which O_2 molecules collide with the surface. These collisions should occur nearly five times more frequently in the liquid on the right, which should result in five times the concentration of dissolved O_2 in that beaker. If the cover on the right is removed and the pure O_2 in it mixes with and is eventually replaced by air, decreasing P_{O_2} values produce decreasing concentrations of dissolved O_2, which eventually match that of the water in the container on the left. This is essentially what happens (though on a longer time scale) when opening carbonated beverages; as the lid opens, the pressure drops and the CO_2 gas escapes from the fluid, releasing bubbles and producing fizz.

The relationship between gas solubility in a liquid and the partial pressure of the gas in the environment surrounding the liquid applies to all sparingly soluble gases. The quantitative statement based on this observation is known as Henry's law in honor of William Henry (1775–1836), a British physician who first proposed the relationship:

where C_{gas} represents the concentration (solubility) of a gas in a particular solvent, k_H is the Henry's law constant for the gas in that solvent, and P_{gas} is the partial pressure of the gas in the environment surrounding the solvent. When C_{gas} is expressed in molarity and P_{gas} in atmospheres, the units of the Henry's law constant are moles per liter-atmosphere, mol/(L · atm). **Table 10.4** lists k_H values for several common gases in water.

Henry's law explains why the concentration of dissolved oxygen in blood is proportional to the partial pressure of oxygen in the air we inhale and thus is proportional to atmospheric pressure. Although this is an accurate statement of Henry's law, the residents of Denver, Colorado, or Kimberley, British Columbia, Canada (average atmospheric pressure 0.85 atm), do not live with less oxygen in their blood than the residents of New York City or Rome, Italy (average atmospheric pressure 1.00 atm). The oxygen transport system in our bodies must adjust to accommodate local atmospheric conditions.

TABLE 10.4 Henry's Law Constants for Gas Solubility in Water at 20°C

Gas	k_H [mol/(L · atm)]
He	3.5×10^{-4}
O_2	1.3×10^{-3}
N_2	6.7×10^{-4}

The amount of oxygen in the blood is related to both the concentration of hemoglobin and the fraction of the hemoglobin sites that contain oxygen as the blood leaves the lungs. This saturation of binding sites depends on the partial pressure of oxygen, as well as on proper lung function. For most people, breathing air with $P_{O2} > 0.11$ atm results in nearly 100% saturation of hemoglobin binding sites. If P_{O_2} decreases to about 0.066 atm (as it does on high mountains), the percent saturation decreases to about 80%. Over several weeks, the body responds to lower oxygen partial pressures by producing more red blood cells and more hemoglobin. This increase in the concentration of hemoglobin, and therefore in the number of O_2 binding sites, compensates for the lower partial pressure of O_2. Even though less than 100% of the oxygen binding sites are saturated, the actual number of oxygen binding sites has increased because of the production of more hemoglobin molecules, and therefore the same amount of O_2 is delivered to tissues. Some endurance athletes try to capitalize on these physiological effects by using a technique known as "live high, train low." They acclimate to higher altitudes, typically defined as any elevation above 1500 meters (5000 ft), to bring about the physiological changes, but they continue to train at lower elevations.

SAMPLE EXERCISE 10.7 Calculating Gas Solubility by Using Henry's Law LO7

Calculate the solubility of oxygen in water in moles per liter at 1.00 atm pressure and 20°C. The mole fraction of O_2 in air is 0.209. (Remember that the sum of the mole fractions of all the gases in a mixture equals 1.)

Collect and Organize We are given the mole fraction of oxygen in air and the total (atmospheric) pressure. Henry's law (Equation 10.3) relates solubility to partial pressure. Table 10.4 gives this Henry's law constant for oxygen at 20°C as 1.3×10^{-3} mol/(L · atm).

Analyze We need the partial pressure of oxygen for Henry's law:

The product of the mole fraction of $O_2 (X_{O_2})$ times its total pressure gives us its partial pressure, which we use in Equation 10.3 to calculate the solubility of oxygen. We predict that oxygen is not very soluble in water because the interactions involved are weak dipole–induced dipole forces.

Solve We calculate the partial pressure of oxygen by using Equation 5.25:

$$P_{O_2} = X_{O_2}P_{\text{total}} = (0.209)\,(1.00\text{ atm}) = 0.209\text{ atm}$$

Substituting this value for P_{O_2} and k_H for O_2 in water in Equation 10.3 gives

---

Think About It We predicted in Sample Exercise 10.5 that oxygen is not very soluble in water because O_2 is a nonpolar solute and water is a polar solvent, and the answer agrees with that prediction.

Practice Exercise Calculate the solubility of oxygen in water at the top of Mt. Everest, where atmospheric pressure is 0.35 atm. (Assume that the Henry's law constant for oxygen at 20°C is unchanged at the top of Mt. Everest.)

SAMPLE EXERCISE 10.8 Integrating Concepts: Testing Drug Candidates

In Section 10.7 we described how dissolving a substance in a mixture of two immiscible liquids, water and 1-octanol, allowed environmental scientists to evaluate the likelihood that the substance would be biologically available to aquatic organisms. The same test is also used by pharmaceutical scientists to determine whether a drug under development is hydrophilic enough to be transported in circulating blood plasma, but at the same time hydrophobic enough to pass through nonpolar cell membranes. The ratio of the concentration of the drug candidate in 1-octanol to its concentration in water provides a measure of how well-balanced are its hydrophobic versus hydrophilic properties.

1. Draw a rough sketch of a tube containing 10 mL of water (density 1.00 g/mL) and 10 mL of octanol (density 0.83 g/mL). Indicate each fluid clearly and suggest what the meniscus would look like.

2. Two anticancer drugs that are best known by the acronyms 5-FU and BCNU are shown in **Figure 10.41**. Which one should have the higher octanol–water concentration ratio. Explain your prediction.

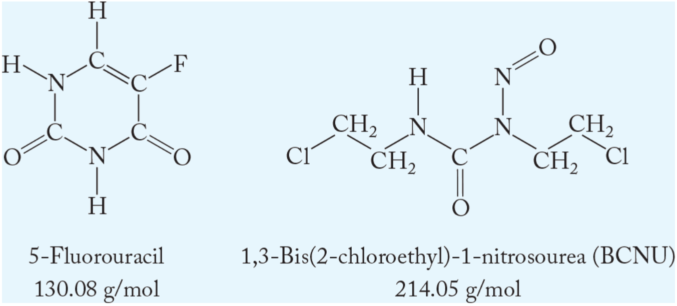

FIGURE 10.41 Structures and molar masses of 5-FU and BCNU.

---

3. The octanol–water concentration ratio for 5-FU is 0.112. If 0.100 g 5-FU are mixed with and dissolved in equal volumes of 1-octanol and water, what mass of the drug should dissolve in the water and how much in the 1-octanol?

Collect and Organize To run the experiment described, we have octanol and water together in a test tube. We are given the structures of two anticancer drugs and the value of one of their octanol–water partition coefficients.

Analyze We know that 1-octanol and water are immiscible liquids and that 1-octanol is less dense than water. Therefore, it will be the top liquid in the test tube and the compound that forms a meniscus with the glass wall of the test tube. To predict solubility trends for the two drug candidates, we need to examine their structures for polar and nonpolar groups and for their capacity to form hydrogen bonds.

Solve

1. The nonpolar character of 1-octanol means it will experience little attraction to the polar glass surface of the test tube, resulting in a meniscus that is much less concave than the one that water would form (**Figure 10.42**).

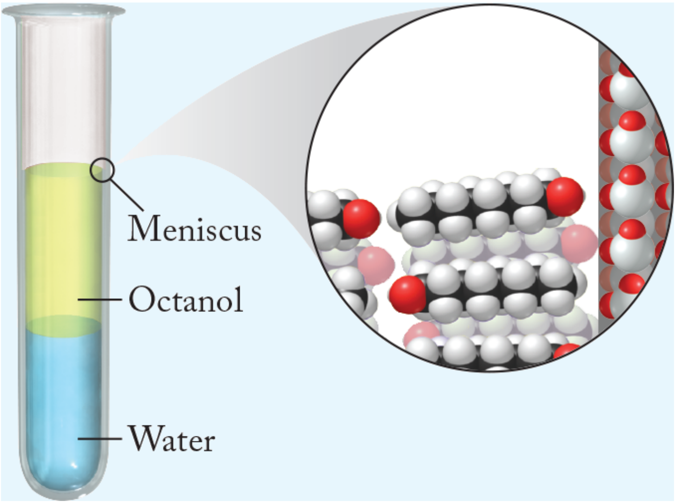

FIGURE 10.42 Test tube containing water and 1-octanol.

2. 5-FU has two –NH groups and two C═O groups capable of hydrogen bonding with water. BCNU has only one –NH group and one C═O group; it also has two other nitrogen atoms, but one is *sp*^{2} hybridized and attached to a more electronegative oxygen atom, so it would not have electrons readily available to bond with a hydrogen atom in water. In addition, the molar mass of BCNU is almost twice that of 5-FU; contributing to this additional mass are four nonpolar CH_2 groups. All these factors suggest that 5-fluorouracil should be the more water-soluble of the two drugs and the one with the smaller 1-octanol–water partition coefficient.
3. Because equal volumes of the two solvents were used, the ratio of concentrations of 5-fluorouracil in them is the same as the ratio of the masses of 5-fluorouracil in them, so that:

$$0.112 = \frac{\text{g drug in octanol}}{\text{g drug in water}}$$

If the total amount of drug added to the test tube is 0.100 g, we can call the amount dissolved in water x and the amount dissolved in octanol $0.100 - x$. Substituting these expressions into the above ratio:

Therefore, the amount of 5-FU dissolved in water is 0.0899 g and the amount dissolved in 1-octanol is 0.0101 g.

Think About It Our analysis of the molecular structure of 5-FU in part (b) disclosed a high density of polar groups, including four capable of forming hydrogen bonds, which should make this compound more hydrophilic than BCNU with a lower 1-octanol–water ratio. These conclusions were supported by the low value (0.112) of the concentration ratio we were given to use in calculating the distribution of 5-FU between the two solvents in part (c). Thus, the results calculated in part (c) served to validate the predictions in part (b).

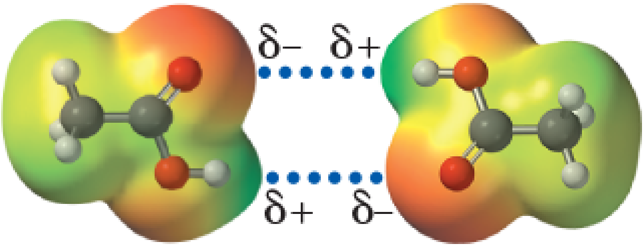
Glossary

Henry's law

the principle that the concentration of a sparingly soluble, chemically unreactive gas in a liquid is proportional to the partial pressure of the gas.

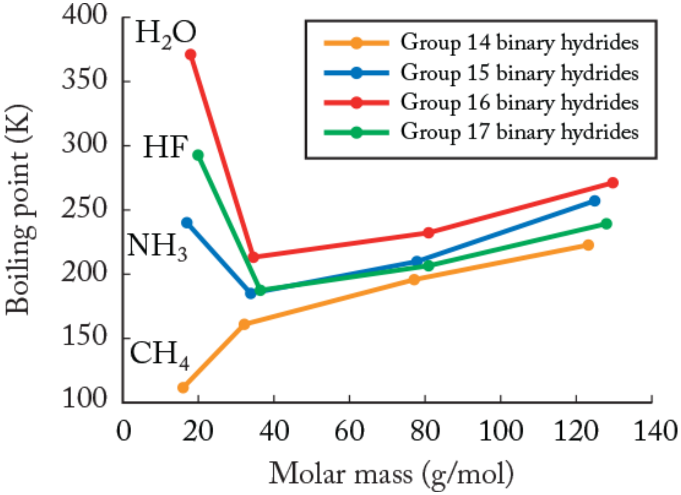
Learning Objectives

- Explain how temperature, pressure, and intermolecular forces influence the solubilities of gases in liquids and use Henry's law to calculate those solubilities **Return to Sample Exercise 10.7**

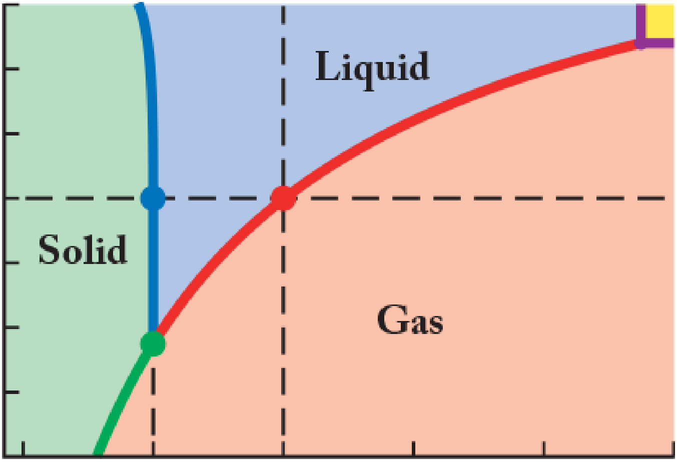


SUMMARY

LO1 The solubility of ionic compounds in water is aided by strong ion–dipole interactions. Asymmetric molecules with permanent dipoles are attracted to each other via dipole–dipole interactions, the strengths of which are linked to their dipole moments. The strongest dipole–dipole interactions are hydrogen bonds that involve H atoms bonded to N, O, or F atoms. All molecules and individual atoms experience dispersion forces that grow in strength with increasing molar mass and particle surface area. These forces are the result of temporary induced dipoles, the strengths of which are linked to the polarizability of particles, which increases with increasing number of electrons surrounding their nuclei. (Sections 10.2 and 10.3)

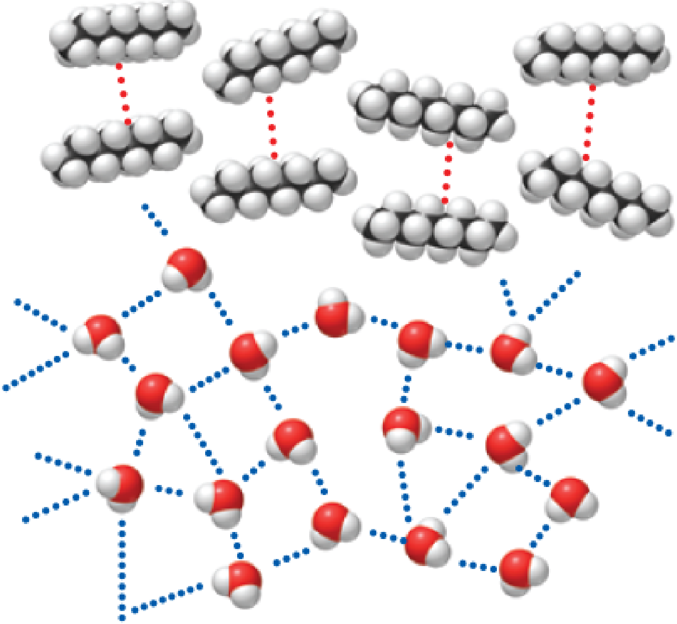


- LO2 The vapor pressures of liquids decrease, and their boiling points increase with increasing strengths of the intermolecular interactions between their molecules. (Section 10.3)
- LO3 The relative volatility of substances depends on the strength of the intermolecular interactions between particles. The Clausius–Clapeyron equation relates vapor pressure, the pressure exerted by a gas in equilibrium with its liquid phase, to absolute temperature. (Section 10.4)



- LO4 The phase diagram of a substance indicates whether the substance exists as a solid, liquid, gas, or supercritical fluid at particular combinations of pressure and temperature. For nearly all substances (except water), solid → liquid, solid → gas, and liquid → gas transitions occur at higher temperatures when pressure is increased. (Section 10.5)

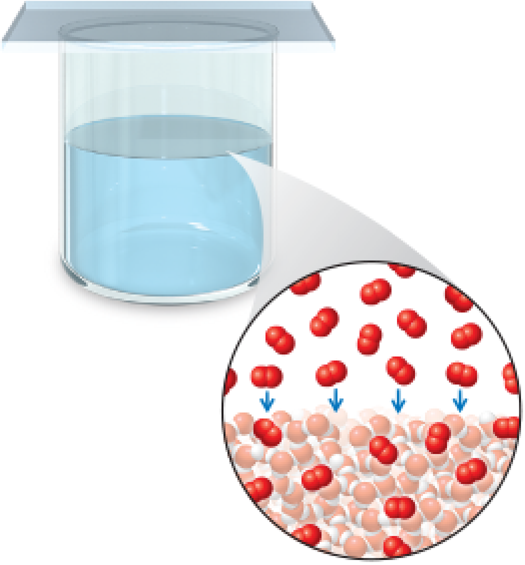
- LO5 The remarkable behavior of water, including its high melting and boiling points, its surface tension, its capillary action, and its viscosity, results from the strength of intermolecular hydrogen bonds. (Section 10.6)



Water–octane mixture

- LO6 Identifying the types of intermolecular forces between particles helps explain solubilities. The relationship is summarized by the phrase “like dissolves like.” Hydrophilic (polar) substances are more soluble in water than are hydrophobic (nonpolar) substances. (Section 10.7)

- LO7 The solubility of a gas in water decreases as the temperature increases because more molecules of dissolved gas have enough energy to overcome solute–solvent interactions. Solubility increases as the partial pressure of the gas increases because more frequent collisions between gas molecules and the water surface increase their concentration in solution. Henry’s law gives the maximum concentration (the solubility) of a sparingly soluble gas in a liquid solvent. (Section 10.8)



PARTICULATE PREVIEW WRAP-UP

Molecules of ethanol and dimethyl ether experience similar dispersion forces because they have the same composition and molar mass. However, the hydrogen bonds between molecules of ethanol are stronger than the dipole–dipole interactions between molecules of dimethyl ether. The additional intermolecular attraction created by these hydrogen bonds is the reason that ethanol is a liquid at room temperature, whereas dimethyl ether is a gas.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts and Equations	Sample Exercises
Explaining differences in boiling points of liquids and trends in boiling points of pure substances	Larger molecules generally have higher boiling points than smaller molecules, with notable exceptions. The presence of polar –OH and –NH groups in molecules of a liquid leads to intermolecular hydrogen bonding that markedly increases the boiling point of the liquid.	10.1, 10.2
Calculating the vapor pressure, enthalpy of vaporization, or temperature of a liquid	Use the Clausius–Clapeyron equation: $$\ln\left(\frac{P_{\text{vap},T_2}}{P_{\text{vap},T_1}}\right) = -\frac{\Delta H_{\text{vap}}}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right) \quad (10.2)$$ and solve for the unknown value.	10.3
Reading a phase diagram	Locate the point (T, P) specified by the question as the starting point for the exercise. Temperature is on the horizontal axis; pressure is on the vertical axis. When you draw a line either horizontally rightward from the pressure axis or vertically upward from the temperature axis, a phase change occurs wherever the line crosses an equilibrium line.	10.4
Predicting solubility in water and the miscibility of liquids	Polar molecules are more soluble in water than nonpolar molecules. Molecules that form hydrogen bonds are more soluble in water than molecules that cannot form hydrogen bonds. Like dissolves like.	10.5, 10.6
Calculating the solubility of a gas by using Henry's law	Use Henry's law: $$C_{\text{gas}} = k_{\text{H}}P_{\text{gas}} \quad (10.3)$$ where C_{gas} is the solubility of the gas; k_{H} is a constant that depends on the gas, the solvent, and the temperature; and P_{gas} is the pressure of the gas (or partial pressure if the gas is part of a mixture of gases).	10.7

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

In Figure P10.1, identify the physical state (solid, liquid, or gas) of xenon and classify the attractive forces between the xenon atoms. How does the particulate representation in Figure P10.1 change as temperature increases?

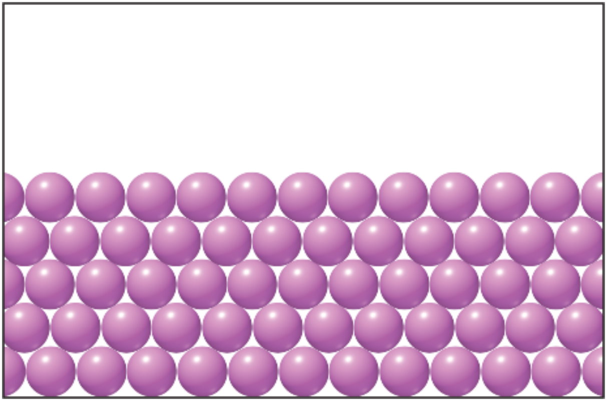


FIGURE P10.1

The molecules of three alkanes are depicted in Figure P10.2. Which of the three has the lowest boiling point? Explain your answer.

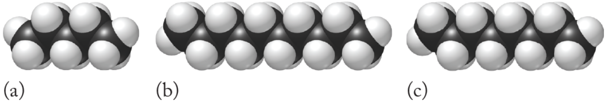

FIGURE P10.2

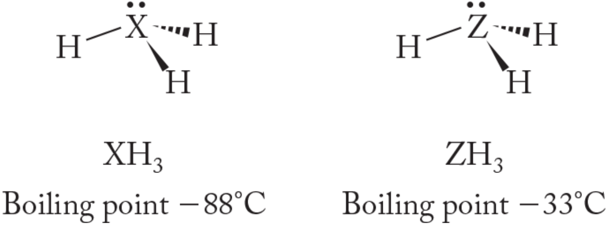
Which of the three alkanes in Figure P10.2 is the least soluble in water? Explain your answer.

Figure P10.4 shows molecules of XH_3 and ZH_3 (not shown to scale) and the boiling points of XH_3 and ZH_3 at 1 atm pressure. One substance is phosphine (PH_3) and the other substance is ammonia (NH_3). Which molecule is phosphine? Explain your answer.



FIGURE

P10.4

The graphs in Figure P10.5 have the same scales and describe the change in ln P_{vap} of two pure liquids as a function of temperature. Which liquid has the stronger intermolecular attractive forces? Explain your answer.

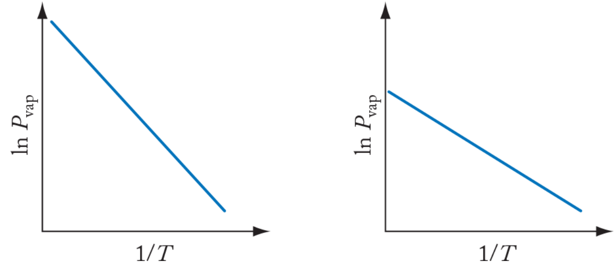


FIGURE P10.5

Which of the drawings in Figure P10.6, both of which are at constant temperature, most likely illustrates the pure liquid with the lower normal boiling point? Explain your choice.

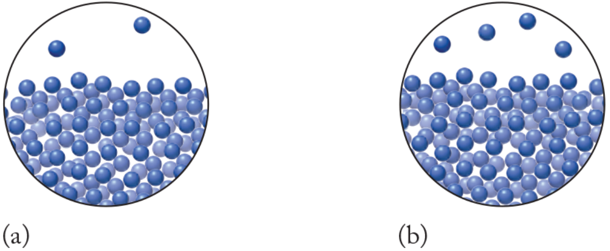

FIGURE P10.6

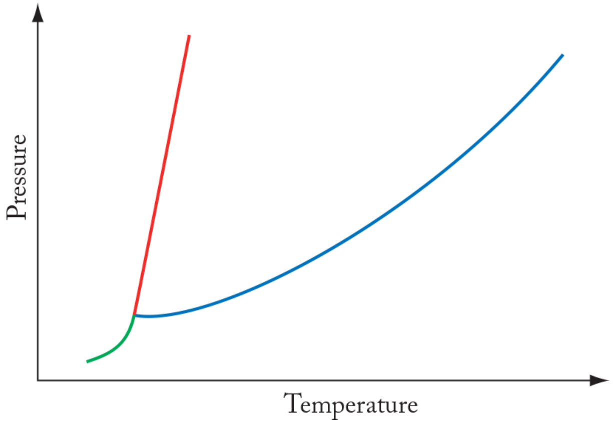
Examine the phase diagram of substance Z in Figure P10.7. (a) Does the freezing point of the substance increase or decrease with increasing pressure? (b) Do you predict the solid phase of substance Z would float on the liquid phase?

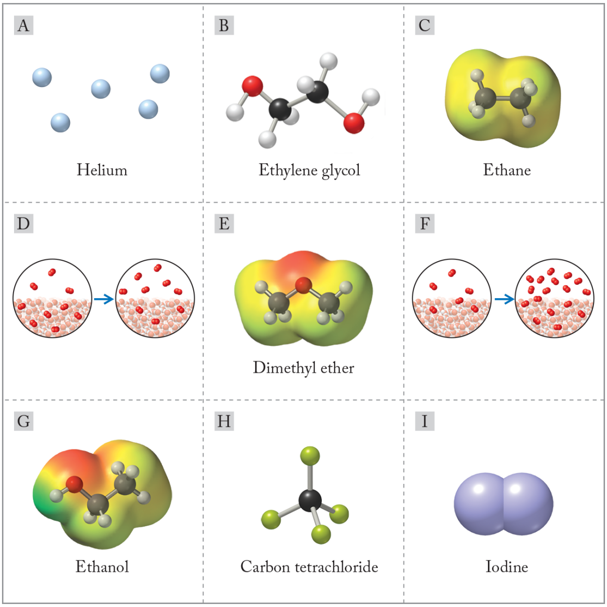


Why?

FIGURE P10.7

Use representations [A] through [I] in Figure P10.8 to answer questions (a)–(f).

1. What are the predominant intermolecular forces in each of the substances in the electrostatic potential maps?
2. Which substance requires the lowest temperature to condense?
3. Which representations are isomers of one another?
4. Consider ethylene glycol and iodine. Which will dissolve in ethanol? Which will dissolve in carbon tetrachloride? Name the intermolecular forces responsible.
5. Which process shows an increase in partial pressure?
6. Which process would occur due to an increase in temperature?



A
Helium
B
Ethylene glycol
C
Ethane
D
E
Dimethyl ether
F
G
Ethanol
H
Carbon tetrachloride
I
Iodine

FIGURE P10.8

QUESTIONS AND PROBLEMS

Dispersion Forces

Concept Review

Which type of intermolecular force exists in all substances?

At room temperature, bromine (Br_2) is a corrosive red liquid, whereas iodine (I_2) is a volatile violet solid. The differences point to different strengths of intermolecular forces between these halogens, with those for I_2 being stronger. What kind of intermolecular force is responsible for these differences?

Why do gases behave nonideally at high pressures and low temperatures?

Why are normal boiling points generally lower for branched hydrocarbons than for straight-chain hydrocarbons of the same molecular mass?

Problems

In each of the following pairs of molecules, which one experiences the stronger dispersion forces? (a) CCl_4 or CF_4; (b) CH_4 or C_3H_8

What kinds of intermolecular forces must be overcome as solid CO_2 sublimes?

Consider the two molecules shown in Figure P10.15. One of these compounds is a liquid at room temperature; the other is a solid. Which is which? Explain why.

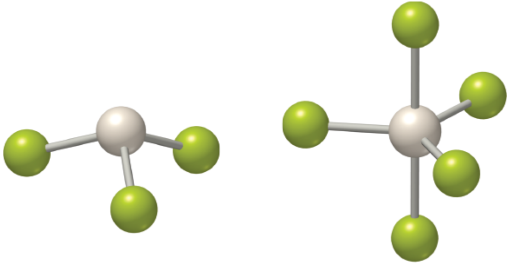


FIGURE P10.15

Consider the two molecules shown in Figure P10.16. One has a boiling point of 57°C; the other, 84°C. Predict which has the higher boiling point and explain your choice.

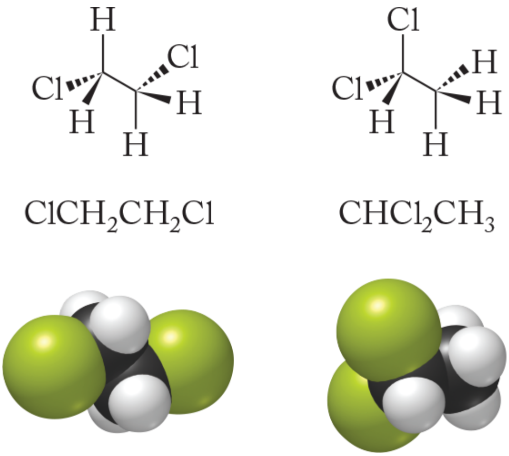

FIGURE P10.16

Interactions Involving Polar Molecules

Concept Review

Why are dipole–dipole interactions generally weaker than ion–dipole interactions?

Two liquids—one polar, one nonpolar—have the same molar mass. Which one is likely to have the higher boiling point? Explain your answer.

Why are hydrogen bonds considered a special class of dipole–dipole interactions?

Can all polar hydrogen-containing molecules form hydrogen bonds? Why or why not?

Problems

The permanent dipole moment of CH_2F_2 (1.93 D) is larger than that of CH_2Cl_2 (1.60 D), yet the boiling point of CH_2Cl_2 (40°C) is much higher than that of CH_2F_2 ($-$ 52°C). Why?

How is it that the permanent dipole moment of HCl (1.08 D) is larger than the permanent dipole moment of HBr (0.82 D), yet HBr boils at a higher temperature?

The Smell of the Sea The distinct odor of the seashore at low tide results in part from the presence of dimethylsulfide (CH_3SCH_3), a molecule with the same structure as dimethyl ether (CH_3OCH_3). Their standard heats of vaporization $\Delta H^\circ_{\text{vap}}$ are different: 28 kJ/mol versus 23 kJ/mol, respectively. Which substance has the stronger intermolecular forces? Can you suggest why?

At the Fish Market Fish emit increasing amounts of trimethylamine, $(CH_3)_3N$, as they decay, accounting for the distinctive odor one senses toward the end of the day at an open-air market. Opening a bottle of household ammonia soon leads to the smell of NH_3 in the immediate vicinity. Based on the thermochemical data for NH_3 ($\Delta H^\circ_{\text{vap}} = 1.16$ kJ/mol) and $(CH_3)_3N$ ($\Delta H^\circ_{\text{vap}} =$ 27 kJ/mol), which substance has the higher boiling point?

Detecting Natural Gas Leaks Energy companies add small amounts of ethanethiol (CH_3CH_2SH) to the CH_4 in their pipelines because ethanethiol has a strong odor and will warn consumers of a leak in their equipment.

1. Ethanethiol and ethanol (CH_3CH_2OH) have the same structure and differ only in which group 16 element is present. Explain why the boiling point of ethanethiol (35°C) is lower than the boiling point of ethanol (78.5°C).
2. To reach your nose, ethanethiol must diffuse through air when a leak occurs. How much faster will methane diffuse than ethanethiol?

Explain the differences in the physical properties of the following pairs of compounds.

1. Why is the melting point of methyl fluoride (CH_3F, − 142°C) higher than the melting point of methane (CH_4, − 182°C).
2. Why is the boiling point of Br_2 (59°C) lower than that of iodine monochloride (ICl, 97°C), even though they have nearly the same molar mass.
3. Will Br_2 and ICl have similar root-mean-square speeds at 100°C?

In which of the following compounds do the molecules experience the strongest dipole–dipole attractions? (a) CF_4; (b) CF_2Cl_2; (c) CCl_4

Which of the following compounds, CO_2, NO_2, SO_2, or H_2S, is expected to have the weakest interactions between its molecules?

Which of the following molecules can form hydrogen bonds among themselves in pure samples of bulk material? (a) methanol (CH_3OH); (b) ethane (CH_3CH_3); (c) dimethyl ether (CH_3OCH_3); (d) acetic acid (CH_3COOH)

Which of the following molecules can form hydrogen bonds with molecules of water? (a) methanol (CH_3OH); (b) ethane (CH_3CH_3); (c) dimethyl ether (CH_3OCH_3); (d) acetic acid (CH_3COOH)

Vapor Pressure of Pure Liquids

Concept Review

Why does the vapor pressure of a liquid increase as temperature increases?

Which of the following factors influences the vapor pressure of a pure liquid?

1. the volume of liquid present in a container

2. the temperature of the liquid
3. the surface area of the liquid

Is vapor pressure an intensive or extensive property of a liquid?

During the development of the U2 advanced reconnaissance aircraft a new jet fuel had to be formulated because existing fuels would boil away at the very high altitudes the aircraft could achieve. Why does boiling point decrease as a function of altitude?

Problems

Rank the following compounds in order of increasing vapor pressure at 298 K. (a) CH_3CH_2OH; (b) CH_3OCH_3; (c) $CH_3CH_2CH_3$

Rank the compounds in Figure P10.36 in order of increasing vapor pressure at 298 K.

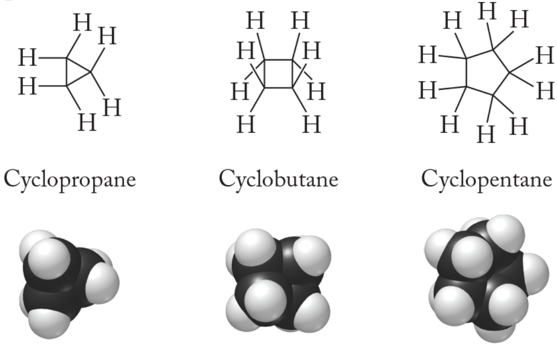

FIGURE P10.36

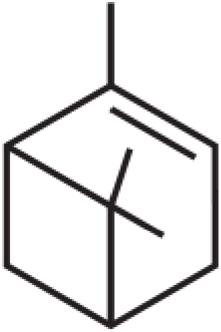
Pine Oil The smell of fresh cut pine arises in part from the cyclic alkene pinene, whose carbon-skeleton structure is shown in Figure P10.37.

1. Use the data in the table to calculate the heat of vaporization (ΔH_{vap}) of pinene.
2. Use the value of ΔH_{vap} determined in part (a) to calculate the

vapor pressure of pinene at room temperature (23°C).



Pinene

Almonds and Cherries Almonds and almond extracts are common ingredients in baked goods. Almonds contain the compound benzaldehyde (shown in Figure P10.38), which accounts for the odor of the nut. Benzaldehyde is also responsible for the aroma of cherries.

1. Use the data in the table to calculate the heat of vaporization (ΔH_{vap}) of benzaldehyde.
2. Use the value of ΔH_{vap} determined in part (a) to calculate the vapor pressure of benzaldehyde at room temperature (23°C).

Skunks The distinctive odor of skunks results from the butanethiol, $CH_3(CH_2)_3SH$, that they spray when threatened. A plot of the natural logarithm of vapor pressure as a function of temperature for butanethiol is shown in Figure P10.39. Calculate the heat of vaporization for $CH_3(CH_2)_3SH$.

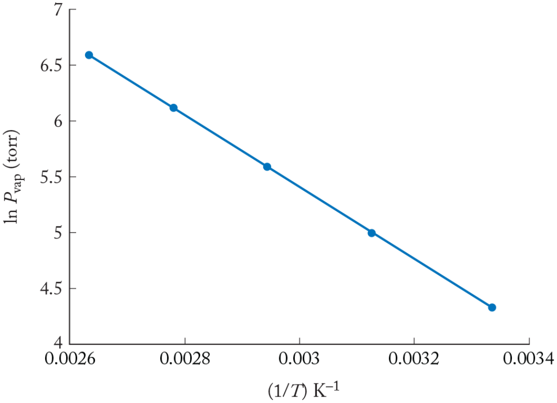

FIGURE P10.39

Chemical Signaling When some Saharan ants are injured, they emit a volatile sulfur compound called dimethyl disulfide (CH_3SSCH_3). A plot of the natural logarithm of vapor pressure as a function of temperature for dimethyl disulfide is shown in Figure P10.40. Calculate the heat of vaporization for CH_3SSCH_3.

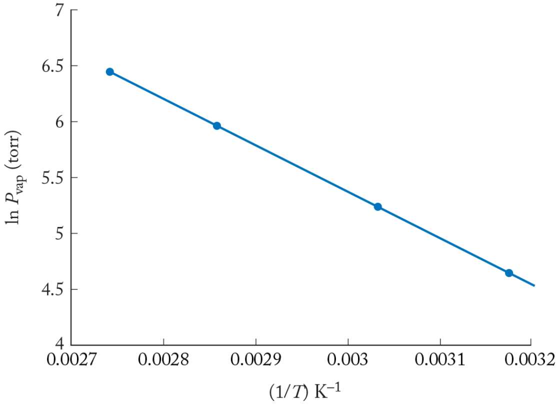

FIGURE P10.40

Phase Diagrams: Intermolecular Forces at Work

Concept Review

What phases of a substance are present at (a) its triple point and (b) its critical point?

Explain how the solid–liquid line in the phase diagram of water differs in character from the solid–liquid line in the phase diagrams of most other substances, such as CO_2.

Which phase of a substance (gas, liquid, or solid) is most likely to be the stable phase: (a) at low temperatures and high pressures; (b) at high temperatures and low pressures?

At what temperature and pressure does a substance behave as a supercritical fluid?

Preserving Food Freeze-drying is used to preserve food at low temperature with minimal loss of flavor. Freeze-drying works by freezing the food and then lowering the pressure with a vacuum pump to sublime the ice. Must the pressure be lower than the pressure at the triple point of H_2O? Why or why not?

Solid helium cannot be converted directly into the vapor phase. Does the phase diagram of helium have a triple point?

Problems

(For help in answering Problems 10.47 through 10.56, consult Figures 10.21, 10.23, and 10.24.)

What is the normal boiling point of bromine?

If water boils at 50°C, what is the pressure?

Which molecules have stronger intermolecular attractive forces: ethylene glycol or ethanol? Explain your choice.

What is the boiling point of diethyl ether at 300 mmHg of pressure?

List the steps you would take to convert a 10.0 g sample of water at 25°C and 1 atm of pressure to water at its triple point.

List the steps you would take to convert a 10.0 g sample of water at 25°C and 2 atm pressure to ice at 1 atm of pressure. At what temperature would the water freeze?

Predict which phase water exists in at 100°C and 5.0 atm. What phase changes, if any, does water undergo when the pressure is reduced to 0.5 atm at constant temperature?

Predict which phase CO_2 exists in at − 80°C and 8.0 atm. What phase changes, if any, does CO_2 undergo when allowed to warm to − 25°C at 5.0 atm?

Glaciers Melting glaciers in Greenland have the potential to significantly raise the level of the ocean. An article on the Jakobshavn Glacier contained the following passage: “Because of the extreme pressures involved, the freezing point of the ice itself changes, making it more susceptible to melting."

1. Is this statement valid?
2. Use the phase diagram of water to estimate the pressure required to reduce the melting point of ice by 0.5°C.

Sequestration of Carbon Dioxide One solution to combat the increasing concentration of CO_2 in Earth's atmosphere is to capture it and store it under high pressure.

1. What are the pressures required to convert CO_2 gas to solid CO_2 (dry ice) and to liquid CO_2 at -50°C?
2. What volume would 1 million grams of CO_2 vapor ($d = 1.977$ g/L at 0°C) occupy when cooled and condensed to liquid CO_2 ($d = 1.101$ g/mL at -37°C)?

Some More Remarkable Properties of Water

Concept Review

Explain why a needle floats on the surface of water but sinks in a container of methanol (CH_3OH).

Explain why different liquids do not reach the same height in capillary tubes of the same diameter.

Explain why pipes filled with water are in danger of bursting when the temperature drops below 0°C.

A hot needle sinks when put on the surface of cold water. Will a cold needle float in hot water? Explain your answer.

The meniscus of water in a glass tube is concave, but that of mercury (Figure P10.61) is convex. Explain why.

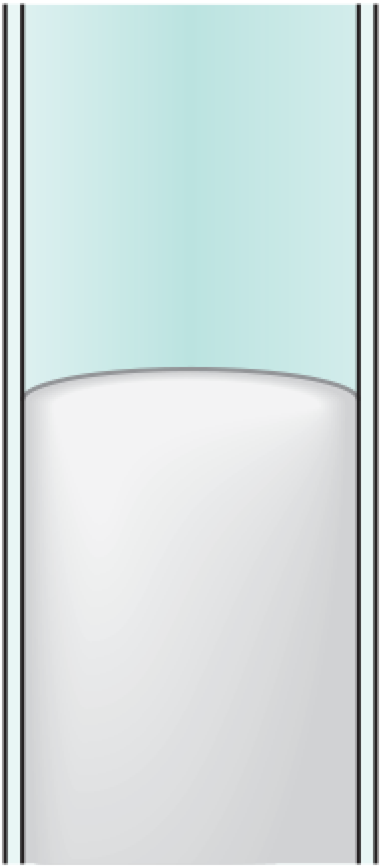

FIGURE P10.61

The mercury level in a capillary tube inserted into a dish of mercury is below the level of the mercury in the dish. Explain why.

Describe the origin of surface tension at the molecular level.

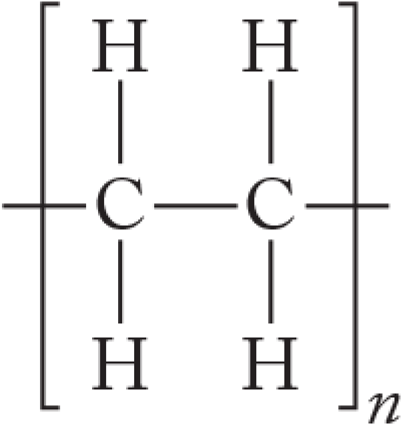
The viscosities of alkane hydrocarbons increase as the number of carbon atoms per molecule increases. Explain why.

Describe how the surface tension and viscosity of a liquid are affected by increasing temperature.

Explain how strong intermolecular forces are expected to result in a relatively high surface tension and viscosity of a liquid.

Problems

One of two glass capillary tubes of the same diameter is placed in a dish of water and the other in a dish of ethanol (CH_3CH_2OH). Which liquid will rise higher in its tube? Explain your answer.



$$\left[\mathrm{CH_2-CH_2} \right]_n$$

FIGURE P10.68

Would you expect water to rise to the same height in a tube made of a polyethylene plastic as it does in a glass capillary tube of the same diameter? Why or why not? The molecular structure of polyethylene is shown in Figure P10.68.

The normal boiling points of liquids A and B are 75.0°C and 151°C, respectively. Which of these liquids would you expect to have the higher surface tension and viscosity at 25°C? Explain your answer.

A simple viscometer consists of a thick-walled glass tube with a 0.5-mm bore. The tube has etched marks at one-quarter and three-quarters of its height. The tube is clamped with its lower end dipped in a container of the liquid to be tested. A pipet filler is used to draw liquid up the bore past the upper mark. The pipet filler is removed from the tube, and the time taken for the liquid meniscus to drain between the upper and lower viscometer marks is measured with a stopwatch. Using this viscometer to measure the drain times for two pure liquids A and B at the same temperature gives 3.45 seconds for liquid A and 4.64 seconds for liquid B.

1. Which liquid is more viscous?
2. Which liquid has weaker intermolecular forces?
3. Would the measured drain times be longer or shorter at a lower experimental liquid temperature?

Polarity and Solubility

Concept Review

What is the difference between the terms *miscible* and *insoluble*?

What properties of water molecules enable them to hydrate and separate cations and anions in aqueous solutions?

One of the compounds in Figure P10.16 is insoluble in water; the other has a water solubility of 0.87 g/100 mL at 20°C. Identify which is which and explain your reasoning.

Azaborine (C_4H_6BN; Figure P10.74) *is isoelectronic with benzene* (C_6H_6). Which of these two compounds is likely to have greater solubility in water?

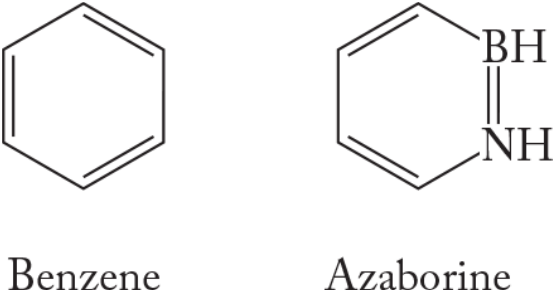


FIGURE P10.74

In what context do the terms *hydrophobic* and *hydrophilic* relate to the solubilities of substances in water?

How does the presence of increasingly longer hydrocarbon chains in the structure affect the solubility of a series of structurally related molecules in water?

Problems

In each of the following pairs of compounds, which compound is likely to be more soluble in water?

1. CCl_4 or $CHCl_3$
2. CH_3OH or $C_6H_{11}OH$
3. NaF or MgO
4. CaF_2 or BaF_2

In each of the following pairs of compounds, which compound is likely to be more soluble in CCl_4?

1. Br_2 or NaBr
2. CH_3CH_2OH or CH_3OCH_3
3. CS_2 or KOH
4. I_2 or CaF_2

Which of these pairs of substances is likely to be miscible?

1. Br_2 and C_6H_6 (benzene)
2. $CH_3CH_2OCH_2CH_3$ (diethyl ether) and CH_3COOH (acetic acid)
3. C_6H_{12} (cyclohexane) and hexane ($CH_3CH_2CH_2CH_2CH_2CH_3$)
4. CS_2 (carbon disulfide) and CCl_4 (carbon tetrachloride)

Which of these pairs of substances is likely to be miscible?

1. CH_3CH_2OH (ethanol) and $CH_3CH_2OCH_2CH_3$ (diethyl ether)
2. CH_3OH (methanol) and methyl amine (CH_3NH_2)
3. CH_3CN (acetonitrile) and acetone (CH_3COCH_3)
4. CF_3CHF_2 (a Freon replacement) and $CH_3CH_2CH_2CH_2CH_3$ (pentane)

Which of the following compounds is likely to be the most soluble in water? (a) NaCl; (b) KI; (c) $Ca(OH)_2$; (d) CaO

Based on the graph in Figure P10.82, which has a greater effect on the solubility of oxygen in water: (a) decreasing the temperature from 20°C to 10°C or (b) raising the pressure from 1.00 atm to 1.25 atm?

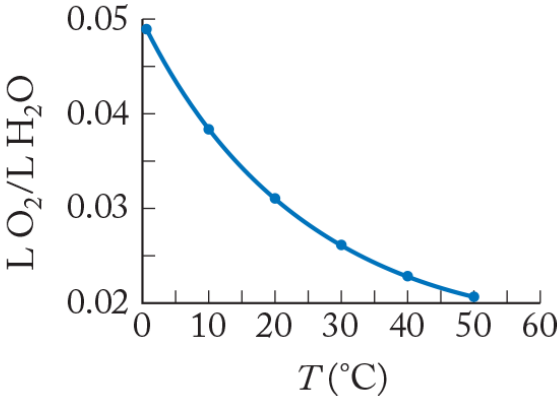

FIGURE P10.82

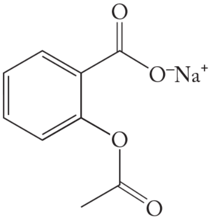
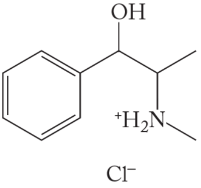
Improving the Solubility of Drugs Many common over-the-counter medications (Figure P10.83) are sold as salts to improve their water solubility. Explain why the salts of acetylsalicylic acid and pseudoephedrine are more soluble in water?



Sodium acetylsalicylate



Pseudoephedrine hydrochloride

FIGURE P10.83

Predict the order of water solubility (from lowest to highest) for the following series of alcohols and explain your reasoning.

1. $CH_3(CH_2)_2CH_2OH$
2. $CH_3(CH_2)_4CH_2OH$
3. $CH_3(CH_2)_6CH_2OH$
4. $CH_3(CH_2)_8CH_2OH$

Which of the compounds in Figure P10.85 are alcohols and which ones are ethers? Place them in order of increasing boiling point.

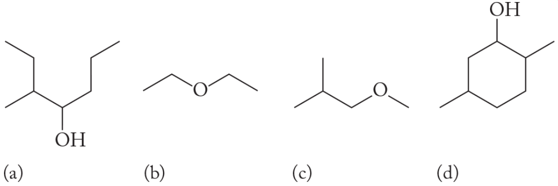


FIGURE P10.85

Which of the compounds in Figure P10.86 are alcohols and which ones are ethers? Place them in order of increasing vapor pressure at 25°C.

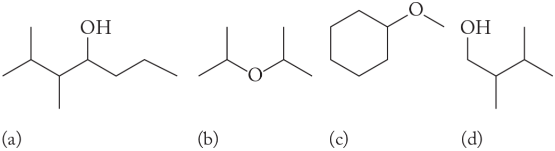

FIGURE P10.86

Solubility of Gases in Water

Concept Review

Why does the solubility of most gases in most liquids increase with decreasing temperature?

Which term, k_H or P, in Henry’s law is affected by temperature?

Air is primarily a mixture of nitrogen and oxygen. Is the Henry’s law constant for the solubility of air in water the sum of

k_H for N_2 and k_H for O_2? Explain why or why not.

Why is the Henry's law constant for CO_2 so much larger than those for N_2 and O_2 at the same temperature?

Which compound in each pair would you predict to be more soluble in nonpolar solvents: SO_2 or SO_3 and CO_2 or NO_2?

A chef observes bubbles while heating a pot of water to 60°C to poach vegetables. What are the gases in the bubbles and where did they come from?

Problems

Arterial Blood Arterial blood contains about 0.25 g of oxygen per liter at 37°C and standard atmospheric pressure. What is the Henry's law constant [in mol/(L · atm)] for O_2 dissolution in blood? The mole fraction of O_2 in air is 0.209.

The solubility of O_2 in water is 6.5 mg/L at an atmospheric pressure of 1 atm and temperature of 40°C. Calculate the Henry's law constant of O_2 at 40°C. The mole fraction of O_2 in air is 0.209.

Oxygen for Climbers and Divers Use the Henry's law constant for O_2 dissolved in arterial blood from Problem 10.93 to calculate the solubility of O_2 in the blood of (a) a climber on Mt. Everest ($P_{atm} = 0.35$ atm) and (b) a scuba diver at 100 feet ($P < 3$ atm).

The solubility of air in water is approximately $7.9 \times 10^{-4} M$ at 20°C and 1.0 atm. Calculate the Henry's law constant for air. Is the k_H value of air approximately equal to the sum of the k_H values for N_2 and O_2, because these two gases make up 99% of the gases in air?

Carbonated Sodas Manufacturers of carbonated beverages dissolve

$CO_2(g)$ in water under pressure to produce sodas. If a manufacturer uses a pressure of 4.16 atm at 25°C to carbonate the water, how many grams of CO_2 are in the average can of soda, the volume of which is 355 mL? The Henry's law constant for CO_2 at 25°C is 0.03360 mol/(L · atm).

What would be the effect on the results of the process described in Problem 10.97 if (a) the temperature of the carbonation process was changed from 25°C to 10°C, or (b) the temperature was held constant, but the pressure was doubled?

Additional Problems

Why do ethers typically boil at lower temperatures than alcohols with the same molecular formula?

Dry Gas During the winter months in cold climates, water condensing in a vehicle's gas tank reduces engine performance. An auto mechanic recommends adding "dry gas" to the tank during your next fill-up. Dry gas is typically an alcohol that dissolves in gasoline and absorbs water. From the structures shown in Figure P10.100, which product do you predict would do a better job—methanol or 2-propanol? Why?

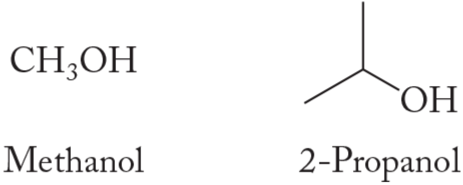

FIGURE P10.100

Does the sublimation point of ice increase or decrease with increasing pressure? Explain why.

Does the sublimation point of CO_2 increase or decrease with increasing pressure? Explain why.

Liquid substances are often compared for their physical properties in different applications. Comparison of two liquids A and B at constant temperature and atmospheric pressure shows that liquid A has higher viscosity and surface tension, a higher boiling point, and lower vapor pressure than liquid B. Are these data all consistent with stronger intermolecular forces in liquid A than in liquid B?

Why is methanol (CH_3OH) miscible with water, but CH_4 is almost completely insoluble in water?

Sketch a phase diagram for element X, which has a triple point at 152 K and a pressure of 0.371 atm, a boiling point of 166 K at a pressure of 1.00 atm, and a normal melting point of 161 K.

The melting point of hydrogen is 14.96 K at 1.00 atm of pressure. The temperature at its triple point is 13.81 K. Does H_2 expand or contract when it freezes?

Explain why water climbs higher in a capillary tube than in a test tube.

Explain why ice floats on water.

Fish Dying in Summer Heat Explain why fish in a pond die if water becomes too warm.

Evaluation of Pharmaceuticals A test done on new pharmaceutical agents early in the development process required the observation of their relative solubilities in octanol and water. A drug had to be sufficiently soluble in water (hydrophilic) to be carried in the bloodstream but also sufficiently hydrophobic (octanol soluble) to move across cell membranes. Pick the molecule from Figure P10.110 that you predict might have comparable solubility in both solvents. Explain your choice.

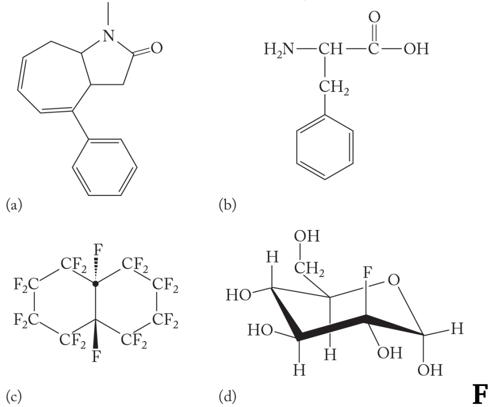

FIGURE P10.110

First Aid for Bruises Compounds with low boiling points may be sprayed on skin as a topical anesthetic—they chill it as they evaporate, providing short-term relief from injuries. Predict which compound among those in Figure P10.111 has the lowest boiling point.

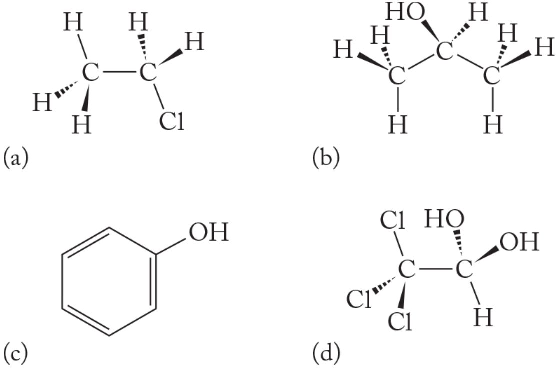

FIGURE P10.111

Refrigerators have a unit called a compressor that liquefies a gas. The refrigerator is cooled by a continuous cycle of compression of the gas to produce the liquid, followed by evaporation of the liquid to provide the cooling. Ammonia (NH_3) and sulfur dioxide (SO_2) were the gases used originally, and hexafluoroethane (C_2F_6) has been used since the 1990s. What are the intermolecular interactions that characterize these substances?

Glossary

ion–dipole interaction

an attractive force between an ion and a molecule that has a permanent dipole moment.

dipole–dipole interaction

an attractive force between polar molecules.

hydrogen bond

the strongest dipole–dipole interaction. It occurs between a hydrogen atom bonded to a small, highly electronegative element (O, N, F) and an atom of oxygen or nitrogen in another polar molecule. Molecules of HF also form hydrogen bonds.

dispersion force (also called London force)

an intermolecular force between molecules caused by the presence of temporary dipoles in the molecules.

induced dipole

the separation of charge produced in an atom or molecule by a momentary uneven distribution of electrons.

polarizability

the relative ease with which the electron clouds surrounding the nuclei of individual atoms or molecules can be distorted, thereby inducing temporary dipoles.

Clausius–Clapeyron equation

a relationship between the vapor pressure of a substance at two temperatures and its heat of vaporization.

vapor pressure

the pressure exerted by a gas at a given temperature in equilibrium with its liquid phase.

phase diagram

a graphical representation of how the stabilities of the physical states of a substance depend on temperature and pressure.

supercritical fluid

a substance at conditions above its critical temperature and pressure, where the liquid and vapor phases are indistinguishable and have some characteristics of both a liquid and a gas.

surface tension

the energy needed to separate the molecules at the surface of a liquid.

capillary action

the rise of a liquid in a narrow tube because of adhesive forces between the liquid and the tube and cohesive forces within the liquid.

viscosity

the resistance to flow of a liquid.

hydrophilic

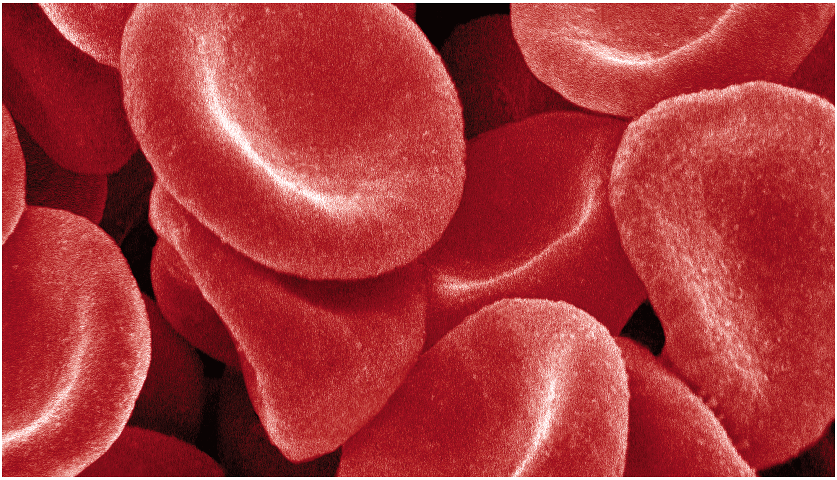
a “water-loving,” or attractive, interaction between a solute and water that promotes water solubility.

hydrophobic

a “water-fearing,” or repulsive, interaction between a solute and water that diminishes water solubility.

Henry’s law

the principle that the concentration of a sparingly soluble, chemically unreactive gas in a liquid is proportional to the partial pressure of the gas.



HEALTHY RED BLOOD CELLS Blood is a complex aqueous mixture of dissolved and suspended components. The latter include red blood cells, which contain hemoglobin, a substance that binds oxygen and transports it from the lungs to tissues.

Solutions
Properties and Behavior

PARTICULATE REVIEW

Size Trends: Neutral Atoms versus Ions

In Chapter 11 we explore the properties of solutions containing dissolved solutes, both molecular and ionic. Colored spheres representing neutral atoms of potassium, sodium, sulfur, and fluorine, along with their most common ions, are shown here. In each case, the neutral atom is above the ion. Answer these questions based on the periodic trends for atomic size.

Which pair is the potassium atom and its ion?

- Which pair is the fluorine atom and its ion?
- Which of the remaining pairs is sulfur and the sulfide ion? Which pair is sodium and its ion?

  (Review Section 7.10 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Solvent versus Solution

The covered containers shown here hold pure water (on the left) and an aqueous solution of NaCl (on the right). As you read Chapter 11, look for ideas that will help you answer these questions:

- When NaCl(*s*) is added to water, what intermolecular forces produce the solution on the right?
- What happens to the amount of water in the vapor phase when salt is added?
- How does the presence of a dissolved solute such as salt affect the boiling point of water?

Learning Outcomes

- LO1 Estimate the relative strengths of ion–ion interactions and explain how these interactions affect the physical properties of ionic compounds

  Sample Exercise 11.1

- LO2 Explain the energy changes that accompany the formation and dissolution of an ionic compound

  Sample Exercises 11.2, 11.3, 11.4

- LO3 Use Raoult's law to relate the vapor pressure of a solution to the concentration of solute particles

  Sample Exercise 11.5, 11.7

- LO4 Relate the fractional distillation of a mixture of volatile compounds to the vapor pressures of the compounds

  Sample Exercise 11.6

- LO5 Relate the molality of a solution to the quantity of solute and mass of solvent

  Sample Exercise 11.8

- LO6 Relate the freezing point or boiling point of a solution to the molal concentration of nonvolatile solute particles

  Sample Exercises 11.9, 11.10

- LO7 Explain the significance of the van ’t Hoff factor and use it to predict the colligative properties of solutions

  Sample Exercises 11.11, 11.12

- LO8 Describe osmosis, predict the direction of solvent flow in osmosis, and calculate osmotic pressure

  Sample Exercises 11.13, 11.14, 11.15

- LO9 Use colligative properties such as osmotic pressure to determine solute molar mass

  Sample Exercise 11.16

$$E \propto \frac{(Q_1 \times Q_2)}{d} \tag{6.3}$$

$$E = 2.31 \times 10^{-16}\,\mathrm{J} \cdot \mathrm{pm}\left(\frac{Q_1 \times Q_2}{d}\right) \tag{11.1}$$

$$E_{\mathrm{CaSO_4}} = 2.31 \times 10^{-16}\,\mathrm{J} \cdot \mathrm{pm}\left(\frac{(2+) \times (2-)}{(100 + 230)\ \mathrm{pm}}\right) = -2.80 \times 10^{-18}\,\mathrm{J}$$

$$E_{\mathrm{NaCl}} = 2.31 \times 10^{-16}\,\mathrm{J} \cdot \mathrm{pm}\left(\frac{(1+) \times (1-)}{(102 + 181)\ \mathrm{pm}}\right) = -8.16 \times 10^{-19}\,\mathrm{J}$$

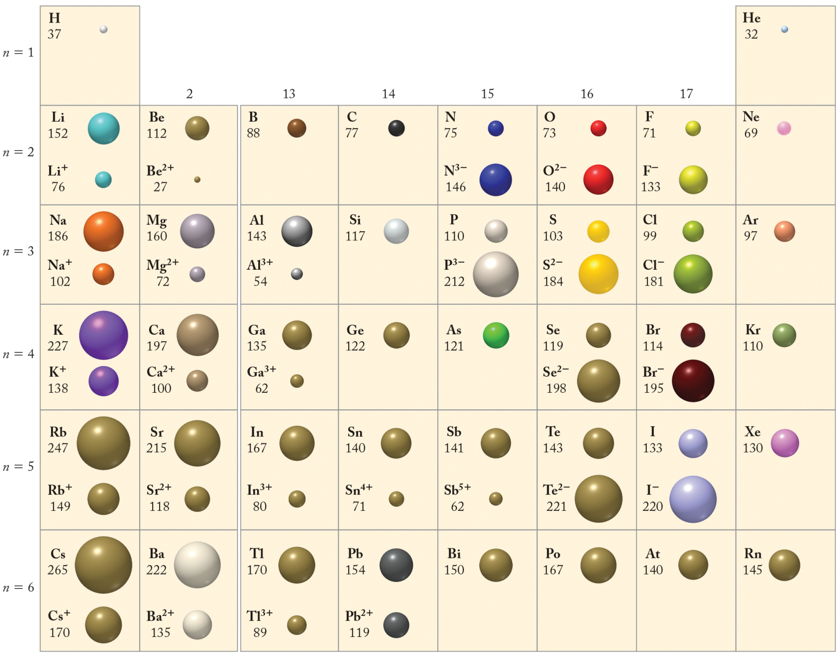

FIGURE 11.1 The radii of anions formed by the main group elements are larger than the radii of their parent atoms. The radii of cations are smaller than the radii of their parent atoms. All values are in picometers. Values from N. N. Greenwood and A. Earnshaw, *Chemistry of the Elements*, 2nd ed. (Boston: Butterworth-Heinemann, 1997); C. E. Housecroft and A. G. Sharpe, *Inorganic Chemistry*, 3rd ed. (Upper Saddle River, NJ: Pearson Prentice Hall, 2008).

$$E_{\mathrm{SrSO_4}} = 2.31 \times 10^{-16}\ \mathrm{J \cdot pm}\left(\frac{(2+) \times (2-)}{(118 + 230)\ \mathrm{pm}}\right) = -2.66 \times 10^{-18}\ \mathrm{J}$$

$$E_{\mathrm{BaSO_4}} = 2.31 \times 10^{-16}\ \mathrm{J \cdot pm}\left(\frac{(2+) \times (2-)}{(135 + 230)\ \mathrm{pm}}\right) = -2.53 \times 10^{-18}\ \mathrm{J}$$

$$E_{\mathrm{Ca_3(PO_4)_2}} = 2.31 \times 10^{-16}\ \mathrm{J \cdot pm}\left(\frac{(2+) \times (3-)}{(100 + 238)\ \mathrm{pm}}\right) = -4.10 \times 10^{-18}\ \mathrm{J}$$

11.1 Interactions between Ions

We began Chapter 4 by noting that marine mammals can regulate the concentrations of electrolytes in their tissues to about one-third the concentrations of the same ions in seawater. Actually, electrolyte concentrations in the tissues and blood of most mammals, including us, must be maintained in narrow ranges for normal body function and good health. Therefore, the fluids dispensed intravenously in hospitals to deliver medications or to restore fluid levels in trauma victims must contain very nearly the same total number of dissolved particles (molecules and ions) in a given volume as there are in the same volume of blood plasma. Too high a concentration of solutes in the intravenous fluid causes dehydration; too low a concentration can cause edema, which is swelling that results from excess fluid in body tissues.

In this chapter we examine the properties of solutions in more detail, including some of the ways in which they differ from the properties of their pure solvents. For example, the solubilities of biopolymers, such as proteins, in aqueous solutions depends on the concentrations of dissolved salts such as NaCl that are also present in these solutions. If salt concentrations are high enough, water molecules that would normally cluster around the ionic groups on the surface of protein molecules, thereby stabilizing the protein in solution, cluster around Na^+ and Cl^- ions instead. The loss of ion–dipole interactions on the surface of the protein destabilizes it and causes it to precipitate. Scientists make use of this *salting out effect* to isolate proteins from samples of biological fluids.

CONNECTION We introduced solutions and several units of concentration in Section 4.2 when discussing how much solute is dissolved in the solvent.

In this chapter we also continue the discussion from Chapter 10 on why some compounds dissolve in water and others do not, but here we focus on why some salts are more soluble in water than others. To visualize this phenomenon, consider the changes of state that begin when an ocean wave crashes on a rocky coast. The plumes of sea spray the wave produces carry small drops of seawater into the atmosphere. As some of the water in these drops evaporates, their concentrations of dissolved ions (e.g., Cl^-, Na^+, Mg^{2+}, Br^-, Ca^{2+}, and SO_4^{2-}) increase. Eventually, the decreased volume of the drops produces saturated solutions of the salts, which then begin to precipitate. Among the first solids to form is $CaSO_4$. Among the last is NaCl, which does not precipitate until 90% of the seawater in a drop has evaporated. This sequence takes place even though the concentrations of Ca^{2+} and SO_4^{2-} ions are much lower than the concentrations of Na^+ and Cl^- ions in seawater. Why does $CaSO_4$ precipitate before NaCl? Put another way: why is $CaSO_4$ less soluble in water than NaCl?

There are several factors that influence the solubility of salts in water. One of the most important is the strength of the bonds that keep ions of opposite charge together in ionic solids and that must be overcome if the salt is to dissolve. These ionic bonds are among the strongest chemical bonds. We have seen (in Chapters 6 and 8) that the strengths of ionic bonds are defined by the electrostatic potential energies, E, between pairs of ions, which are functions of the product of their charges, $(Q_1 \times Q_2)$, divided by the distance between the centers of the ions (d):

We can turn this expression into an equation by replacing its proportionality symbol with a constant of proportionality:

The value of this constant gives us energy in joules when we express the distance between ion centers in picometers. Calculating the value of d involves summing the appropriate ionic radii shown in **Figure 11.1** and listed in **Table 11.1**. The values of Q are the relative charges on the ions, such as $2+$ for Ca^{2+} and $1-$ for Cl^-. Let's use Equation 11.1 to calculate the electrostatic potential energies between the pairs of oppositely charged ions in $CaSO_4$ and NaCl:

TABLE 11.1 Estimated Radii of Polyatomic Ions

Polyatomic Ion	Radius (pm)
CO_3^{2-}	185
NO_3^{-}	189
SO_4^{2-}	230
PO_4^{3-}	238

Values from R. B. Heslop and K. Jones. *Inorganic Chemistry: A Guide to Advanced Study* (New York: Elsevier, 1976), p. 123.

The ratio of these two E values: $(-2.80 \times 10^{-18}\ \text{J})/(-8.16 \times 10^{-19}\ \text{J}) = 3.43$, tells us that the electrostatic potential energy between pairs of Ca^{2+} and SO_4^{2-} ions is nearly 3.5 greater than that between pairs of Na^+ and Cl^- ions. This greater energy of attraction between its ions plays a major role in making $CaSO_4$ less soluble in water than NaCl.

CONNECTION We introduced ion–ion interactions in Section 6.2 and revisited them in Section 8.1 in discussing how they lead to the formation of ionic bonds.

CONNECTION In Section 7.10 we explained how ionic radii are used to calculate the distance between the nuclear centers in an ionic bond.

SAMPLE EXERCISE 11.1 Relate the Strengths of Ion–Ion Interactions to the Charges and Sizes of Ions LO1

Ionic compounds such as strontium sulfate and barium sulfate are major components of the exoskeletons of some single-celled organisms. The principal component of mammalian skeletons is calcium phosphate. List $SrSO_4$, $BaSO_4$, and $Ca_3(PO_4)_2$ in order of decreasing strength of the attractions between their ions.

Collect and Organize We need to rank three ionic compounds based on decreasing strength of the attraction between their ions. Equation 11.1 relates the strengths of ion–ion interactions to the charges on the ions and the distance between their centers, which should be equal to the sum of the radii of the ions involved. The following ionic charge and radii data are available in Figure 11.1 and Table 11.1:

[illegible]									
[illegible] Ionic Radius (pm)									

Analyze The difference in the sizes of two anions is only 8 pm, so the difference in their charges, 3− versus 2−, should be the more significant factor in defining the attraction (electrostatic potential energy) between these anions and the cations in their compounds. All three cations are from group 2 in the periodic table and have a charge of 2+. The smallest one, Ca^{2+}, is bonded to the anion with the greater charge, $PO_4{}^{3-}$. Therefore, these two ions should experience the strongest ion–ion attraction among the ion pairs in the three compounds. The only difference between the other two pairs is the size of their cations: Sr^{2+} ions are smaller than Ba^{2+} ions; so, Sr^{2+} and $SO_4{}^{2-}$ ions should experience a greater attraction than Ba^{2+} and $SO_4{}^{2-}$ ions.

Solve Calculate the values of electrostatic potential energy between the oppositely charges ions in the three compounds:

More negative *E* values represent greater attraction, so the three in decreasing order of ion–ion attraction are $Ca_3(PO_4)_2 > SrSO_4 > BaSO_4$.

Think About It The predicted order of decreasing attraction was confirmed by the calculated electrostatic potential energy values. The biggest gap in these values separates $Ca_3(PO_4)_2$ from the other two, which are sulfate compounds. Thus, the difference in the charges on the phosphate and sulfate ions is the primary factor influencing interaction strengths among these compounds. The much smaller difference in the *E* values of $SrSO_4$ and $BaSO_4$ arose from the different sizes of their cations, which resulted in a slightly smaller *d* value in the denominator of the *E* equation for $SrSO_4$ (348 pm) versus $BaSO_4$ (365 pm).

Practice Exercise Arrange the ionic compounds $CaCl_2$, BaO, and KCl in order of decreasing strength of the interaction between their ions.

(Answers to Practice Exercises are in the back of the book.)

The results of Sample Exercise 11.1 illustrate an important point about the strength of ion–ion interactions among the most common ions: differences in their radii tend to produce smaller differences in the strength of ion–ion interactions than do differences in their charges.

CONCEPT TEST

Rank the following sets of ions in order of increasing distance (*d*) between their nuclear centers: (a) KF, LiF, NaF; (b) $CaBr_2$, $CaCl_2$, CaF_2.

(Answers to Concept Tests are in the back of the book.)

Learning Objectives

- Estimate the relative strengths of ion–ion interactions and explain how these interactions affect the physical properties of ionic compounds **Return to Sample Exercise 11.1**

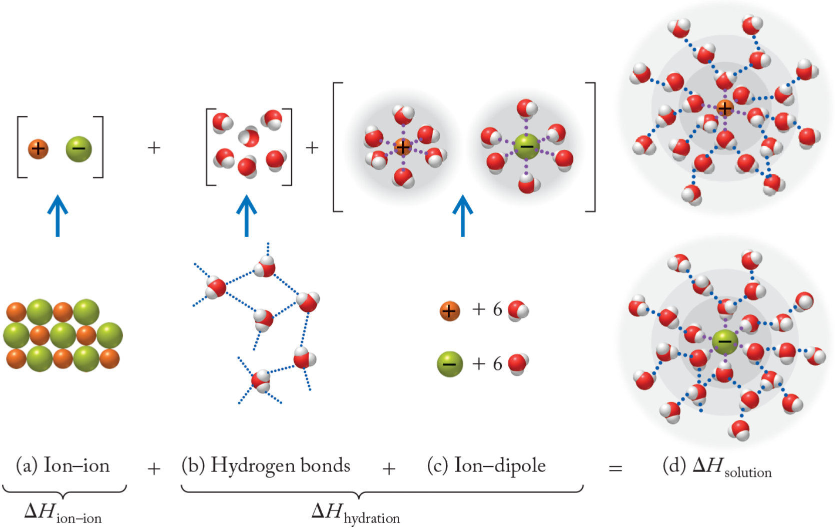

FIGURE 11.2 A homogeneous solution of an ionic compound in water consists of hydrated ions distributed throughout the solvent. We can account for the energy associated with establishing a solution by considering (a) the energy required to separate the ions from their lattice ($\Delta H_{\text{ion–ion}} = -U$), (b) the energy required to overcome hydrogen bonding in the solvent ($\Delta H_{\text{hydrogen bonding}}$; in water, these are hydrogen bonds), and (c) the energy released when ion–dipole bonds form between solvent and solute particles ($\Delta H_{\text{ion–dipole}}$). The sum of (b) and (c) is $\Delta H_{\text{hydration}}$, the enthalpy of hydration. (d) The sum of all three processes is $\Delta H_{\text{solution}}$, the enthalpy of solution.

$$\Delta H_{\text{solution}} = \Delta H_{\text{ion–ion}} + \Delta H_{\text{hydrogen bonding}} + \Delta H_{\text{ion–dipole}} \tag{11.2}$$

$$\Delta H_{\text{hydration}} = \Delta H_{\text{hydrogen bonding}} + \Delta H_{\text{ion–dipole}} \tag{11.3}$$

$$\Delta H_{\text{solution}} = \Delta H_{\text{ion–ion}} + \Delta H_{\text{hydration}} \tag{11.4}$$

$$U = \frac{k(Q_1 \times Q_2)}{d} \tag{11.5}$$

$$\Delta H_{\text{solution}} = \Delta H_{\text{hydration}} - U \tag{11.6}$$

11.2 Energy Changes during Formation and Dissolution of Ionic Compounds

In Section 10.3 we discussed the role of ion–dipole interactions in making salts soluble in water, and we described qualitatively how the combined effect of many ion–dipole interactions could overcome ion–ion interactions in a crystal of solute to produce hydrated ions in solution. Now we take the next step and *quantify* the actual changes in energy associated with these interactions. We then use these quantitative observations to understand further what happens at the particle level when solutes dissolve in solvents.

CONNECTION Figure 10.5 shows the dissociation of NaCl into Na^+ and Cl^- ions, each surrounded by a hydration sphere. Figure 10.6 shows the inner and outer spheres of hydration in more detail.

We can apply the qualitative picture of the dissolution process we developed in Chapter 10 to describe the factors that contribute to the overall enthalpy change that accompanies dissolution of an ionic compound in a polar solvent such as water. The ions must be separated from one another (**Figure 11.2a**), a process that requires energy to break the ion–ion interactions that hold the particles in the crystal lattice ($\Delta H_{\text{ion–ion}}$). Solvent molecules must also be separated from one another, so they can bind to the ions (**Figure 11.2b**); this process requires energy to break the dipole–dipole interactions—in water, these are hydrogen bonds—between solvent molecules ($\Delta H_{\text{dipole–dipole}}$). Last, energy is released when solvent molecules associate with the solute ions via ion–dipole interactions ($\Delta H_{\text{ion–dipole}}$) and form solvated (or *hydrated* if the solvent is water) ions (**Figure 11.2c**). The sum of the enthalpies of these interactions is the enthalpy of solution ($\Delta H_{\text{solution}}$), which defines the overall change in enthalpy when an ionic solute dissolves in a polar solvent (**Figure 11.2d**).

We can combine the strengths of hydrogen bonding and ion–dipole interactions into a single term called the enthalpy of hydration ($\Delta H_{\text{hydration}}$) if the solvent is water, or the enthalpy of solvation ($\Delta H_{\text{solvation}}$) for any polar solvent:

Combining Equations 11.2 and 11.3 we have

Let’s examine each of these terms describing the enthalpy changes that accompany the dissolution of an ionic solid in water in more detail.

TABLE 11.2 Lattice Energies (U) of Common Binary Ionic Compounds

Compound	U (kJ/mol)
LiF	1047
LiCl	864
NaCl	786
KCl	720
KBr	691
$MgCl_2$	2540
MgO	3791

The strength of ion–ion interactions is contained within the lattice energy (U) of an ionic compound, which is the change in energy when free ions in the gas phase combine to form 1 mole of a solid ionic compound. The lattice energies of some common binary ionic compounds are listed in **Table 11.2**. The formula for lattice energy is

This equation resembles Equation 11.1 except that the value of its proportionality constant, k, depends on the structure of the ionic solid. We examine the structures of solids in Chapter 12, at which point we will learn about the multiple interactions that each ion experiences in an ionic solid. A key point here is that the same value of k may be used for all compounds that have the same or nearly the same arrangement of ions. We can then substitute the lattice energy, U, of an ionic compound in Equation 11.5 for $\Delta H_{\text{ion–ion}}$:

$$\Delta H_{\text{solution}} = -U + \Delta H_{\text{hydration}}$$

or

The lattice energy term in Equation 11.6 is negative because U is defined as the enthalpy change when gas-phase ions *combine* to form an ionic solid. In Equation 11.6 we are calculating an enthalpy change that includes *separating* the ions in an ionic compound. Recall from Section 6.4 that the enthalpy change for a process in one direction has the same magnitude but opposite sign of the process in the reverse direction.

Lattice energies affect not only the energetics of dissolving ionic compounds, but also their melting and boiling points. Melting ionic structures in which the ions are held together tightly should require more thermal energy (and higher temperatures) than melting structures in which the ions are held together less tightly. We can observe this trend experimentally in the properties of LiF ($U = -1047$ kJ/mol) and MgO ($U = -3791$ kJ/mol). The lattice energy of MgO is nearly four times more negative than that of LiF, which makes sense because the $(Q_1 \times Q_2)$ term for MgO in Equation 11.5 is four times more negative than that of LiF. Also, the sums of the radii of their cations and anions are about the same: $(76 + 133 = 209)$ pm for LiF and $(72 + 140 = 212)$ pm for MgO. Thus, the difference in d values in Equation 11.5 has little to do with the big difference in U values. As expected, the melting point of MgO (2825°C) is also much higher than that of LiF (848°C). Likewise, the boiling point of MgO (3600°C) is much higher than that of LiF (1673°C).

SAMPLE EXERCISE 11.2 Ranking Lattice Energies and Melting Points LO2

Rank the ionic compounds NaF, KF, and RbF in order of (a) increasing (more negative) lattice energy and (b) increasing melting point. Assume these compounds have the same crystal structure and k value in Equation 11.5.

Collect, Organize, and Analyze We are asked to rank three group 1 fluorides in order of increasing lattice energies and increasing melting points. The ions in all three compounds have the same charges and their crystal structures are the same; so, significant differences in their lattice energies must be related to differences in the radii of the cations because the anions in all three compounds are fluoride ions. According to the images and numerical data in Figure 11.1, the trend in the ionic radii of the three cations is $Na^+ < K^+ < Rb^+$. Earlier in this section we described how increasingly negative lattice energies correlate with increasing melting points of ionic compounds.

Solve **Figure 11.3** shows the increasing sizes of the ion pairs in the three compounds: NaF < KF < RbF. Lattice energy is inversely proportional to the distance between the centers of paired cations and anions. Therefore, (a) the compounds in order of increasing lattice energy are RbF < KF < NaF and (b) the same trend should apply to the melting points of the compounds: RbF < KF < NaF.

Think About It The proposed order in part (a) is reasonable given the lattice energy trends in Table 11.1, and the link between increasingly negative lattice energy and increasing melting point makes sense because melting ionic solids in which the oppositely charged ions experience stronger attractions should require more energy and higher temperature. Moreover, the predicted order is confirmed by the compounds' observed melting points: 775°C for RbF, 846°C for KF, and 988°C for NaF.

Practice Exercise Predict which compound has the highest melting point: $CaCl_2$, $PbBr_2$, or TiO_2. All three compounds have nearly the same structure and therefore the same value of k in Equation 11.5. The radius of Ti^{4+} is 60.5 pm.

Calculating Lattice Energies by Using the Born–Haber Cycle

We predicted the relative order of lattice energies by considering atomic radii and bond distances, but we can also calculate values for lattice energies. Calculations are necessary because measuring lattice energies directly is difficult. We can calculate the lattice energy of a binary ionic compound from its standard enthalpy of formation (ΔH°_f). We use Hess's law to determine the enthalpies of reaction (ΔH_{rxn}) associated with a series of reactions that take the constituent elements from their standard states to ions in the gas phase and then to ions in the ionic solid.

Consider the formation of NaCl:

The reaction is exothermic, and the enthalpy produced (411.2 kJ per mole of NaCl formed—see Table A4.3 in the Appendix) has been determined using calorimetry. In terms of Hess's law, this enthalpy of formation is the algebraic sum of all the enthalpy changes associated with five reactions that together form a Born–Haber cycle (**Figure 11.4**):

1. Sublimation of 1 mole of Na(*s*) atoms into 1 mole of Na(*g*) atoms: the molar enthalpy of sublimation of sodium, ΔH_{sub}.
2. Breaking covalent bonds in $\frac{1}{2}$ mole of $Cl_2(g)$ molecules to make 1 mole of Cl(*g*) atoms: $\frac{1}{2}\Delta H_{BE}$, where ΔH_{BE} is the enthalpy change needed to break 1 mole of $Cl_2(g)$ bonds.
3. Ionization of 1 mole of Na(*g*) atoms to 1 mole of $Na^+(g)$ ions and 1 mole of electrons: IE_1, the first ionization energy of sodium.
4. Combination of 1 mole of Cl(*g*) atoms with 1 mole of electrons to form 1 mole of $Cl^-(g)$ ions: EA_1, the first electron affinity of chlorine.

5. Formation of 1 mole of NaCl(s) from 1 mole of $Na^+(g)$ ions and 1 mole of $Cl^-(g)$ ions: $U = \Delta H_{\text{lattice}}$, the lattice energy of NaCl.

CONNECTION We introduced Hess's law in Section 6.7 to determine enthalpies of reactions that are difficult to measure experimentally. In Section 6.8 we defined a formation reaction as one in which 1 mole of a substance is produced from its constituent elements in their standard states.

TABLE 11.3 Born–Haber Cycle for Formation of NaCl(*s*)

Step	PROCESS	Chemical Equation	Enthalpy Change (kJ)
1	Sublime 1 mol Na(*s*)	$Na(s) \rightarrow Na(g)$	$\Delta H_{\text{sub,Na}} = 109$
2	Break $\frac{1}{2}$ mol Cl—Cl bonds	$\frac{1}{2}\,Cl_2(g) \rightarrow Cl(g)$	$\frac{1}{2}\Delta H_{\text{BE,Cl}_2} = \frac{1}{2}(240) = +120$
3	Ionize 1 mol Na(*g*) atoms, forming 1 mol $Na^+(g)$ ions	$Na(g) \rightarrow Na^+(g) + e^-$	$IE_{1,\text{Na}} = 495$
4	1 mol Cl(*g*) atoms acquires 1 mol electrons, forming 1 mol $Cl^-(g)$ ions	$Cl(g) + e^- \rightarrow Cl^-(g)$	$EA_{\text{Cl}} = -349$
5	1 mol $Na^+(g)$ ions combines with 1 mol $Cl^-(g)$ ions, forming 1 mol NaCl(*s*)	$Na^+(g) + Cl^-(g) \rightarrow NaCl(s)$	$\Delta H_{\text{lattice}} = U$

This reaction sequence is summarized in **Table 11.3**. To use the Born–Haber cycle to calculate the lattice energy of NaCl(s), we start with an equation relating the value of $\Delta H°_f$ for NaCl to the sum of the enthalpy changes of the five reactions in Table 11.3:

Inserting the values from Table 11.3 and solving for U:

Besides lattice energies, the Born–Haber cycle can also be used to calculate other values, such as electron affinities, which can be difficult to measure, provided thermochemical values are known for all other steps in the cycle.

SAMPLE EXERCISE 11.3 Calculating Lattice Energy LO2

Based on the relative charges on the ions, the ion–ion attractions in

CaF_2 should be greater than those in NaF. Confirm this prediction by calculating the lattice energies of (a) NaF and (b) CaF_2, given the following data:

Collect and Organize We are asked to calculate the lattice energies of two ionic compounds, using enthalpy values for processes that can be summed to describe an overall process that produces a salt from its constituent elements. We can use a Born–Haber cycle to calculate the unknown lattice energy. According to Table A4.3 in the Appendix, the standard enthalpy of formation values for NaF and CaF_2 are −569.0 kJ/mol and −1228.0 kJ/mol, respectively. These enthalpy changes apply to the formation of 1 mole of the two compounds by combining their component elements in their standard states.

Analyze Figure 11.5 summarizes the Born–Haber cycles for calculating the lattice energies of NaF and CaF_2. The lattice energy *U* is the only unknown value in both cycles. We must include both the first and second ionization energies for calcium because Ca loses two electrons when it forms Ca^{2+} ions. Because two fluorine atoms are needed to react with a single calcium atom, we do not need the factor of $\frac{1}{2}$ in front of the term for energy to break a mole of F—F bonds. However, we need to multiply the electron affinity of F by 2 because 2 moles of fluorine atoms gain 2 moles of electrons to form 2 moles of fluoride ions. From the charges on the ions, their ionic radii, and Equation 11.5, we predict that the lattice energy of CaF_2 should be greater than the lattice energy of NaF.

Solve

1. The Born–Haber cycle for the formation of NaF(*s*) from Na(*s*) and $F_2(g)$ is illustrated in Figure 11.5a. The overall enthalpy change in the reaction producing NaF is

$$\Delta H^\circ_f = \Delta H_{\text{sub,Na}(s)} + \tfrac{1}{2}\Delta H_{\text{BE,F}_2(g)} + \Delta H_{\text{IE}_1\text{,Na}(g)} + \Delta H_{\text{EA}_1\text{,F}(g)} + U_{\text{NaF}(s)}$$

Substituting the values given:

$$-569.0\ \text{kJ} = (+109\ \text{kJ}) + \tfrac{1}{2}(+154\ \text{kJ}) + (+495\ \text{kJ}) + (-328\ \text{kJ}) + U$$

Solving for U:

$$U = (-569\ \text{kJ}) - (+109\ \text{kJ} + 77\ \text{kJ} + 495\ \text{kJ} - 328\ \text{kJ}$$

$$= -922\ \text{kJ/mol NaF}(s)\ \text{formed}$$

2. The Born–Haber cycle for the formation of $CaF_2(s)$ from $Ca(s)$ and $F_2(g)$ is illustrated in Figure 11.5b. The overall enthalpy change in the reaction producing CaF_2 is

$$\Delta H^\circ_f = \Delta H_{\text{sub,Ca}(s)} + \Delta H_{\text{BE,F2 }(g)} + [\ = \Delta H_{\text{IE1,Ca}(g)} + \Delta H_{\text{IE2,Ca}(g)}] + 2\ \Delta H_{\text{EA1,F}(g)} + U_{\text{CaF}(s)}$$

Substituting the values given:

$$-1228.0\ \text{kJ} = (+154\ \text{kJ}) + (+154\ \text{kJ}) + [(+590\ \text{kJ}) + (+1145\ \text{kJ})] + 2(-328\ \text{kJ}) + U$$

Solving for U:

$$U = (-1228.0\ \text{kJ}) - (+154\ \text{kJ} + 154\ \text{kJ} + 495\ \text{kJ} - (590\ \text{kJ} + 1145\ \text{kJ}) - 656\ \text{kJ}]$$

$$= -2615\ \text{kJ/mol CaF}_2(s)\ \text{formed}$$

Think About It We predicted that the lattice energy of CaF_2 is stronger than that of NaF. The calculated values of U confirm this prediction.

Practice Exercise Burning magnesium metal in air produces MgO and a very bright white light, making the reaction popular in fireworks and signaling devices:

The enthalpy change that accompanies this reaction is −602 kJ/mol MgO. Calculate the lattice energy of MgO from the following enthalpy changes:

Process	Enthalpy Change (kJ/mol)
$Mg(g) \rightarrow Mg^{2+}(g) + 2\ e^-$	[illegible]
$O(g) + 2\ e^- \rightarrow O^{2-}(g)$	[illegible]

Enthalpies of Hydration

Once we have calculated the lattice energy of an ionic compound, we can use an experimentally determined $\Delta H_{solution}$ value and Equation 11.6 to calculate a $\Delta H_{hydration}$ value as shown in **Figure 11.6**. Figure 11.6 is another example of a Born–Haber cycle. If the measured enthalpy of solution of sodium chloride is 4 kJ/mol and the lattice energy of NaCl is -786 kJ/mol, then:

The quantity $\Delta H_{hydration,NaCl(g)}$ represents the enthalpy change that occurs when gas-phase Na^+ and Cl^- ions dissolve in water. In this case, the value for $\Delta H_{hydration,NaCl(g)}$ is negative, indicating that the process is exothermic. The sign of $\Delta H_{hydration,NaCl(g)}$ also tells us something about the relative strengths of the hydrogen bonding interactions in water and the ion–dipole interactions in aqueous NaCl. If $\Delta H_{hydration,NaCl(g)} < 0$, then according to Equation 11.6 the formation of ion–dipole interactions must release more energy than is needed to disrupt the hydrogen bonds in water.

TABLE 11.4 Enthalpies of Hydration for Selected Cations and Anions[a]

Cation	$\Delta H_{hydration}$ (kJ/mol)
Li^+	−536
Na^+	−418
K^+	−335
Rb^+	−305
Cs^+	−289
Mg^{2+}	−1903
Ca^{2+}	−1591
Anion	$\Delta H_{hydration}$ (kJ/mol)
F^-	−502
Cl^-	−368

Br^-	−335
I^-	−293
ClO_4^-	−238
NO_3^-	−301
SO_4^{2-}	−1017

With careful measurements and calculations, we can even separate $\Delta H_{\text{hydration,NaCl}(g)}$ into enthalpies of hydration for the individual ions:

$$\Delta H_{\text{hydration,NaCl}(g)} = \Delta H_{\text{hydration,Na}^+(g)} + \Delta H_{\text{hydration,Cl}^-(g)}$$

The values for $\Delta H_{\text{hydration}}$ for selected cations and anions are listed in **Table 11.4** and can be used to calculate $\Delta H_{\text{solution}}$ for an ionic compound if we know the lattice energy, or to calculate the lattice energy if the enthalpy of solution is known. The values in Table 11.4 are the results of several experiments and include an inherent uncertainty. The sum of the values for Na^+ and Cl^- is −786 kJ/mol, which is close to the −782 kJ/mol value calculated earlier.

SAMPLE EXERCISE 11.4 Calculating Lattice Energy by Using Enthalpies of Hydration LO2

Calcium sulfate is used to prepare "plaster of Paris" for casting broken limbs. Use the appropriate enthalpy of hydration values in Table 11.4 and $\Delta H_{\text{solution}} = -16.7$ kJ/mol for $CaSO_4$ to calculate the lattice energy of $CaSO_4$.

Collect and Organize The enthalpies of hydration for Ca^{2+} and SO_4^{2-} are −1591 kJ/mol and −1017 kJ/mol, respectively. We can use the enthalpy of solution and Equation 11.6 to calculate the lattice energy.

Analyze To calculate U_{CaSO_4}, we must obtain a value for $\Delta H_{\text{hydration}}$ for $CaSO_4$:

From our calculations in Sample Exercises 11.1 and 11.3, we know that ionic charges greatly influence the strength of ion–ion interactions. Therefore, we expect the lattice energy of $CaSO_4$ to be much greater than that for NaF (-922 kJ/mol), for example, because the interaction between Ca^{2+} and $SO_4{}^{2-}$ is much greater than the interaction between Na^+ and F^-.

Solve Solving for the enthalpy of hydration of $CaSO_4$:

$$\Delta H_{\text{hydration,CaSO4}(g)} = \Delta H_{\text{hydration,Ca}^{2+}(g)} + \Delta H_{\text{hydration,SO4}^{2-}(g)}$$

$$= -1591 \text{ kJ/mol} + (-1017 \text{ kJ/mol}) = -2608 \text{ kJ/mol}$$

Substituting $\Delta H_{\text{hydration,CaSO4}(g)}$ and $\Delta H_{\text{solution,CaSO4}(aq)}$ into Equation 11.6:

$$\Delta H_{\text{solution,CaSO4}(aq)} = \Delta H_{\text{hydration,CaSO4}(g)} - UCaSO_{4(s)}$$

$$-16.7 \text{ kJ/mol} = (-2608 \text{ kJ/mol}) - UCaSO_{4(s)}$$

Solving for $UCaSO_{4(s)}$:

$$U_{\text{CaSO4}(s)} = -2608 \text{ kJ/mol} - (-16.7 \text{ kJ/mol}) = -2591 \text{ kJ/mol}$$

Think About It To check on the accuracy of the calculated lattice energy, let's compare it to the lattice energy of NaCl in Table 11.2 (-2591 kJ/mol/-786 kJ/mol) = 3.30. In Section 11.1 we calculated the ratio of the electrostatic potential energies between pairs of Ca^{2+} and $SO_4{}^{2-}$ ions to pairs of Na^+ and Cl^- ions and found it to be 3.43. The similar values of these two ratios indicates that the calculated lattice energy of $CaSO_4$ is reasonable.

Practice Exercise Calculate the lattice energy for $NaClO_4$ by using the data in Table 11.4 and $\Delta H_{\text{solution,NaClO4}(aq)} = 14$ kJ/mol.

Glossary

enthalpy of solution ($\Delta H_{\text{solution}}$)

the overall change in enthalpy that occurs when a solute dissolves in a solvent.

enthalpy of hydration ($\Delta H_{\text{hydration}}$)	the energy change when gas-phase ions dissolve in water.
lattice energy (U)	the enthalpy change that occurs when 1 mole of an ionic compound forms from its free ions in the gas phase.
Born–Haber cycle	a series of steps with corresponding enthalpy changes that describes the formation of an ionic solid from its constituent elements.

$$X_{\text{water}} = \frac{55.49\ \text{mol}}{55.49\ \text{mol} + 17.95\ \text{mol}} = 0.7556$$

11.3 Vapor Pressure of Solutions

In Section 10.4 we discussed how intermolecular interactions affect the vapor pressure and the normal boiling point of pure liquids. What happens to vapor pressure when nonvolatile solutes such as salts are dissolved in water?

When adjoining compartments of seawater (water that contains many dissolved nonvolatile solutes) and pure water are sealed in a chamber (**Figure 11.7**), the volume of fluid on the seawater side increases over time, while the volume on the side of pure water decreases at the same rate. Eventually, nearly all the water ends up in the seawater compartment. The transfer of the pure water is due to the dissolved solutes in the seawater.

CONNECTION For pure liquids, the vapor pressure is the pressure of a gas in equilibrium with its liquid, and the normal boiling point is the temperature at which the vapor pressure equals 1 atm (review Section 10.4).

As the water in both compartments evaporates, the concentration of water vapor in the air space of the sealed chamber increases. As the concentration of water vapor increases, the pressure the water vapor exerts on the two liquid surfaces increases. At constant temperature, this pressure eventually stabilizes at a value equal to the vapor pressure of water at that temperature. At this point, the rate of evaporation from the compartments is equal to the rate of condensation, which means a dynamic equilibrium has been established, as we discussed in Chapter 10.

If the evaporation and condensation rates for the pure water and the seawater were the same, the liquid levels in the compartments would not change over time. However, the liquid levels do change. The gas-phase water molecules in the sealed chamber are free to condense into either compartment, so the rate of condensation into both compartments is the same—but the rates of evaporation are not: the presence of dissolved solutes in the seawater affects its rate of evaporation. Given that most of the pure water ends up in the seawater compartment, the pure water must have a higher rate of evaporation than the seawater. This conclusion leads to another—namely, if the seawater evaporates at a lower rate, it must have a lower vapor pressure than the pure water at the same temperature.

More water vapor enters the air in the chamber from the pure-water compartment than from the seawater compartment because the vapor pressure of the pure water is greater than the vapor pressure of the seawater. Because the condensation rates are the same, the pure water loses more water over time than is restored to it by condensation, while the seawater gains more water than it loses by evaporation. The process depicted in Figure 11.7 illustrates the following general observation: at a given temperature, the vapor pressure of the solvent in a solution containing nonvolatile solutes is *less* than the vapor pressure of the pure solvent.

Raoult's Law

The connection between the vapor pressure of a solution and the concentration of nonvolatile solutes dissolved in the solvent was studied extensively by the French chemist François Marie Raoult (1830–1901). He discovered that the relation between the vapor pressure of a solution, P_{solution}, and that of the pure solvent, $P^{\circ}_{\text{solvent}}$, is

where X_{solvent} is the mole fraction of solvent. This relationship is now known as Raoult's law.

CONNECTION Recall from the discussion of partial pressures of gases in Section 5.7 that the *mole fraction* is the ratio of the number of moles of a component in a mixture to the total number of moles in the mixture.

Let's take another look at the two compartments in Figure 11.7. When the temperature in the chamber is 20°C, the vapor pressure of pure water is 0.0231 atm. What is the vapor pressure produced by evaporation of water from seawater if the mole fraction of water in the sample is 0.980? We can use Raoult's law (Equation 11.7) to answer this question:

$$P_{\text{solution}} = (0.980)(0.0231\ \text{atm}) = 0.0226\ \text{atm}$$

Because the vapor pressure of seawater at 20°C is slightly *lower* than the vapor pressure of pure water at 20°C, seawater evaporates more slowly than pure water.

The lower vapor pressure of a solution in relation to the vapor pressure of pure solvent depends only on the concentration of solute particles, not on their identity. Properties of solutions that depend only on the concentration of particles and not on their identity are called colligative properties. We examine them in detail in Section 11.5.

Solutions that obey Raoult's law are called ideal solutions. In ideal solutions, the solute and solvent experience similar intermolecular forces. For the most part, we treat solutions as ideal systems, but you should be aware that deviations from ideal behavior exist in liquids just as they do in gases. Deviations from ideal behavior typically occur when solute–solvent interactions are much stronger than solute–solute and solvent–solvent interactions. We address such situations in Section 11.4 when we discuss the distillation of crude oil to produce gasoline and other fuels.

CONNECTION As we first explained in Section 1.5, intensive properties of matter are independent of the amount of material present, whereas extensive properties depend on the quantity of substance present.

CONCEPT TEST

Is the vapor pressure of a pure solvent an intensive or an extensive property? Is the vapor pressure of a solution an intensive or an extensive property?

SAMPLE EXERCISE 11.5 Calculating the Vapor Pressure of a Solution LO3

The liquid used in automobile cooling systems is prepared by dissolving ethylene glycol ($HOCH_2CH_2OH$, molar mass 62.07 g/mol) in water. What is the vapor pressure of a solution prepared by mixing 1.000 L of ethylene glycol (density 1.114 g/mL) with 1.000 L of water (density 1.000 g/mL) at 100.0°C? Assume that the mixture obeys Raoult’s law.

Collect and Organize The vapor pressure of a solution is a colligative property that depends on the number of solute particles and hence the concentration. We have the volume and density of the components and can use them to determine the concentration of ethylene glycol. We may treat ethylene glycol as a nonvolatile solute whose aqueous solutions obey Raoult’s law. According to Figure 10.20, the vapor pressure of pure water at 100.0°C (its normal boiling point) is 760 torr, whereas the vapor pressure of ethylene glycol at that temperature is less than 20 torr.

Analyze We have a mixture of equal volumes of two liquids. The solvent is the one present in the greater number of moles.

We can determine the numbers of moles of each by the following calculation:

From these values we can decide which liquid is the solvent and calculate its mole fraction in the mixture. Water and ethylene glycol are both capable of hydrogen bonding, so their intermolecular interactions are similar, and we may treat the solution as ideal.

Solve Moles of ethylene glycol in 1.000 L:

Moles of water in 1.000 L:

Water, then, is the solvent, which allows us to use the model of a mixture that consists of a volatile solvent and nonvolatile solute. The mole fraction of water is

Ethylene glycol is essentially nonvolatile, so the vapor pressure of the solution results only from the solvent, and $P_{\text{solvent}} = P^\circ_{\text{H2O}} =$ 760 torr. Using this value and the calculated mole fraction of water in the mixture yields

$$P_{\text{solution}} = X_{\text{H2O}} \times P^\circ_{\text{H2O}} = (0.7556)(760 \text{ torr}) = 574 \text{ torr}$$

Think About It The presence of a nonvolatile solute causes the vapor pressure of the solution to be less than the vapor pressure of a pure solvent, giving us confidence in our result.

Practice Exercise Glycerol [$HOCH_2CH(OH)CH_2OH$] can be treated as a nonvolatile, water-soluble liquid. Its density is 1.25 g/mL. Predict the vapor pressure of a solution of 275 mL of glycerol in 375 mL of water at the normal boiling point of water.

To boil the solution described in Sample Exercise 11.5, we must heat it above 100°C—to a temperature at which the vapor pressure of the solution is 1 atm. This is why antifreeze works in an automobile engine: it not only lowers the freezing point of water, protecting the radiator, but also raises the boiling point of the coolant above that of pure water, making it possible for the coolant to remove more energy from the engine while staying in the liquid state.

Glossary

Raoult's law	the principle that the vapor pressure of the solvent in a solution is equal to the vapor pressure of the pure solvent multiplied by the mole fraction of the solvent in the solution.
ideal solution	a solution that obeys Raoult's law.

11.4 Mixtures of Volatile Solutes

Thus far we have considered only the effect of essentially *nonvolatile* solutes on the vapor pressure of a volatile solvent. In our everyday lives, however, we encounter many solutions containing *volatile* solutes. For example, the natural gas used for heating and the gasoline we use to power vehicles are mixtures of hydrocarbons. Gasoline comes from crude oil, a complex mixture of compounds composed mostly of carbon and hydrogen. Depending on its source, crude oil contains varying concentrations of hydrocarbons with five or more carbon atoms in their molecular structures. The hydrocarbons with one to four carbon atoms are usually found in deposits of natural gas, although they are also dissolved in crude oil. Most hydrocarbons in gasoline have from five to nine carbon atoms per molecule. Each of these compounds is volatile and has a measurable vapor pressure at 25°C. Because of this volatility, we can separate gasoline from crude oil by distillation. In this section we explore distillation on a molecular level and consider the effects of volatile solutes on the vapor pressure of a solution.

CONNECTION We introduced simple distillation in Section 1.3 as a way to make drinking water from seawater.

Vapor Pressures of Mixtures of Volatile Solutes

In Section 6.3 we discussed the process of distillation as a way to purify liquids (see Figure 6.15), and in Section 10.4 we discussed the vaporization of pure liquids and the role of intermolecular forces in determining the normal boiling point. In addition, we saw that the temperature at which a pure liquid boils remains constant throughout the vaporization process. Another type of distillation, called fractional distillation (**Figure 11.8**), is used to separate the volatile components of a mixture. This method is based on the observation that the boiling point of a mixture changes as the mixture is distilled.

As a mixture of volatile liquids is heated, the vapor that rises and fills the space above the liquid has a different composition from the composition of the mixture: the concentration of the component with the lowest boiling point is higher in the vapor than in the liquid. If this enriched vapor is collected, condensed, and redistilled, the vapor this time is even richer in the component with the lowest boiling point. In a fractional distillation apparatus, repeated distillation steps allow components with only slightly different boiling points to be separated from one another.

To see how a mixture behaves when boiled and how fractional distillation uses that behavior to separate the components, let's compare the heating curves of a pure substance and a solution of two volatile liquids. **Figure 11.9a** is the heating curve for pure octane (C_8H_{18}, bp 126°C). As in the heating curves of Section 6.5, the phase change from liquid to vapor takes place at a constant temperature of 126°C. **Figure 11.9b** shows the heating curve for a mixture of heptane (C_7H_{16}, bp 98°C) and octane. Here the portion of the curve from point 1 to point 2 again represents a vapor–liquid phase change, but in this case the temperature is not constant during the phase change. The increasing temperature of the mixture as it vaporizes means that the vapors it produces as the mixture begins to boil are richer in the more volatile (lower boiling point) component (heptane) leaving behind a boiling liquid that becomes richer in the higher-boiling component (octane). As the mixture continues to evaporate, the vapors it produces become richer in the higher-boiling component (octane). Thus, the two components co-distill over a range of temperatures, producing vapor that initially has a relatively high concentration of heptane, but that is never 100% heptane.

Now let's analyze the graphs describing how fractional distillation can achieve complete separation of two volatile liquids. **Figure 11.9c** shows how the composition of the vapor above a series of boiling solutions differs from the compositions of the solutions. Note that the concentration of the lower-boiling (more volatile) component is always greater in the vapor than in the solution that produced it. This is the key to how fractional distillation separates mixtures.

Suppose we use the distillation apparatus from Figure 11.8 to heat 100 mL of a solution that is 50% by volume heptane and 50% octane (50:50). The blue curve in Figure 11.9c gives the temperature of the boiling solution, and point 1 on the curve tells us that the boiling point of the 50:50 solution is about 108°C. The red line in the graph represents the composition of the vapor above the solution at a given temperature. To find the composition of the vapor at 108°C, we move horizontally to the left along the dashed line between points 1 and 2. This horizontal line corresponds to a temperature of 108°C on the *y*-axis. Point 2 corresponds to a different composition (on the *x*-axis) for the vapor than for the solution at point 1. The vapor at point 2 is enriched in the lower-boiling component: it is about 65% heptane and only 35% octane.

This 65:35 vapor rises in the distillation column, cools, and condenses in the next region of the column, a process represented by the red arrow from point 2 to point 3. The condensed liquid in this flask is 65% heptane and 35% octane. Continued heating of the column warms this liquid, and it begins boiling at about 104°C, which is the temperature at point 3. To find the concentration of the vapor above this boiling liquid, we move left from point 3 until we intersect the red curve (point 4). Reading down from point 4 to the concentration axis, we see that the vapor concentration is now about 80% heptane and only 20% octane. This vapor with 80:20 composition rises, then cools and condenses, and the distillation cycle is repeated.

If we continue this process of redistilling mixtures with increasing concentrations of heptane and then cooling and condensing the vapors, we eventually obtain a condensate that is pure heptane. If we monitor the temperature at which vapors condense at the very top of our distillation column, we will see a profile of temperature versus volume of distillate produced (**Figure 11.10**). The first liquid to be produced is pure heptane, which has a boiling point of 98°C. Ideally, over time, all 50 mL of heptane in the original sample is recovered. As we continue to add energy at the bottom of the column, the temperature at the top rises to 126°C, signaling that the second component (pure octane, bp 126°C) is being collected. In the real world, the separation may not be as complete as described in this idealized presentation.

CONCEPT TEST

Dimethyl ether (CH_3OCH_3) and acetone [$CH_3C(O)CH_3$], shown in **Figure 11.11**, have similar molar masses but different dipole moments: 1.30 D and 2.88 D, respectively. Which compound would you expect to distill first from a mixture of acetone and dimethyl ether? Why?

SAMPLE EXERCISE 11.6 Predicting the Results of Fractional Distillation LO4

How would the graph in Figure 11.10 be different if (a) we started with a mixture of 75 mL of octane (C_8H_{18}) and 25 mL of heptane (C_7H_{16}) and (b) we started with a mixture of 75 mL of octane (C_8H_{18}) and 25 mL of nonane (C_9H_{20})? The normal boiling points of heptane, octane, and nonane are 98°C, 126°C, and 151°C, respectively.

Collect and Organize The graph in Figure 11.10 is an idealized plot of the temperature of the solution as a function of the volume of distillate for a 50:50 mixture of C_7H_{16}:C_8H_{18}. We want to describe the changes in the graph if we change the ratio of the components and if we change the identity of one of the components. We are given the normal boiling points of all compounds.

Analyze Fractional distillation separates solutions of volatile liquids into pure substances based on their different boiling points. The components distill in the order of their boiling points, with the lowest-boiling component distilling first. Ideally, the total volume of distillate equals the total volume of the solution, and the volume of each fraction reflects the volume of the component in the original solution.

Solve

1. The first component that distills is the lower-boiling heptane. Ideally, 25 mL of heptane would distill at 98°C. Then, the only remaining component (75 mL of octane) would distill at 126°C. The idealized graph (**Figure 11.12**) shows the boiling points of the two substances along the *y*-axis and the volume of distillate along the *x*-axis. The lengths of the horizontal lines at 98°C and 126°C are in a 1:3 ratio, reflecting the composition of the mixture, 25 mL of C_7H_{16} and 75 mL of C_8H_{18}.
2. The first component that distills in the second mixture is the lower-boiling octane. Ideally, 75 mL of octane would distill at 126°C. Once the octane is removed from the solution, the only remaining component (25 mL of nonane) would distill at 151°C. The idealized graph (**Figure 11.13**) shows the boiling points of the two substances along the *y*-axis and the volume of distillate along the *x*-axis.

Think About It The constant temperature plateaus in the distillation graphs make sense because multiple vaporization–condensation cycles in the fractionating column mean that the vapor reaching the top of the column and flowing into the condenser is composed entirely of the most volatile component (remaining) in the distillation mixture. The constant temperature of the vapor matches the boiling point of that component.

Practice Exercise Draw an idealized graph of the temperature versus volume of distillate collected when a solution consisting of 30 mL of hexane (boiling point 69°C), 50 mL of heptane (boiling point 98°C), and 20 mL of nonane (boiling point 151°C) is fractionally distilled.

Raoult’s Law

Now that we know how fractional distillation works, the next step is to understand *why* it works. We return to Raoult's law, which we used in Section 11.3 to describe the influence of nonvolatile solutes on the boiling point of a pure solvent. Raoult's law also applies to homogeneous mixtures of volatile compounds, such as crude oil. Because the solutes in a solution of crude oil are volatile, they contribute to the solution's overall vapor pressure. The total vapor pressure equals the sum of the vapor pressures of each component ($P°_x$ is the equilibrium vapor pressure of the pure component at the temperature of interest) multiplied by the mole fraction of that component in the solution (X_x):

SAMPLE EXERCISE 11.7 Calculating the Vapor Pressure of a Solution of Volatile Substances LO3

Ethanol (CH_3CH_2OH) is used to disinfect the skin prior to getting a shot, such as a flu vaccine. The solution quickly evaporates at 37°C, roughly the body temperature of a healthy human. Calculate the vapor pressure of a solution prepared by dissolving 5.0 g of water in 78.0 g of ethanol (CH_3CH_2OH) at 37°C. By what factor does the concentration of the more volatile component in the vapor exceed the concentration of this component in the liquid? The vapor pressures of ethanol and water at 37°C are 115 torr and 47 torr, respectively.

Collect and Organize We can use Equation 11.8 to determine the total vapor pressure of the solution from the vapor pressures of the components after we determine the composition of the solution in terms of mole fractions.

Analyze To calculate the mole fraction of each component, we need the molar masses of water and ethanol. The mole fraction is then equal to the number of moles of each component divided by the total number of moles of material in the solution.

The vapor pressure of the solution must lie between the vapor pressures of the pure compounds.

Solve The number of moles of each component is

The total number of moles of material is (1.69 mol + 0.28 mol) = 1.97 mol.

Thus, the mole fraction of each component in the mixture is

Using these values and the vapor pressures of the two substances in Equation 11.8, we have

$$
\begin{aligned}
P_{\text{total}} &= X_{\text{water}}P^\circ_{\text{water}} + X_{\text{ethanol}}P^\circ_{\text{ethanol}} \\
&= 0.142(47\ \text{torr}) + 0.858(115\ \text{torr}) \\
&= 6.7\ \text{torr} + 98.7\ \text{torr} = 105.4\ \text{torr}
\end{aligned}
$$

To calculate how enriched the vapor phase is in the more volatile component (i.e., in ethanol, the component with the greater vapor pressure), we need to recall Dalton's law of partial pressures (Section 5.7) and the concept that the partial pressure of a gas in a mixture of gases is proportional to its mole fraction in the mixture. Therefore, the ratio of the mole fraction of ethanol to that of water is the ratio of their two vapor pressures:

The mole ratio of ethanol to water in the liquid mixture is

Therefore, the vapor phase is enriched in ethanol by a factor of

Think About It The vapor pressure of the mixture (105.4 torr) is between the vapor pressures of the separate components (47 torr and 115 torr). This result illustrates how fractional distillation works. The vapor is enriched in the lower-boiling component.

Practice Exercise Benzene (C_6H_6) is a trace component of gasoline. What is the mole ratio of benzene to octane in the vapor above a solution of 10% benzene and 90% octane by mass at 25°C? The vapor pressures of octane and benzene at 25°C are 11 torr and 95 torr, respectively.

Solutions such as the hydrocarbons in crude oil obey Raoult's law when the strengths of solvent–solvent, solute–solute, and solute–solvent interactions are similar. Under these conditions, a solution behaves ideally. A mixture of hydrocarbons is expected to behave like an ideal solution because intermolecular interactions between the components are all London forces acting on molecules of similar structure and size.

If the solute–solvent interactions are *stronger* than the solvent–solvent or solute–solute interactions, the solute inhibits the solvent from vaporizing and the solvent inhibits the solute from vaporizing. This situation produces negative deviations from the vapor pressures predicted by Raoult's law (**Figure 11.14a**). In such a solution, the rate of evaporation is slower because the vapor pressure of the mixture is lower than predicted. Because solvent and solute molecules are held at the surface by solute–solvent attractive interactions, more energy is required to separate them from the surface, and fewer vaporize at a given temperature.

If solute–solvent interactions are much *weaker* than solvent–solvent interactions, less energy is required to separate solute molecules from the surface, and more solute molecules vaporize. In this case the vapor pressure is greater than the value predicted by Raoult's law (**Figure 11.14b**).

CONCEPT TEST

Which of the following solutions is least likely to follow Raoult's law: (a) acetone–ethanol, (b) pentane–hexane, or (c) pentanol–water? The skeletal molecular structures of the compounds are given in **Figure 11.15**.

Glossary

fractional distillation	a method of separating a mixture of compounds based on their different boiling points.

Learning Objectives

- Relate the fractional distillation of a mixture of volatile compounds to the vapor pressures of the compounds **Return to Sample Exercise 11.6**
- Use Raoult's law to relate the vapor pressure of a solution to the concentration of solute particles **Return to Sample Exercise 11.5, 11.7**

FIGURE 11.16 Combined phase diagram for pure water and a solution of a nonvolatile solute in water. Notice that the solution's boiling point is higher than the boiling point of water (the pure solvent) and that the solution's freezing point is lower than the freezing point of water. The line depicting the phase change from solid to liquid bends ever so slightly to the left. Compare this with Figure 10.23, where the negative slope of this line is clearer at pressures above 1 atm.

FIGURE 11.19 (a) The experimentally measured freezing point of a 0.010 *m* solution of NaCl is the same as the theoretical value obtained with Equation 11.15. This agreement means that the solution behaves ideally and little or no ion pairing takes place. (b) The experimentally measured freezing point of a 0.10 *m* solution is about 0.04°C higher than the theoretical value because some of the Na^+ and Cl^- ions form ion pairs, as shown inside the red ovals. The formation of ion pairs causes the concentration of solute particles to be less than the theoretical number—as a result, the van ’t Hoff factor for the solution is less than the theoretical value of 2, and the decrease in the freezing point is less than expected.

11.5 Colligative Properties of Solutions

We saw in Section 11.3 that the vapor pressure of a solution containing a nonvolatile solute is lower than the vapor pressure of the pure solvent. In this section we explain how many other physical properties of a solvent are changed when a nonvolatile solute is added to it. These properties of solutions that depend only on the concentration of solute particles, but not on the identity of the solute, are called colligative properties. Solutions generally have greater densities than the solvent alone, and an aqueous solution containing a nonvolatile solute has a higher boiling point and a lower freezing point than pure water. As we saw in Section 11.3, antifreeze, an aqueous solution of ethylene glycol used to cool automobile engines, boils above 100°C and freezes below 0°C. As a result, it has a higher boiling point and a lower freezing point than pure water.

Figure 11.16 shows the combined phase diagram of water and an aqueous solution of a nonvolatile solute. The red line representing boiling/condensation points of the solution lies below the orange line for pure water. The blue melting/freezing line for the solution lies to the left of the light blue line for pure water. Following the dashed line from left to right at $P = 1$ atm, we see that the solution freezes at a lower temperature than pure water and boils at a higher temperature than pure water. Furthermore, the higher boiling point for the solution indicates that the solution has a lower vapor pressure than pure water.

Boiling point elevation and freezing point depression are both colligative properties. As noted in Section 11.3, only the number of particles in solution determines the impact of the solute on the colligative properties of the solvent. Before we can quantify these properties, though, we must introduce a new concentration unit.

CONNECTION Phase diagrams (Section 10.5) show how the physical states of substances change with changing temperatures and pressures.

Molality

Molarity (Section 4.2) is the concentration unit of choice when we run reactions in solutions, usually at constant temperature, so that we can measure volumes of solutions and know the number of moles of reactants we are dealing with. When we work with colligative properties, however, we frequently deal with the properties of systems as a function of temperature. Because volumes change with temperature, molarity changes with temperature. If we want to quantify certain colligative properties, therefore, the approach is to use a different concentration unit, called molality (m), which is defined as the number of moles of solute (n_{solute}) per kilogram of solvent:

The difference between these two similar-sounding concentration units is that molarity is the number of moles of solute *per liter of solution*, whereas molality is the number of moles of solute *per kilogram of solvent*. Because solvent mass does not change with temperature, a concentration expressed in molality does not change with temperature.

To illustrate the difference between the molarity and molality of a solution, let's use the procedure outlined in **Figure 11.17** to calculate the molality of 1 L of an aqueous solution of sodium chloride that is 0.558 M in NaCl (approximately the NaCl concentration in seawater) at 25°C. To calculate molality, we need the density of the solution so that we can convert liters of solution into kilograms of solvent. The density of the solution is 1.022 g/mL at 25°C, so 1 L of solution has a mass of

Of this 1022 g of solution, the mass of dissolved NaCl in it is

Subtracting the mass of NaCl from the mass of solution gives us the mass of the solvent in 1 L of the solution: (1022 g − 32.6 g) = 989 g = 0.989 kg. The molality of the solution (i.e., the number of moles of solute per kilogram of solvent) is

The two concentration values, 0.558 M and 0.564 m, are close but not quite equal. Like any aqueous solution, its molality is greater than its molarity.

CONCEPT TEST

The difference between the molarity and molality concentrations of a dilute aqueous solution is small. Why?

SAMPLE EXERCISE 11.8 Preparing a Solution of Known Molality LO5

How many grams of Na_2SO_4 should be added to 275 mL of water to prepare a 0.750 *m* solution of Na_2SO_4? Assume the density of water is 1.000 g/mL.

Collect and Organize We want to determine the mass of sodium sulfate (the solute) needed to prepare a 0.750 *m* solution. The volume of water (the solvent) is 275 mL.

Analyze Following the procedure shown in Figure 11.17:

We can then work backward from molality to mass of solute:

Our goal is to prepare a relatively small volume $(\sim \frac{1}{4}\ \mathrm{L})$ of a dilute solution (< 1 *m*), so we predict that the mass of solute needed is probably less than $\frac{1}{4}$ mole of solute, which has a molar mass of about 142 g/mol, or about 35 g.

Solve Multiplying 275 mL of water by the density of water gives the mass of water we start with:

We can rearrange Equation 11.9 to determine the number of moles of solute needed, using the fact that a molality of 0.750 is equivalent to 0.750 mol of solute in 1 kg of solvent:

The molar mass of Na_2SO_4 is 142.04 g/mol, so the number of grams of Na_2SO_4 needed is

Dissolving 29.3 g of Na_2SO_4 in 275 mL of water produces a 0.750 *m* solution.

Think About It The calculated value of 29.3 g of Na_2SO_4 is consistent with our prediction that about 35 g of solute would be required. Taking a different approach to this sample exercise, we could calculate the molality of a solution in which 29.3 g Na_2SO_4 is dissolved in 275 mL H_2O:

Practice Exercise What is the molality of a solution prepared by dissolving 78.2 g of ethylene glycol ($HOCH_2CH_2OH$) in 1.50 L of water? Assume the density of water is 1.000 g/mL.

TABLE 11.5 Molal Freezing-Point-Depression and Boiling-Point-Elevation Constants for Selected Solvents

[illegible]
Water (H_2O)
Benzene (C_6H_6)
Ethanol (CH_3CH_2OH)
Carbon tetrachloride (CCl_4)

Boiling Point Elevation

In Section 11.3 we discussed how the vapor pressure of a solution is reduced and the boiling point is elevated with respect to pure solvent, and at the beginning of this section we examined the phase diagrams of solutions. Now we can look quantitatively at how much the boiling points and freezing points of liquids change when solutes are present.

Boiling point elevation is a colligative property of the solvent. It is described in equation form as

where ΔT_b is the increase in temperature above the boiling point of the pure solvent, K_b is the *boiling-point-elevation constant* of the solvent, and m is the molality of the solution. The values of K_b for several solvents are listed in **Table 11.5**. The units of K_b are °C/*m*, so the concentration of particles in solution must also have units of molality (*m*):

Adding the increase in boiling point to the normal boiling point of pure solvent, T°_b, gives us an equation for calculating the boiling point (T_b) of any solution based on that solvent:

The K_b of water is 0.52°C/*m*, which means that for every mole of particles that dissolves in 1 kg of water (1 *m*), the boiling point of the solution rises by 0.52°C:

Therefore, the boiling point (T_b) of the solution is

$$T_b = T^\circ_b + \Delta T_b = 100.00^\circ\text{C} + 0.52^\circ\text{C} = 100.52^\circ\text{C}$$

SAMPLE EXERCISE 11.9 Calculating the Boiling Point Elevation of an Aqueous Solution LO6

Maple syrup is produced by evaporating most of the water from sap collected from maple trees in early spring. Suppose a 100.0 g sample of maple syrup contains 61.2 g of sucrose ($\mathscr{M}$ = 342.3 g/mol), 6.8 g of fructose and glucose, which have the same molar mass (180.2 g/mol), and a variety of other trace organic and inorganic ingredients that do not contribute significantly to boiling point elevation. At what temperature does the syrup sample boil?

Collect and Organize We are asked to calculate the boiling point of maple syrup and are given the concentration of the three principal solutes in it. Equation 11.11 relates the boiling point of a solution to that of pure solvent and to the molal concentration of solute particles. The boiling-point-elevation constant of water is $K_b = 0.52°C/m$, and the normal boiling point of pure water is 100.0°C.

Analyze To use Equation 11.11, we must first convert concentration values in g solute/g solution to mol solute/kg solvent (H_2O). The following unit conversions should accomplish this task:

Sugars make up over $\frac{2}{3}$ of the mass of the sample, which means that less than $\frac{1}{3}$ of it is water. A kilogram of this syrup would have nearly 700 g, or about 2 moles, of the sugars in about $\frac{1}{3}$ of a kilogram of water for a molality around 6 *m* and a boiling point near $(100 + 0.5 \times 6)$ or 103°C.

Solve

Think About It The calculated boiling point is near the predicted value, so is reasonable.

Practice Exercise Crude oil pumped out of the ground may be accompanied by *formation water*, a solution that contains high concentrations of NaCl and other salts. If the boiling point of a sample of formation water is 2.3°C above the boiling point of pure water, what is the molality of dissolved particles in the sample?

Freezing Point Depression

As we mentioned when discussing Figure 11.16, *freezing point depression* is a colligative property that is put to good use in car radiators to ensure that their fluid does not freeze in cold weather. The magnitude of the freezing point depression is directly proportional to the molal concentration of dissolved solute:

where ΔT_f is the change in the freezing temperature of the solvent, K_f is the *freezing-point-depression constant* of the solvent, and m is the molality of the solution. The values of K_f for several solvents are listed in Table 11.5. The freezing point (T_f) of a solution is

The flowchart in **Figure 11.18** summarizes calculations of freezing point depression and boiling point elevation.

SAMPLE EXERCISE 11.10 Calculating the Freezing Point of a Solution LO6

What is the freezing point of radiator fluid prepared by mixing 1.00 L of ethylene glycol ($\mathcal{M}$ = 62.07 g/mol, density = 1.114 g/mL) with 1.00 L of water (density 1.000 g/mL)?

Collect and Organize We are asked to determine the freezing point of a solution of ethylene glycol in water from the volumes of the two liquids, their densities, and K_f for water. Equation 11.13 relates the freezing point of a solution to the normal freezing point of the solvent (0.0°C), the freezing-point-depression constant, K_f, which is 1.86°C/m for water, and the total molal concentration of all solute particles in solution.

Analyze To use Equation 11.13, we first need to calculate the molal concentration of the solute (ethylene glycol) in the solvent (water) using the following conversion steps:

We have equal volumes of each substance, but it is logical for us to choose water as the solvent because ethylene glycol has a much higher molar mass (see Sample Exercise 11.5). The mass of 1 L of ethylene glycol is 1114 g. This mass divided by the molar mass (62 g/mol) is roughly 1000 g/60 g/mol or 17 mol, which forms a 17 m solution when dissolved in 1 kg of H_2O. Multiplying 17 m by

$1.86^\circ\text{C}/m$ produces a ΔT_f near $-\ 30^\circ\text{C}$.

Solve The solvent mass is

The moles of ethylene glycol in 1.00 L are

Calculating the molal concentration of ethylene glycol:

Using this concentration in Equation 11.13:

Think About It The answer makes sense because it is close to the predicted value. Also, engine coolant with this freezing point would provide adequate protection against radiator fluid freezing during most winters in most of the United States, though not in much of Canada or Alaska where 60%–70% by volume solutions of ethylene glycol are often used to prevent engines from freezing up.

Practice Exercise Concentrated solutions of ionic compounds are used in biochemistry laboratories to disrupt the structure of proteins. What is the freezing point of a solution whose ion concentration is 8.15 *m*?

The van ’t Hoff Factor

Recall from Section 4.4 that compounds called *electrolytes* dissociate into ions when in solution, whereas *nonelectrolytes* remain intact. If a solute is a nonelectrolyte, then every mole of solute yields 1 mole of particles. If the solute is an electrolyte, however, then the number of moles of particles depends on the total concentration of cations and anions in solution. For example, if we approximate seawater as 0.574 *m* sodium chloride, then each kilogram of water contains $2 \times 0.574 = 1.148$ moles of particles because NaCl forms

Na^+ and Cl^- ions when it dissolves.

CONNECTION An electrolyte is a substance that dissociates into ions when it dissolves (Section 4.4).

Because freezing point depression and boiling point elevation are colligative properties, the dissolution of 1 mole of a strong electrolyte such as NaCl in a given quantity of water produces the same changes in freezing point and boiling point as 1 mole of the strong electrolyte KNO_3, even though the latter has a much higher molar mass. Each of these salts adds 2 moles of particles (1 mole of cations and 1 mole of anions) to the water for every 1 mole of salt that dissolves. When a nonelectrolyte such as ethylene glycol is dissolved in water, on the other hand, 1 mole of the solute produces only 1 mole of particles (1 mole of molecules) in the solution.

Dutch chemist Jacobus van ’t Hoff (1852–1911) studied colligative properties and defined a term *i*, now called the van ’t Hoff factor (or *i* factor), which is the ratio of the experimentally measured value of a colligative property to the value expected if the solute were a nonelectrolyte (i.e., no dissociation into ions). For example, suppose we make a solution that is 0.010 *m* in NaCl by dissolving 0.5844 g of NaCl in 1 kg of water. If NaCl was a nonelectrolyte, then the freezing point of the solution should be lower than that of pure water by

However, the observed freezing point depression for 0.0100 *m* NaCl is not 0.0186°C, but instead is 0.0372°C: *twice* as much as that predicted for a nonelectrolyte. The factor of 2 difference in the observed change in freezing point compared to that of a nonelectrolyte is the van ’t Hoff factor for NaCl. Its value makes sense because sodium chloride is a strong electrolyte and forms 2 moles of ions from each mole of NaCl. Like all colligative properties, the observed changes are proportional to *total concentration of dissolved particles* present in solution.

Equations such as 11.10 and 11.12 can be modified to include the *i* factor:

If the solute is molecular (such as ethylene glycol) and therefore a nonelectrolyte, then $i = 1$ because each mole of solute produces 1 mole of dissolved particles. If the solute is a strong electrolyte, then $i =$ the number of ions in one formula unit. For NaCl, $i = 2$; for Na_2SO_4, $i = 3$ (two Na^+ ions and one SO_4^{2-} ion). We do *not* break a polyatomic ion such as SO_4^{2-} into its atoms when determining an i factor; polyatomic ions stay intact.

SAMPLE EXERCISE 11.11 Using the van ’t Hoff Factor LO7

The salt lithium perchlorate ($LiClO_4$) is one of the most water-soluble salts known. At what temperature does a 0.130 *m* solution of $LiClO_4$ freeze? The K_f of water is 1.86°C/*m*; assume $i = 2$ for $LiClO_4$ and the freezing point of pure water is 0.00°C.

Collect and Organize We are asked to determine the freezing point of a salt solution. We know the formula of the solute, its molal concentration, and K_f of the solvent. We know that the freezing point of the pure solvent is 0.00°C. We are given the value of the van ’t Hoff factor as $i = 2$.

Analyze We use Equation 11.15 to solve for the freezing point depression. The value of K_f is close to 2, the value of i is 2, and the concentration of solute is close to 0.1 *m*, so we predict that the freezing point of the solution will be about 0.4°C lower than that of pure water.

Solve

The freezing point of the solution is $(0.00 - 0.484)°C = -0.48°C$.

Think About It Lithium perchlorate dissolves in aqueous solution to form 2 moles of ions for every mole of solute that dissolves: 1 mole of Li^+ cations and 1 mole of ClO_4^- anions, consistent with $i = 2$. The calculated value is consistent with our prediction.

Practice Exercise Determine the value of the van ’t Hoff factor and calculate the boiling point of a 1.75 *m* aqueous solution of barium nitrate, $Ba(NO_3)_2$. $K_b = 0.52°C/m$ for water.

CONCEPT TEST

Which aqueous solution has the lowest freezing point: (a) 3 *m* glucose ($C_6H_{12}O_6$), (b) 2 *m* potassium iodide (KI), or (c) 1 *m* sodium sulfate (Na_2SO_4)?

Using Equations 11.14 and 11.15 to calculate boiling point elevations and freezing point depressions for concentrated solutions of strong electrolytes often gives larger values than the experimentally measured values. The reason is that the cations and anions produced when strong electrolytes dissolve may not be totally independent of one another. As concentration increases, cations and anions may form ionic clusters. The simplest cluster, an ion pair, consists of a cation and an anion that associate in solution, acting as a single particle. Thus, the overall concentration of particles is reduced when ion pairs form, and experimentally measured boiling point elevations and freezing point depressions are smaller than the theoretical values obtained with Equations 11.14 and 11.15 (**Figure 11.19**).

The extent to which free ions form when a strong electrolyte dissolves is expressed by the van ’t Hoff factor. The van ’t Hoff factor for NaCl in water is 2 if the solution behaves ideally, because ideally 2 moles of ions are produced for each mole of NaCl that dissolves. The value of *i* is 2 for 0.010 *m* NaCl, but a little less than 2 for 0.10 *m* NaCl. Whenever a calculation for *i* gives a noninteger value, solute particles are associating in solution, and the behavior is nonideal. **Figure 11.20** gives some theoretical and experimentally measured values of the van ’t Hoff factor for several substances.

CONCEPT TEST

Which drawing in **Figure 11.21** best represents the distribution of the ions and the observed freezing point of a 1.26 *m* aqueous solution of $CaBr_2$? (Solvent molecules have been omitted.)

SAMPLE EXERCISE 11.12 Assessing Particle Interactions in Solution LO7

The experimentally measured freezing point of a 1.90 *m* aqueous solution of NaCl is $-6.57°C$. What is the value of the van ’t Hoff factor for this solution? Is the solution behaving ideally, or is there evidence that solute particles are interacting with one another? The freezing-point-depression constant of water is $K_f = 1.86°C/m$, and the freezing point of pure water is 0.00°C.

Collect and Organize We are asked to calculate the *i* factor for a solution of known molality. We are given the measured freezing point and the K_f value. We are also asked whether the solution is behaving ideally.

Analyze We can rearrange Equation 11.15 ($\Delta T_f = iK_f m$) to solve for *i* before substituting the values for ΔT_f, K_f, and *m*. If the solution behaves ideally, we would expect $i = 2$ for a strong electrolyte like NaCl; however, given the high concentration of NaCl (1.90 *m*), we predict a value less than 2.

Solve Rearranging Equation 11.15 gives us

The value of *i* is not an integer, so the solution is *not* behaving ideally. Ion pairs must be forming in solution.

Think About It As predicted, the value of *i* for this solution is less than the theoretical value of 2.

Practice Exercise The van ’t Hoff factor for a 0.050 *m* aqueous solution of magnesium sulfate is 1.3. What is the freezing point of the solution?

The extent of ion pairing in a solution of a strong electrolyte generally increases with solute concentration. For any salt, the theoretical value of *i* obtained with Equation 11.14 or 11.15 is an upper limit of possible values. If ion pairing occurs, the experimentally measured value must be less than the theoretical value.

Osmosis and Osmotic Pressure

The final colligative property we look at in this chapter is *osmotic pressure*, the result of the process called osmosis—the movement of a solvent through a semipermeable membrane from a region of lower solute concentration to a region of higher solute concentration. A *semipermeable membrane* allows particles of solvent to pass through it but not particles of solute.

To emphasize the importance of osmosis, we start with the observation that we all need water to survive. More than 97% of the water on Earth is seawater, however, and none of that is fit to drink. Why is that? The liquid inside each cell in the body is a complex solution of many solutes, with the average concentration of these solutes being about one-third the concentration of solutes in seawater. When cells are exposed to seawater, this substantial difference in solute concentration is the driving force for osmosis, with the cell membrane acting as the necessary semipermeable membrane (**Figure 11.22**). Because the solute concentration is higher outside the cell, water from inside the cell crosses the cell membrane and enters the seawater, moving from the low-solute-concentration side of the membrane to the high-solute-concentration side. As water leaves the cell, the cell shrivels and ultimately ceases to function.

Osmotic Pressure

Water molecules migrate through a cell membrane, or through any other semipermeable membrane, because a force makes it happen—a force caused by the different concentrations of solutes on the two sides of the membrane. When we divide the magnitude of this force, F, by the surface area, A, of the membrane, we get pressure: $P = F/A$. Osmotic pressure (Π) is the pressure required to halt the flow of solvent from a dilute solution through a semipermeable membrane into a more concentrated solution. Osmotic pressure exactly balances the pressure (F/A) driving solvent through the membrane so that no net flow of solvent takes place.

The Greek letter pi (Π) is used to symbolize osmotic pressure to distinguish it from the pressure exerted by gases. In **Figure 11.23a**, the solution on the right has a lower concentration and lower osmotic pressure (Π_{NaCl}) than the solution on the left (Π_{seawater}): $\Pi_{\text{NaCl}} < \Pi_{\text{seawater}}$. The result is a net flow of solvent (water) from right to left until the pressure on both sides is equal. **Figure 11.23b** shows how the volumes of both solutions change: the difference in volume reflects the difference in osmotic pressures, $\Delta\Pi = \Pi_{\text{seawater}} - \Pi_{\text{NaCl}}$, in the original solutions. This process is profoundly important in living systems, where the solution inside each cell exerts an osmotic pressure on the cell membrane—a pressure that pushes toward the outside of the cell. At the same time, blood or other liquid outside the cell exerts an osmotic pressure on the cell membrane, and this pressure pushes toward the cell's interior.

The osmotic pressure Π depends on the solute concentration, the absolute temperature, and the constant R, 0.0821 L · atm/(mol · K):

$$\Pi = MRT$$

where M is the molarity of the solute. Molarity is used to express concentration in calculating Π because the expression for Π can be derived from an equation similar to the ideal gas equation:

The term n/V has units of moles per liter, which matches the definition of molarity. Osmotic pressure is a colligative property because Π is proportional to the concentration of solute particles and does not depend on the identity of the solute. Therefore, molarity must be multiplied by the van ’t Hoff factor *i* for the solute:

Because the units of *R* are L · atm/(mol · K) and *i* has no units, the product *iMRT* gives Π in units of atmospheres.

A 1.0 *M* solution of NaCl should produce the same osmotic pressure as 1.0 *M* KCl or 1.0 *M* $NaNO_3$ because all three solutions are nearly 2.0 *M* in total ions ($i = 2$). These solutions should have nearly twice the osmotic pressure of a 1.0 *M* solution of glucose at a given temperature because glucose is a nonelectrolyte and produces a solution that is only 1.0 *M* in dissolved particles (glucose molecules).

CONCEPT TEST

If a 1.0 *M* glucose solution is on one side of a semipermeable membrane and a 1.0 *M* KCl solution is on the other side, in which direction does the water flow?

SAMPLE EXERCISE 11.13 Calculating Osmotic Pressure I LO8

The concentration of solutes in a red blood cell is about a third of that of seawater—more precisely, about 0.30 *M*. If red blood cells are immersed in pure water, they swell, as shown in Figure 11.22c. Calculate the osmotic pressure at 25°C of red blood cells across the cell membrane from pure water.

Collect and Organize We are asked to calculate an osmotic pressure. We are given the total particle concentration (0.30 *M*) and temperature (25°C) of the solution. We must convert the temperature to kelvin.

Analyze Osmotic pressure is related to the total concentration of all particles in solution and the absolute temperature. The total particle concentration, 0.30 M, is the value of the $i \times M$ in Equation 11.16. Estimating the answer by assuming $i \times M = 0.3$, R is about 0.1, and T is about 300 K, and we get $0.3 \times 0.1 \times 300 = 9$ atm.

Solve First we need to convert the temperature from degrees Celsius to kelvin: $T(°\text{C}) + 273 = T(\text{K})$. Inserting the values of i, M, R, and T into Equation 11.16 gives

Think About It Our answer is in line with our estimation. The calculated pressure across the membranes of red blood cells in pure water is more than the gauge pressure in most bicycle tires and enough to rupture the membranes.

Practice Exercise Calculate the osmotic pressure across a semipermeable membrane separating pure water from seawater at 25°C. The total concentration of all the ions in seawater is 1.15 M. Assume $i = 0.92$.

CONCEPT TEST

Which has the greater effect on the osmotic pressure of a 1.0 M solution: increasing the temperature from 10°C to 20°C or adding enough solute to raise the concentration to 2.0 M?

In Sample Exercise 11.13, we calculated the osmotic pressure of a solution in relation to pure solvent. In Figure 11.23a, however, the two solutions have different osmotic pressures, Π_{NaCl} and Π_{seawater}. For these kinds of situations, we need to derive an equation for the difference between the osmotic pressures, $\Delta\Pi$, in terms of M, R, and T.

Earlier in this section we said that $\Delta\Pi = \Pi_{\text{seawater}} - \Pi_{\text{NaCl}}$, and that the osmotic pressures of both solutions are described by

Equation 11.16:

Taking the difference in Π expressions:

The total ion concentration in seawater is about 1.15 *M*, so $iM = 1.15\ M$. If a solution of that concentration is put on one side of a semipermeable membrane and a solution of 0.10 *M* NaCl on the other side, then $iM_{\text{NaCl}} = (2 \times 0.10\ M)$, and the osmotic pressure difference between the two solutions at 25°C is

SAMPLE EXERCISE 11.14 Calculating Osmotic Pressure II LO8

Red blood cells placed in seawater shrivel, as shown in Figure 11.22(b). Calculate the pressure across the semipermeable cell membrane separating the solution inside a red blood cell from seawater at 25°C if the total concentration of all the particles inside the cell is 0.30 *M* and the total concentration of ions in seawater is 1.15 *M*. Compare the result with the answer from Sample Exercise 11.13.

Collect and Organize We can use Equation 11.17 to calculate the difference in osmotic pressure between the two solutions. As in Sample Exercise 11.13, we must convert the temperature to units of kelvin.

Analyze We know that the concentration of particles in seawater is greater than inside a red blood cell, so solvent will flow from the cell to the seawater. In addition, the osmotic pressure across the membrane is the difference between Π_{seawater} and Π_{cell}, or $\Delta\Pi$. The value of $\Delta\Pi$ should be greater than the Π calculated in Sample Exercise 11.13, where red blood cells were immersed in pure water, because the difference in solute concentrations is greater.

Solve First we need to convert the temperature from degrees Celsius to kelvin: $T(^\circ\text{C}) + 273 = T(\text{K})$. Inserting the values of *i*, *M*, *R*, and *T* in Equation 11.17 for seawater and cells, we have

The pressure across a semipermeable membrane separating seawater from red blood cells, 21 atm, is greater than the pressure across the membrane separating red blood cells from pure water by almost a factor of three.

Think About It The values compare as we predicted, though we need to keep in mind that the osmotic pressure of 7.3 atm in Sample Exercise 11.13 would somehow have to be applied inside the red blood cell to keep pure water from entering it, whereas the 21 atm of osmotic pressure calculated in this sample exercise would have to be applied to the seawater outside the cell to keep water from inside the cell migrating through the cell wall and into the seawater.

Practice Exercise Calculate the osmotic pressure at 25°C across a semipermeable membrane separating seawater (1.15 *M* total particles) from a 0.50 *M* solution of aqueous NaCl.

The osmotic pressures across cell membranes in Sample Exercises 11.13 and 11.14 are very large. The pressure of more than 7 atm calculated in Sample Exercise 11.13 for red blood cells immersed in pure water is more than three times the air pressure in a typical automobile tire and about the same as the water pressure experienced by a diver at a depth of 80 m. A pressure of 21 atm across the walls of a steel-reinforced concrete building is enough to cause major structural damage or even collapse the building. The possibility of serious structural damage to cells because of such huge pressure differentials across membranes is one reason why solutions dispensed intravenously (IV) or intramuscularly (IM) must be carefully constituted.

During a medical emergency, medication may need to be administered to a patient intravenously (**Figure 11.24**), and it is crucial that the osmotic pressure exerted by the intravenous solution on the body's cells be identical to the osmotic pressure exerted by the solution inside the cells. The solute concentrations in such solutions are said to be *isotonic* because they exert the same osmotic pressure as the blood exerts. As we saw in Figure 11.22, solutions with higher (*hypertonic*) or lower (*hypotonic*) solute concentrations cause the body's cells to either shrink as water leaves or swell as water enters the cell.

Physiological saline and D5W are two solutions that are widely used to administer intravenous medications, depending on the clinical situation. Physiological saline contains 0.92% NaCl by mass—that is, 0.92 g of NaCl for every 100 g of solution. The density of dilute aqueous solutions is close to 1.00 g/mL, so 100 g of this solution has a volume of 100 mL, which means a concentration of 0.92 g/100 g is nearly the same as 0.92 g/100 mL $=$ 9.2 g/L.

D5W is a 5.5% solution by mass of dextrose (another name for glucose; molar mass 180.16 g/mol) in water. Because this solution must be isotonic with blood and therefore isotonic with physiological saline solution, it must contain about the same concentration of solute particles as saline solution. A 5.5% solution of D5W contains 5.5 g of dextrose in 100 g of water, 5.5 g of dextrose in 100 mL of water, or 55 g of dextrose/L.

To compare the solute levels of these two solutions, we compare molarities:

The molar concentration of dextrose is about twice that of the saline solution, which makes sense because the theoretical i value for NaCl is 2, meaning that a 0.16 M NaCl solution contains about 0.32 M of Na^+ and Cl^- ions. Actually, the total concentration of ions should be slightly less than that because neutral NaCl ion pairs are present in the saline solution (see Figure 11.19). As a result, the solute particle concentrations in 0.92% NaCl and 5.5% D5W are essentially the same and so are their osmotic pressures.

The values used in these examples are for normal conditions in a healthy patient. Depending on the clinical condition presented, doctors may need to use solutions with different concentrations of solutes to respond most effectively to the patient's needs.

Reverse Osmosis

Many people in the world suffer from a lack of fresh water. A recent report from the United Nations (UN-Water Policy Brief on Water Quality, UN-Water 2011) suggested that by 2025, two out of three people in the world could be living in water-stressed areas—that is, places without enough fresh water to drink or grow crops. The sea is already the source of drinking water in several desert countries bordering the Persian Gulf; to make the seawater drinkable, it must be *desalinated*, which means the salts must be removed. One way to desalinate saltwater is to distill it, but distillation requires a great deal of energy to heat seawater to its boiling point and convert it to steam.

The process of osmosis can also be applied to the desalination of seawater. As we have seen, osmosis is the movement of water from a region of low solute concentration to a region of high solute concentration. However, if a sufficiently high pressure is applied to the region of high solute concentration, the water can be forced to move from the region of high solute concentration to the region of low solute concentration. This technique, called reverse osmosis, is another way of desalinating seawater to make it drinkable.

The desalination apparatus shown in **Figure 11.25** consists of an outer metal tube containing many inner tubes made of a semipermeable membrane. Seawater is forced through the outer tube so that it washes over the exterior of all the inner tubes, which are initially filled with flowing pure water. Ordinarily, the direction of osmosis would be from the inner tubes (zero solute concentration) into the seawater (very high solute concentration), and indeed, the pure water does exert an osmotic pressure on the interior of the tube membranes. However, when an external pressure—a *reverse osmotic pressure*—greater than the osmotic pressure is exerted on the seawater side of the membranes, water molecules in the seawater move across the membranes into the inner tubes. The desalinated water entering the inner tubes flows into a collector and is ready for use.

Some municipal water-supply systems use reverse osmosis to make saline (brackish) water fit to drink. Some industries use this method to purify conventional tap water, and it is a common way for ships at sea to desalinate ocean water. However, very tough semipermeable membranes are necessary because reverse osmosis systems operate at very high pressures. The continued development of technologies using reverse osmosis has resulted in millions of people being supplied with sanitary drinking water. **Figure 11.26** shows the range of reverse osmosis facilities available, from one of the world's largest desalination plants capable of converting 625 million liters of seawater into drinkable water daily, to a portable unit, to a small device for a home drinking water supply.

SAMPLE EXERCISE 11.15 Calculating Pressure for Reverse Osmosis LO8

What is the reverse osmotic pressure required at 20°C to purify brackish well water containing 0.355 *M* dissolved particles if the purified water is to contain no more than 87 mg of dissolved solids (measured as NaCl equivalents) per liter?

Collect and Organize We are asked to calculate the reverse osmotic pressure needed to purify water to a stated solute concentration. We are given the temperature, the solute concentration in the water to be purified, and the amount of solute (expressed as NaCl) tolerable in the product water. We can adapt Equation 11.17 to calculate the difference in osmotic pressure between the two solutions.

Analyze We need the molarity of the less concentrated solution (the drinkable water) to calculate the osmotic pressure exerted by the drinkable water, and we can calculate that from the given information. We can also calculate the osmotic pressure once we know the difference in the molarities of the solutions on the two sides of the semipermeable membrane.

Solve First we convert 87 mg of NaCl/L to molarity:

The total ion concentration for a $1.5 \times 10^{-3} M$ NaCl solution is $2(1.5 \times 10^{-3}) = 0.0030\ M$ because $i = 2$ for NaCl. Using Equation

11.17:

If we maintain an osmotic pressure of exactly 8.47 atm on the side of the membrane with the brackish well water, no net flow of solvent will occur between the two solutions. Pressures greater than 8.47 atm will force water molecules from the well water through the membrane, producing water containing less than 87 mg of NaCl per liter. (We can never obtain pure water in this process; in practice, some Na^+ and Cl^- ions inevitably pass through the membrane from the well water to the drinkable water.)

Think About It The answer makes sense based on the results in Sample Exercise 11.13 in which we calculated the osmotic pressure (7.3 atm) of the liquid inside red blood cells (0.30 *M* in total ions). The osmotic pressure calculated here is $(8.47/7.3) = 1.16$ or 16% higher than the value calculated in Sample Exercise 11.13 and is based on a total ion concentration that is $(0.355 - 0.0030)/0.30 = 1.17$ or 17% higher.

Practice Exercise Calculate the minimum external pressure that must be applied in a reverse osmosis system to seawater with a total ion concentration of 1.15 *M* at 20°C if the maximum concentration allowed in the product water is 174 mg of NaCl per liter.

CONCEPT TEST

If you were using the apparatus in Figure 11.26c to purify water by reverse osmosis, what advantage might there be in running the system at 50°C rather than 20°C?

Using Osmotic Pressure to Determine

Molar Mass

In principle, we can determine the molar mass of any solute by dissolving a known quantity of the solute in a known quantity of solvent and then measuring the effect that the dissolved solute has on any colligative property of the solvent. In practice, methods based on colligative properties work only for nonelectrolytes that have a van ’t Hoff factor of 1. There are also several compelling reasons for using osmotic pressure rather than boiling point elevation or freezing point depression in these measurements: (1) very small osmotic pressures can be measured precisely, which means osmotic pressure can be used to accurately determine much smaller solute concentrations or larger molar masses than by the other methods; (2) pressure measurement equipment can be miniaturized so that only minute quantities of solute are needed; and (3) measurements can be made at room temperature and not near solvent freezing or boiling points at which solute stability may be compromised. The following sample exercise illustrates how osmotic pressure can be used to determine molar mass.

CONNECTION In Section 3.8 we used molar masses determined by mass spectrometry to convert empirical formulas derived from elemental analyses to molecular formulas. In Section 5.6 we combined density measurements with the ideal gas law to calculate molar masses of gases.

SAMPLE EXERCISE 11.16 Using Osmotic Pressure to Determine Molar Mass LO9

A molecular compound that is a nonelectrolyte was isolated from a South African tree. A 47 mg sample was dissolved in water to make 2.50 mL of solution at 25°C, and the osmotic pressure of the solution was 0.489 atm. Calculate the molar mass of the compound.

Collect and Organize We are given the mass of a substance, the volume of its aqueous solution, and the osmotic pressure and temperature of the solution. We can relate these parameters to the concentration of the solution using Equation 11.16, using the value $i = 1$ because the substance is a nonelectrolyte.

Analyze After calculating the molar concentration of the solution using Equation 11.16, we can then multiply that value by the volume of the sample to calculate the number of moles of solute in the solution. Dividing that value into the known mass of the solute in the sample will give us the solute's molar mass.

Solve Rearranging Equation 11.16 to isolate *M* and substituting the given values:

Multiplying the solution's molarity by its volume:

We know that this number of moles of solute has a mass of 47 mg. Therefore, the molar mass of the solute is

Think About It The calculated concentration value (0.0200 *M*) used to determine molar mass makes sense because the results of Sample Exercise 11.13 showed that 7.3 atm of osmotic pressure is produced by a 0.30 *M* solution at 25°C. Therefore, an osmotic pressure of 0.489 atm corresponds to a concentration of 0.489 atm $\times$ (0.30 *M*)/7.3 atm $=$ 0.0200 *M*. This exercise also demonstrates the capacity of an osmotic pressure measurement to determine the molar mass of a relatively small (47 mg) sample of a compound with relatively large molar mass (940 g/mol).

Practice Exercise A solution was made by dissolving 5.00 mg of a polysaccharide (a polymer made of sugar molecules) in water to give a final volume of 1.00 mL. The osmotic pressure of this solution was 1.91×10^{-3} atm at 25°C. Calculate the molar mass of the polysaccharide, which is a nonelectrolyte.

Glossary

colligative properties

characteristics of solutions that depend on the concentration and not the identity of particles dissolved in the solvent.

van ’t Hoff factor (also called *i* factor)

the ratio of the experimentally measured value of a colligative property to the theoretical value expected for that property if the solute were a nonelectrolyte.

van ’t Hoff factor (also called *i* factor)

the ratio of the experimentally measured value of a colligative property to the theoretical value expected for that property if the solute were a nonelectrolyte.

ion pair

a cluster formed when a cation and an anion associate with each other in solution.

osmosis

the flow of a fluid through a semipermeable membrane to balance the concentration of solutes in solutions on the two sides of the membrane. The solvent particles’ flow proceeds from the more dilute solution into the more concentrated one.

osmotic pressure (Π)

the pressure applied across a semipermeable membrane to stop the flow of solvent from the compartment containing pure solvent or a less concentrated solution to the compartment containing a more concentrated solution. The osmotic pressure of a solution increases with solute concentration, M, and with solution temperature, T.

reverse osmosis

a process in which solvent is forced through semipermeable membranes, leaving a more concentrated solution behind.

molality (m)

concentration expressed as the number of moles of solute per kilogram of solvent.

Learning Objectives

- Relate the molality of a solution to the quantity of solute and mass of solvent **Return to Sample Exercise 11.8**
- Relate the freezing point or boiling point of a solution to the

molal concentration of nonvolatile solute particles **Return to Sample Exercises 11.9, 11.10**

- Relate the freezing point or boiling point of a solution to the molal concentration of nonvolatile solute particles **Return to Sample Exercises 11.9, 11.10**
- Explain the significance of the van ’t Hoff factor and use it to predict the colligative properties of solutions **Return to Sample Exercises 11.11, 11.12**
- Explain the significance of the van ’t Hoff factor and use it to predict the colligative properties of solutions **Return to Sample Exercises 11.11, 11.12**
- Describe osmosis, predict the direction of solvent flow in osmosis, and calculate osmotic pressure **Return to Sample Exercises 11.13, 11.14, 11.15**
- Describe osmosis, predict the direction of solvent flow in osmosis, and calculate osmotic pressure **Return to Sample Exercises 11.13, 11.14, 11.15**
- Describe osmosis, predict the direction of solvent flow in osmosis, and calculate osmotic pressure **Return to Sample Exercises 11.13, 11.14, 11.15**
- Use colligative properties such as osmotic pressure to determine solute molar mass **Return to Sample Exercise 11.16**

FIGURE 11.27 Residential water softeners use ion exchange to remove $2+$ ions (such as Ca^{2+}) that make water hard. The ion-exchange resin contains cation-exchange sites that are initially occupied by Na^+ ions. These ions are replaced by $2+$ "hardness" ions as water flows through the resin. Eventually most of the ion-exchange sites are occupied by $2+$ ions, and the system loses its water-softening ability. The resin is then backwashed with a saturated solution of NaCl (*brine*), displacing the hardness ions (which wash down the drain) and restoring the resin to its Na^+ form.

11.6 Ion Exchange

In Section 11.5 we examined how reverse osmosis is used to reduce the concentration of salts in water to make it potable (drinkable). In this section we discuss a technology that is used to *replace* some ions with others to make already drinkable water softer. What is *soft* water? To answer this question, let's turn it around and examine why the presence of certain metal ions—principally Ca^{2+} and Mg^{2+}—makes water *hard.* The presence of these ions causes several problems in industrial and residential water supplies: Ca^{2+} and Mg^{2+} ions combine with soap to precipitate a gray scum that can discolor clothes laundered in hard water. The limited solubility of the compounds these ions form with common anions, such as $CO_3{}^{2-}$ and $SO_4{}^{2-}$, produces *scale* (an incrustation) in boilers, pipes, and fixtures, which diminishes their ability to conduct heat and carry water, and sometimes accumulation of these compounds produces unpleasant odors.

A common method of *water softening* (i.e., removing the ions responsible for water hardness) involves passing it through a system that replaces Ca^{2+} and Mg^{2+} ions with Na^{+} ions (**Figure 11.27**) in a process called ion exchange. The equipment used consists of one or more cartridges packed with porous plastic resin (R) to which is bonded anions capable of binding with hard-water cations—mainly

Ca^{2+}, Mg^{2+}, and Fe^{2+}. The carboxylate anion (COO^-) is often used, and water in the ion-exchange cartridge contains Na^+ to balance the negative charges on the anions, producing ($R–COO^-$)Na^+ ion-exchange sites. As hard water flows through the cartridge, 2+ ions in the water exchange places with sodium ions on the resin. This exchange takes place because cations with 2+ and 3+ charges bind more strongly to the $R–COO^-$ groups on the resin than do Na^+ ions. The ion-exchange reaction with calcium ions is

$$2\,(R–COO^-)Na^+(s) + Ca^{2+}(aq) \rightarrow (R–COO^-)_2Ca^{2+}(s) + 2\,Na^+(aq)$$

Hard water that has been softened in this way contains increased concentrations of sodium ions. Although this may not be a problem for healthy children and adults, people suffering from high blood pressure often must limit their intake of Na^+ and should not drink water softened by this kind of ion-exchange reaction.

Naturally occurring porous minerals called zeolites are also used as water softeners and purifiers and as livestock feed additives and odor suppressants. These zeolites are formed by chemical reactions between molten lava from volcanic eruptions and seawater. Synthetic zeolites have similar structures. All zeolites have a rigid three-dimensional structure like a honeycomb (**Figure 11.28**), consisting of a network of interconnecting tunnels and cages. As water flows through tunnels (pores) lined with Na^+ ions, the sodium ions exchange with cations dissolved in the water.

Zeolites have replaced environmentally harmful phosphates that are added to detergents to bind Ca^{2+} and Mg^{2+} ions. They are also used in municipal drinking water purification plants to remove toxic metal ions such as Cd^{2+} and Pb^{2+} from contaminated waste streams, and in swimming pools to keep the water clean and clear. They are even used for odor control in barns and feedlots where animals are confined. Animal waste contains large quantities of ammonium ions (NH_4^+) that can participate in acid–base reactions with basic materials that produce ammonia gas, NH_3, which contributes to the characteristic smell of cat boxes and barnyards. However, these NH_4^+ ions can be exchanged for the naturally occurring cations in zeolites, thereby reducing the odor problem.

Other ions can be exchanged for the sodium ion to prepare zeolites with special properties. Certain zeolites may be poured directly on wounds to stop bleeding by absorbing water from the blood, thereby concentrating clotting factors to promote coagulation. If the cations in these zeolites are exchanged for silver ions (Ag^+), the resulting product also has an antimicrobial effect and not only stems bleeding but also reduces the risk of infection.

SAMPLE EXERCISE 11.17 Integrating Concepts: Fun with Eggs

The shell of a chicken's egg, which is mostly calcium carbonate [($\mathscr{M} = 100.1$ g/mol)], is lined with a semipermeable membrane. Explain what happens during the following series of steps, all carried out at room temperature (21°C) and answer all the associated questions.

1. A chicken egg is weighed (its mass is 57 g) and then placed in 500 mL of vinegar (a 5.0 g/100 mL aqueous solution of acetic acid (CH_3COOH, $\mathscr{M} = 60.05$ g/mol). Gas bubbles form on the outside of the shell (**Figure 11.29a**). (a) Write a balanced chemical equation describing the reaction. (b) How much egg shell ($CaCO_3$) could be dissolved by the vinegar? (c) Is the gaseous product more likely to dissolve in the vinegar or escape into the air? Explain your answer.
2. After the shell has dissolved, the egg is contained within a saclike membrane. It is gently removed from the vinegar bath, dried, and weighed. Its mass is 66 g, and the volume of the egg is greater than when it was in its shell (**Figure 11.29b**). (d) Explain what process caused the mass and volume of the egg to increase.
3. The egg is then covered in 250 mL of light corn syrup, which is a food syrup used in baking and to make jellies and jams. It is an aqueous solution that is about 75% sucrose ($C_{12}H_{22}O_{11}$) and other sugars. After 8 hours, the visibly shriveled egg (**Figure 11.29c**) is removed from the syrup, rinsed with water, dried, and weighed. Its mass is 46 g. (e) Why did its mass decrease?
4. Next, the shriveled egg is submerged in distilled water for 8 hours, during which time its volume increases (**Figure**

11.29d). The egg is then removed and reweighed; its mass is now 82 g. (f) Why did its mass and volume increase?

Collect and Organize We have the starting materials (calcium carbonate and dilute acetic acid) for a chemical reaction in which the egg's shell dissolves, and we are asked to identify the products and calculate the capacity of the vinegar bath to dissolve $CaCO_3$. Then we are asked to explain the mass and volume changes that the egg without its shell undergoes when it is immersed in corn syrup and in pure water.

Analyze The reaction between a carbonate and acetic acid is likely to be an acid–base neutralization reaction because, as discussed in Section 4.6, acetic acid is a H^+ donor (which makes it an acid) and CO_3^{2-} ions are H^+ acceptors (which makes them bases), forming HCO_3^- ions after accepting one H^+ and, after accepting a second, H_2CO_3, which decomposes into H_2O and CO_2 (see Sample Exercise 4.10). The observed changes in mass and volume probably involve osmosis across a semipermeable membrane (Section 11.5) because of different solute concentrations within and surrounding the egg.

Solve

1. A chemical equation describing the dissolution of the egg shell is

   $$CaCO_3(s) + 2\ CH_3COOH(aq) \rightarrow$$

   $$Ca(CH_3COO)_2(aq) + H_2O(\ell) + CO_2(g)$$

2. The stoichiometry of this chemical equation allows us to calculate the mass of $CaCO_3$ that could dissolve in 500 mL of 5.0% acetic acid (which we abbreviate HAc in this calculation):

   $$500\ \cancel{\text{mL HAc}} \times \frac{5.0\ \cancel{\text{g HAc}}}{100\ \cancel{\text{mL HAc}}} \times \frac{1\ \cancel{\text{mol HAc}}}{60.05\ \cancel{\text{g HAc}}}$$

   $$\times \frac{1\ \cancel{\text{mol CaCO}_3}}{2\ \cancel{\text{mol HAc}}} \times \frac{100.1\ \text{g CaCO}_3}{1\ \cancel{\text{mol CaCO}_3}} = 21\ \text{g CaCO}_3$$

3. The gas given off is CO_2, which forms bubbles on the egg

shell, indicating that it has limited solubility in vinegar. Its limited solubility is also typical of other nonpolar gases (Table 10.4). Therefore, most of the gas escaped into the air.

4. One reason why the egg gained mass and volume in the vinegar bath as its shell dissolved is that solute particle concentrations were lower and the concentration of water in the bath was higher than in the egg. Therefore, water flowed from the bath into the egg by osmosis through the membrane.
5. The egg loses mass and volume when immersed in corn syrup because the solute concentration in the syrup is higher than the concentration of the solution within the egg sac. Osmosis causes water to leave the egg sac and enter the surrounding solution.
6. The egg gains mass and volume when immersed in distilled water because osmosis causes water molecules to flow from pure water (no solute) through the sac and into the egg.

Think About It There were no calculations of osmotic pressure in this exercise because we did not know the total concentration of solute particles inside the egg or in the acetic acid solution after dissolving the shell, or in the corn syrup. However, the observed changes in egg volume and mass strongly suggest that osmosis added water to the egg when immersed in acetic acid, removed it from the egg when immersed in corn syrup, and added it to the egg when immersed in pure water. The results of the calculation in part (b) are expressed to 2 significant figures because that is the precision with which the vinegar volume could be measured (see Figure 11.29a).

Glossary

ion exchange

a process by which one ion is displaced by another.

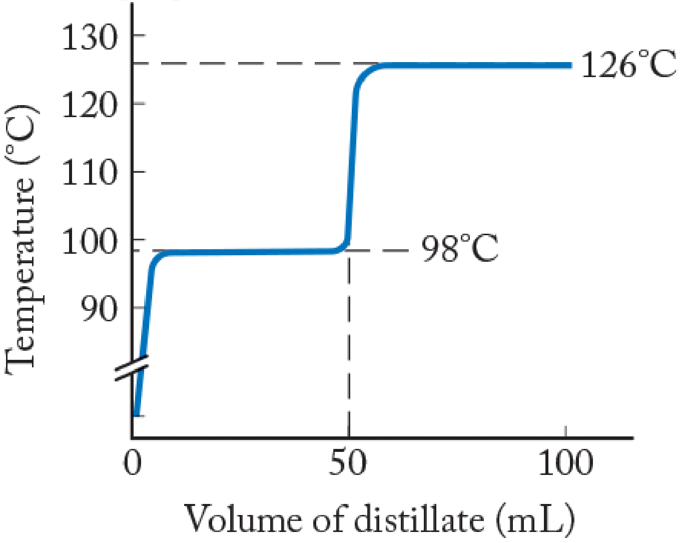
zeolites

natural crystalline minerals or synthetic materials consisting of three-dimensional networks of channels that contain sodium or other $1+$ cations.

SUMMARY

LO1 Ion–ion interactions hold ionic solids together. Their magnitude depends upon the charges of the ions and the distance between them. (Section 11.1)

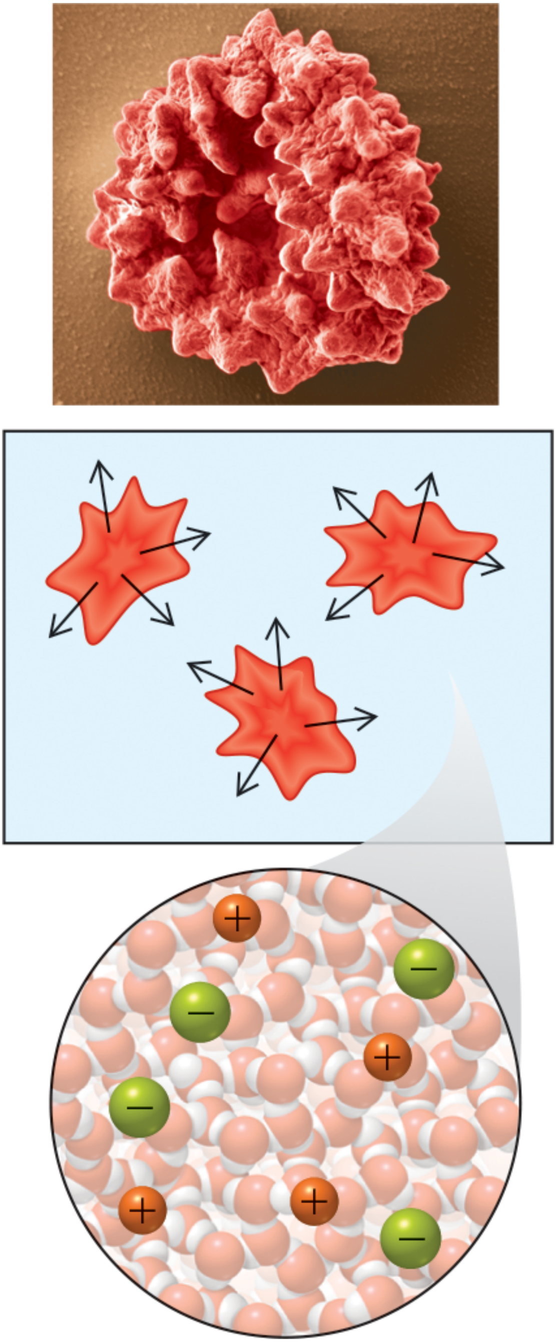
- LO2 The enthalpy of solution($\Delta H_{\text{solution}}$) for an ionic compound is the sum of the lattice energy (U) and the enthalpy of hydration($\Delta H_{\text{hydration}}$). Lattice energies can be calculated with a Born–Haber cycle, an application of Hess's law. (Section 11.2)
- LO3 The vapor pressure of a liquid is proportional to the fraction of its molecules that enter the gas phase. Raoult's law relates the vapor pressure of a solution to its composition and to the vapor pressure of the solvent. (Section 11.3)



- LO4 The vapor pressure of an ideal solution of volatile compounds follows Raoult's law. Fractional distillation can be used to separate solutions of volatile compounds. (Section 11.4)
- LO5 The concentration units used for colligative property measurements include molarity (M) and molality (m).

(Section 11.5)

- LO6 Nonvolatile solutes in solution elevate the solvent’s boiling point and depress its freezing point. (Section 11.5)



- LO7 The van ’t Hoff factor accounts for the colligative properties of electrolytes and the formation of solute ion pairs in concentrated solutions. (Section 11.5)

- LO8 In osmosis, solvent flows through a semipermeable membrane. Osmotic pressure (Π) is the pressure required to halt the flow of solvent from the more dilute solution across the membrane. (Section 11.5)
- LO9 The molar mass of a compound can be determined by measuring the freezing point depression, boiling point elevation, or osmotic pressure of a solution of the compound. (Section 11.5)

PARTICULATE PREVIEW WRAP-UP

Ion–dipole forces form between the sodium cations and the δ− oxygen atoms and between the chloride anions and the δ+ hydrogen atoms. The amount of vapor above a solution is reduced compared to that above pure solvent, and consequently the boiling point increases.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts	Equations	Sample Exercise
Predicting relative strengths of ion–ion interactions	To predict relative strengths of ion–ion interactions, use The value of E is negative for any interaction between oppositely charged particles. More negative values of E correspond to stronger ion–ion attractions.	$E \propto \frac{(Q_1Q_2)}{d}$ (6.3)	11.1
Ranking lattice energies, solubility, and melting points	Rank lattice energies, solubilities, and melting points by using More negative values of U correspond to stronger lattice energies, higher melting points, and generally lower solubilities.	$U = \frac{k(Q_1 \times Q_2)}{d}$ (11.5)	11.2
Calculating lattice energy with a Born–Haber cycle	Use the standard enthalpy of formation of an ionic solid and equations such as this one for NaCl to calculate lattice energy (U).	$U_{\text{NaCl}} = \Delta H_f^\circ - (\Delta H_{\text{sub,Na}} + \frac{1}{2}\Delta H_{\text{BE,Cl}_2} + \Delta H_{\text{1E}_1\text{,Na}} + \Delta H_{\text{EA}_1\text{,Cl}})$	11.3

Calculating lattice energy by using enthalpies of hydration

11.4

Use the enthalpies of hydration ($\Delta H_{\text{hydration}}$) and enthalpies of solution ($\Delta H_{\text{solution}}$) to calculate lattice energy:

$$\Delta H_{\text{solution}} = \Delta H_{\text{hydration}} - U \quad (11.6)$$

where

$\Delta H_{\text{hydration}} = \Delta H_{\text{hydration,cation}} + \Delta H_{\text{hydration,anion}}$

Calculating vapor pressure of a solution

11.5, 11.6, 11.7

Use Raoult's law,

$$P_{\text{solution}} = X_{\text{solvent}}P^{\circ}_{\text{solvent}} \quad (11.7)$$

where P_{solution} is the vapor pressure of the solution at a given temperature, X_{solvent} is the mole fraction of the solvent in the solution, and $P^{\circ}_{\text{solvent}}$ is the vapor pressure of the pure solvent at the same temperature.

$$P_{\text{total}} = X_1P^{\circ}_1 + X_2P^{\circ}_2 + X_3P^{\circ}_3 \ldots \quad (11.8)$$

Calculating molal concentrations

11.8

Molality is defined as

$$m = \frac{n_{\text{solute}}}{\text{kg solvent}} \quad (11.9)$$

where n_{solute} is the number of moles of solute.

Calculating boiling point elevation or freezing point depression of a solution

11.9, 11.10

For nonelectrolytes, use

$$\Delta T_b = K_bm \quad (11.10)$$

where ΔT_b is the elevation in the boiling point of the solvent, K_b is a constant that depends only on the solvent, and m is the molality of the solution. For the freezing point, use

$$\Delta T_f = K_fm \quad (11.12)$$

where ΔT_f is the depression in the freezing point of the solvent, K_f is a constant that depends only on the solvent, and m is the molality of the solution.

Assessing interactions among particles in solution by comparing the theoretical value of the van 't Hoff factor *i* with the experimentally measured value

11.11, 11.12

For electrolytes, use

$$\Delta T_b = iK_bm \quad (11.14)$$

and

$$\Delta T_f = iK_fm \quad (11.15)$$

where the theoretical value of i is the number of particles created when an electrolyte dissociates completely: $i = 2$ for NaCl, 3 for $CaCl_2$, and 4 for Na_3PO_4. For real solutions of electrolytes, where ΔT_b, ΔT_f, K_b, K_f, and m are known, rearrange $\Delta T_b = iK_bm$ and $\Delta T_f = iK_fm$ to calculate the value of i and compare the result with the theoretical value.

Calculating osmotic pressure and reverse osmotic pressure

11.13, 11.14, 11.15

Use

$$\Pi = iMRT \quad (11.16)$$

where Π is the osmotic pressure, i is the van ’t Hoff factor, M is the molar concentration of the solution, R is the ideal gas constant, and T is the absolute temperature of the solution.

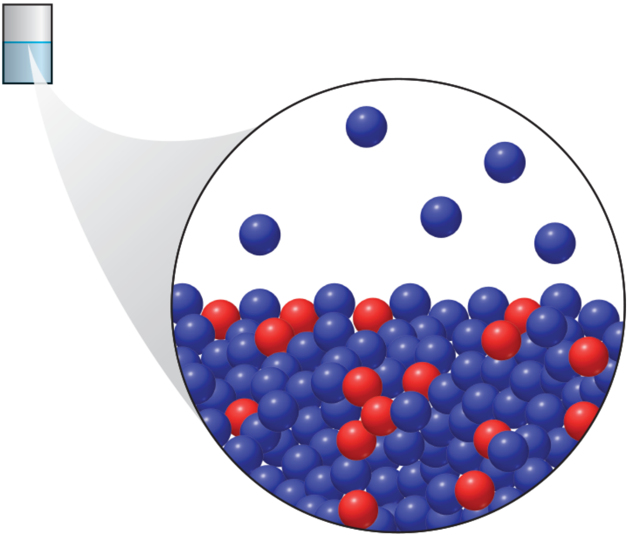
11.16 Determining molar mass from osmotic pressure Use $\Pi = iMRT$ to calculate the molarity of a solution of a nonelectrolyte. Then use the molarity and volume of the solution and the mass of solute in it to calculate the molar mass of the solute.

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

Figure P11.1 shows a particle-level view of a sealed container partially filled with a solution that has two components: X (blue spheres) and Y (red spheres). Which of the following statements about substances X and Y are true?

1. X is the solvent in this solution.
2. Pure Y is a volatile liquid.
3. If Y were *not* present, there would be fewer X particles in the gas above the liquid solution.
4. The presence of Y increases the vapor pressure of X.



FIGURE

Interactions between Ions

Concept Review

Which of these substances contains the largest anions? (a) NaCl; (b) CsF; (c) LiI; (d) KBr

Which of these substances contains the smallest cations? (a) $BaCl_2$; (b) Al_2O_3; (c) Mg_3N_2; (d) SrS

Describe how the strengths of ion–ion interactions help explain why $CaSO_4$ is less soluble in water than is NaCl?

For these three ionic compounds, KCl, $CaCl_2$, and $ScCl_3$, describe two reasons why the strengths of attraction between their cations and Cl^- ions increase with the number of Cl^- ions in their formulas?

Problems

Rank the following ionic compounds in order of increasing attraction between their ions: KBr, $SrBr_2$, CsBr.

Rank the following ionic compounds in order of increasing attraction between their ions: BaO, $BaCl_2$, CaO.

Which has the higher melting point, LiF or MgO?

Which has the higher boiling point, NaCl or $CaCl_2$?

Energy Changes during Formation and Dissolution of Ionic Compounds

Concept Review

Define the terms in the equation $\Delta H_{\text{solution}} = \Delta H_{\text{hydration}} - U$.

Explain why higher melting points of ionic solids are associated with more negative lattice energy values.

Explain why those ionic compounds with the most negative lattice energies tend to be the least soluble in water.

Which is the more important factor in explaining the difference in the lattice energies of LiCl and MgO: (1) the charges of their ions or (2) the radii of their ions?

Problems

How do the melting points of the series of sodium halides NaX (X = F, Cl, Br, I) relate to the atomic number of X?

Rank the following ionic compounds in order of (a) increasing melting point and (b) increasing water solubility: BaF_2, $CaCl_2$, $MgBr_2$, and SrI_2.

Which substance has the least negative lattice energy? (a) MgI_2; (b) $MgBr_2$; (c) $MgCl_2$; (d) MgF_2

Rank the following from lowest to highest lattice energy: NaBr, $MgBr_2$, $CaBr_2$, and KBr.

Use a Born–Haber cycle to calculate the lattice energy of potassium chloride (KCl) from the following data:

Ionization energy of K(*g*) = 425 kJ/mol

Electron affinity of Cl(*g*) = − 349 kJ/mol

Energy to sublime K(*s*) = 89 kJ/mol

Bond energy of Cl_2(*g*) = 240 kJ/mol

$$\Delta H_f \text{ for } K(s) + \tfrac{1}{2}\,Cl_2(g) \rightarrow KCl(s) = -438 \text{ kJ/mol}$$

Calculate the lattice energy of sodium oxide (Na_2O) from the following data:

Ionization energy of Na(*g*) = 495 kJ/mol

Electron affinity of O(*g*) for 2 electrons = 603 kJ/mol

Energy to sublime Na(*s*) = 109 kJ/mol

Bond energy of O_2(*g*) = 499 kJ/mol

ΔH_f for $2\ Na(s) + \frac{1}{2}\ O_2(g) \rightarrow Na_2O(s) = -416$ kJ/mol

Using the values in Table 11.4 and $\Delta H_{solution} = 19.9$ kJ/mol, calculate the lattice energy of KBr.

Using the values in Table 11.4 and $\Delta H_{solution} = -17.7$ kJ/mol, calculate the lattice energy of KF.

Vapor Pressure of Solutions

Concept Review

Explain the term *nonvolatile solute.*

Which has the higher vapor pressure at constant temperature, pure water or seawater? Explain your answer.

Why does the vapor pressure of a liquid increase with increasing temperature?

In the experiment shown in Figure 11.7, the vapor pressure of one of the solutions remains constant throughout the experiment, whereas the vapor pressure of the other solution changes. Which solution is which?

An experiment like that shown in Figure 11.7 is set up with the compartment containing pure ethanol full to the brim and the compartment containing a solution of sugar in ethanol half-full. Explain why the compartment that contains the ethanol–sugar solution will eventually overflow.

Will the vapor pressure of a solution containing 0.11 *m* NaCl and 0.11 *m* KCl be greater than, less than, or the same as a 0.22 *m* solution of just NaCl? Will $P_{solution}$ be greater than, less than, or the same as a 0.22 *m* solution of $CaCl_2$?

Problems

A solution contains 3.5 moles of water and 1.5 moles of nonvolatile glucose ($C_6H_{12}O_6$). What is the mole fraction of water in this solution? What is the vapor pressure of the solution at 25°C, given that the vapor pressure of pure water at 25°C is 23.8 torr?

A solution contains 4.5 moles of water, 0.3 moles of sucrose ($C_{12}H_{22}O_{11}$), and 0.2 moles of glucose. Sucrose and glucose are nonvolatile. What is the mole fraction of water in this solution? What is the vapor pressure of the solution at 35°C, given that the vapor pressure of pure water at 35°C is 42.2 torr?

Another way of stating Raoult's law is that the fractional lowering of the vapor pressure of the solvent in a solution $(P^\circ_{\text{solvent}} - P_{\text{solvent}})/P^\circ_{\text{solvent}}$ is equal to the mole fraction of the solute, X_{solute}. Use Equation 11.7 to show that this is true.

Use the statement of Raoult's law in Problem 11.39 to determine the mole fraction of glucose in Problem 11.37.

Mixtures of Volatile Solutes

Concept Review

In an equimolar mixture of C_5H_{12} and C_7H_{16}, which compound is present in higher concentration in the vapor above the solution?

Why does the boiling point of a mixture of volatile hydrocarbons increase over time during a simple distillation?

Would you expect a solution of cyclohexane (C_6H_{12}) in benzene (C_6H_6) to behave ideally? Explain your answer.

Explain the origin of negative deviations from Raoult's law for the predicted vapor pressure of a solution of two volatile liquids.

Problems

Greener Fuel Most gasoline sold in the United States contains ethanol (C_2H_5OH) in addition to a mixture of hydrocarbons such as octane (C_8H_{18}). At 20°C, the vapor pressure of ethanol is 45 torr and the vapor pressure of octane is 10 torr. What is the vapor pressure at 20°C of a solution prepared by mixing 8.16 g of ethanol and 63.3 g of octane?

Alcohol Fuels Using butanol (C_4H_9OH) rather than ethanol as a gasoline additive has an advantage in providing a higher fuel value when mixed with octane. At 20°C, the vapor pressure of butanol is 5 torr and the vapor pressure of octane is 10 torr. What is the vapor pressure at 20°C of a solution prepared by mixing 16.2 g of butanol and 127 g of octane?

At 90°C, the vapor pressure of styrene (C_8H_8) is 134 torr and that of ethylbenzene (C_8H_{10}) is 183 torr. A solution of 38% by weight styrene and 62% by weight ethylbenzene is separated by fractional distillation at reduced pressure so that it begins to boil when the solution in the distillation flask reaches 90°C.

1. What is the ratio of ethylbenzene to styrene in the vapor phase as the mixture first begins to boil?
2. What will be the temperature of the first distillate that comes off the top of the column? (i) lower than 90°C; (ii) 90°C; (iii) higher than 90°C

A bottle is half-filled with a 50:50 (mole-to-mole) mixture of heptane (C_7H_{16}) and octane (C_8H_{18}) at 25°C. What is the mole ratio of heptane vapor to octane vapor in the air space above the liquid in the bottle? The vapor pressures of heptane and octane at 25°C are 31 torr and 11 torr, respectively.

Colligative Properties of Solutions

Concept Review

Explain why freezing point depression, boiling point elevation, and the osmotic pressure of ionic solutes cannot be used to measure their formula masses.

What is the definition of the concentration scale called *molality* that is used to determine the molar mass of a nonvolatile solute by measuring the solute’s effect on the freezing and boiling points of the solvent? Why must a mass-based concentration scale be used (i.e., *not* molarity)?

Making Syrup Evaporating maple tree sap converts the dilute sugar solution into the viscous amber syrup we pour on pancakes and waffles. How do the boiling points and vapor pressures of the sap change during the evaporation process?

Diet Soft Drinks The thermostat in a refrigerator filled with cans of soft drinks malfunctions and the temperature of the refrigerator drops below 0°C. The contents of the cans of diet soft drinks freeze, rupturing many of the cans and causing an awful mess, whereas none of the cans containing regular, nondiet soft drinks rupture. Why?

Why is it important to know if a substance is a molecular compound or an ionic compound before predicting its effect on the boiling and freezing points of a solvent?

Refer to the phase diagram in Figure 11.16 and explain in your own words why the change in the vapor pressure of a solution caused by a nonvolatile solute results in a higher boiling point and a lower melting point.

Explain how the theoretical value of the van ’t Hoff factor *i* for substances such as CH_3OH, NaBr, and K_2SO_4 can be predicted from their formulas.

Is it possible for an experimentally measured value of a van ’t Hoff factor to be greater than the theoretical value? Explain your answer.

What is a semipermeable membrane?

A pure solvent is separated from a solution containing the same solvent by a semipermeable membrane. In which direction does the solvent flow across the membrane, and why?

A dilute solution is separated from a more concentrated solution containing the same solvent by a semipermeable membrane. In which direction does the solvent tend to flow across the membrane, and why?

How is the osmotic pressure of a solution related to its molar concentration and its temperature?

Explain the principle of reverse osmosis.

Explain how the minimum pressure for purification of seawater by reverse osmosis can be estimated from its composition.

Aqueous solutions of physiological saline (NaCl) and dextrose (glucose) are used to deliver intravenous medications. Why must their molar concentrations differ by a factor of two?

Why do red blood cells undergo hemolysis when they are placed in pure water?

Problems

Calculate the molality of each of the following solutions:

1. 0.433 mol of sucrose ($C_{12}H_{22}O_{11}$) in 2.1 kg of water
2. 71.5 mmol of acetic acid (CH_3COOH) in 125 g of water

3. 0.165 mol of baking soda ($NaHCO_3$) in 375.0 g of water

Table 4.1 lists molarities of the major ions in seawater. Using a density of 1.022 g/mL for seawater, convert the concentrations into molalities.

What mass of the following solutions contains 0.100 mol of solute? (a) 0.135 *m* NH_4NO_3; (b) 3.92 *m* ethylene glycol, $HOCH_2CH_2OH$; (c) 1.07 *m* $CaCl_2$

How many moles of solute are there in the following solutions?

1. 0.750 *m* glucose solution made by dissolving the glucose in 10.0 kg of water
2. 0.183 *m* Na_2CrO_4 solution made by dissolving the Na_2CrO_4 in 900.0 g of water
3. 1.425 *m* urea solution made by dissolving the urea in 750.0 g of water

Fish Kills High concentrations of ammonia (NH_3), nitrite ions, and nitrate ions in water can kill fish. Lethal concentrations of these species for rainbow trout are 1.1 mg/L, 0.40 mg/L, and 1361 mg/L, respectively. Express these concentrations in molality units, assuming a solution density of 1.00 g/mL.

The concentrations of six important elements in a sample of river water are 0.050 mg/kg of Al^{3+}, 0.040 mg/kg of Fe^{3+}, 13.4 mg/kg of Ca^{2+}, 5.2 mg/kg of Na^+, 1.3 mg/kg of K^+, and 3.4 mg/kg of Mg^{2+}. Express each of these concentrations in molality units.

Cinnamon The distinctive aroma of cinnamon comes from cinnamaldehyde (C_9H_8O). Determine the boiling point elevation of a solution of 100 mg of cinnamaldehyde dissolved in 1.00 g of carbon tetrachloride (K_b = 5.02°C/*m*).

Spearmint Determine the boiling point elevation of a solution of 125 mg of carvone ($C_{10}H_{14}O$, oil of spearmint) dissolved in 1.50 g of carbon disulfide ($K_b = 2.34°C/m$).

What molality of a nonvolatile, nonelectrolyte solute is needed to lower the melting point of camphor by 1.000°C if $K_f = 39.7°C/m$?

What molality of a nonvolatile, nonelectrolyte solute is needed to raise the boiling point of water by 7.60°C if $K_b = 0.52°C/m$?

Saccharin Determine the melting point of an aqueous solution made by adding 186 mg of saccharin ($C_7H_5O_3NS$) to 1.00 mL of water (density = 1.00 g/mL, $K_f = 1.86°C/m$).

Determine the boiling point of an aqueous solution that is 2.50 *m* ethylene glycol ($HOCH_2CH_2OH$); K_b for water is 0.52°C/*m*. Assume that the boiling point of pure water is 100.00°C.

Arrange the following aqueous solutions in order of increasing boiling point:

1. 0.06 *m* $FeCl_3$ ($i = 3.4$)
2. 0.10 *m* $MgCl_2$ ($i = 2.7$)
3. 0.20 *m* KCl ($i = 1.9$)

Arrange the following solutions in order of increasing freezing point depression:

1. 0.10 *m* $MgCl_2$ in water, $i = 2.7$, $K_f = 1.86°C/m$
2. 0.20 *m* toluene in diethyl ether, $i = 1.00$, $K_f = 1.79°C/m$
3. 0.20 *m* ethylene glycol in ethanol, $i = 1.00$, $K_f = 1.99°C/m$

The following pairs of aqueous solutions are separated by a semipermeable membrane. In which direction will the solvent flow?

1. A = 1.25 M NaCl; B = 1.50 M KCl
2. A = 3.45 M $CaCl_2$; B = 3.45 M NaBr
3. A = 4.68 M glucose; B = 3.00 M NaCl

The following pairs of aqueous solutions are separated by a semipermeable membrane. In which direction will the solvent flow?

1. A = 1.00 L of 0.48 M NaCl; B = 55.85 g of NaCl dissolved in 1.00 L of solution
2. A = 1.00 mL of 0.982 M $CaCl_2$; B = 16 g of NaCl in 100 mL of solution
3. A = 1.00 mL of 6.56 mM $MgSO_4$; B = 5.24 g of $MgCl_2$ in 250 mL of solution

Calculate the osmotic pressure of each of the following aqueous solutions at 20°C:

1. 2.39 M methanol (CH_3OH)
2. 9.45 mM $MgCl_2$
3. 40.0 mL of glycerol ($C_3H_8O_3$) in 250.0 mL of aqueous solution (density of glycerol = 1.265 g/mL)
4. 25 g of $CaCl_2$ in 350 mL of solution

Calculate the osmotic pressure of each of the following aqueous solutions at 27°C:

1. 10.0 g of NaCl in 1.50 L of solution
2. 10.0 mg/L of $LiNO_3$
3. 0.222 M glucose
4. 0.00764 M K_2SO_4

Determine the molarity of each of the following solutions from its osmotic pressure at 25°C. Include the van ’t Hoff factor for the solution when the factor is given.

1. $\Pi = 0.674$ atm for a solution of ethanol (CH_3CH_2OH)
2. $\Pi = 0.0271$ atm for a solution of aspirin ($C_9H_8O_4$)

$\Pi = 0.605$ atm for a solution of $CaCl_2$, $i = 2.47$

Determine the molarity of each of the following solutions from its osmotic pressure at 25°C. Include the van 't Hoff factor for the solution when the factor is given.

$\Pi = 0.0259$ atm for a solution of urea $[CO(NH_2)_2]$
$\Pi = 1.26$ atm for a solution of sucrose ($C_{12}H_{22}O_{11}$)
$\Pi = 0.697$ atm for a solution of KI, $i = 1.90$

How many milliliters of water must be added to 48.5 mL of a 1.00 *M* solution of glucose ($C_6H_{12}O_6$) to make it isotonic with a D5W solution whose osmotic pressure is 7.89 atm at 37°C?

How many milliliters of water must be added to 102.6 mL of a 1.00 *M* solution of sodium chloride to make it isotonic with a solution of physiological saline whose osmotic pressure is 7.89 atm at 37°C?

Making Maple Syrup Traditional methods for making maple syrup concentrate the sap from maple trees by boiling away much of the water. Some maple syrup producers have started to use reverse osmosis to reduce the concentration before heating. If the average concentration of sugars in the sap is 2% sucrose ($C_{12}H_{11}O_{12}$) by mass, what pressure must be applied to double the concentration by reverse osmosis?

Suppose you have 1.00 *M* aqueous solutions of each of the following solutes: glucose ($C_6H_{12}O_6$), NaCl, and acetic acid (CH_3COOH). Which solution has the highest pressure requirement for reverse osmosis?

Ion Exchange

Concept Review

Explain how a mixture of anion and cation exchangers can be used to deionize water.

Describe the process by which the ion exchanger in a home water-softening system is regenerated for further use.

(a) Use the solubility rules to write the balanced net ionic equation for each of the following reactions. If there is no net reaction, write “NR.” (b) Which of these three reactions give clear visual evidence of the ion-exchange process?

1. $NaCl(aq) + AgNO_3(aq) \rightarrow AgCl(s) + NaNO_3(aq)$
2. $NaCl(aq) + KNO_3(aq) \rightarrow NaNO_3(aq) + KCl(aq)$
3. $MgCl_2(aq) + KOH(aq) \rightarrow Mg(OH)_2(s) + KCl(aq)$

(a) Use the solubility rules to write the balanced net ionic equation for each of the following reactions. If there is no net reaction, write “NR.” (b) Which of these three reactions give clear visual evidence of the ion-exchange process?

1. $BaCl_2(aq) + Na_2CO_3(aq) \rightarrow BaCO_3(s) + NaCl(aq)$
2. $NaCl(aq) + KOH(aq) \rightarrow NaOH(aq) + KCl(aq)$
3. $Na_3PO_4(aq) + CaCl_2(aq) \rightarrow Ca_3(PO_4)_2(s) + NaCl(aq)$

Measuring the Molar Mass of a Solute by Using Colligative Properties

Concept Review

What effect does dissolving a solute have on the following properties of a solvent? (a) its osmotic pressure; (b) its freezing point; (c) its boiling point

How can measurements of osmotic pressure, freezing point depression, and boiling point elevation be used to find the molar mass of a solute? Why are such determinations usually carried out on molecular substances as opposed to ionic ones?

Problems

Human Hemoglobin The hemoglobin found in human red blood cells (see Figure 11.22) has a molar mass of about 6.2×10^4 g/mol. What concentration range of hemoglobin will result in an osmotic pressure between 0.35 and 0.55 atm at 37°C in aqueous solution?

Antifreeze Proteins Northern cod produce proteins that protect their cells from damage caused by subzero temperatures. Measurements of the osmotic pressure for two different "antifreeze" proteins at 18°C yielded the following data: 50.4 mg of protein A in 1.5 mL of water had an osmotic pressure of $\Pi = 0.299$ atm, whereas an osmotic pressure of 0.218 atm was measured for a solution of 52.6 mg of protein B in 1.75 mL of water. What is the apparent range of molar masses for these proteins?

Cloves Eugenol is one of the compounds responsible for the flavor of cloves. A 111 mg sample of eugenol was dissolved in 1.00 g of chloroform ($K_b = 3.63$°C/m), increasing the boiling point of the chloroform by 2.45°C. Calculate eugenol's molar mass. Eugenol is 73.17% C, 7.32% H, and 19.51% O by mass. What is the molecular formula of eugenol?

Caffeine The freezing point of a solution prepared by dissolving 150 mg of caffeine in 10.0 g of camphor is lower than that of pure camphor ($K_f = 39.7$°C/m) by 3.07°C. What is the molar mass of caffeine? Elemental analysis of caffeine yields the following results: 49.49% C, 5.15% H, 28.87% N, and the remainder O. What is the molecular formula of caffeine?

Additional Problems

Consider the particulate views of the reaction between sodium metal and chlorine gas in Figure 11.4. Describe in your own words the chemical changes and the changes in energy that sodium atoms and chlorine molecules undergo as they form solid sodium chloride.

Calculate the lattice energy of magnesium chloride ($\Delta H^\circ_f = -641$ kJ/mol) by using (a) the Born-Haber cycle and (b) the enthalpy of solution of $MgCl_2$ ($\Delta H^\circ_{\text{solution}} = -158$ kJ/mol). Compare the values of U obtained from two methods. The following data should prove useful:

Ionization energy of Mg to $Mg^{2+} = 2188$ kJ/mol

Electron affinity of Cl $= -349$ kJ/mol

Energy to sublime Mg $= 150$ kJ/mol

Bond energy of $Cl_2 = 240$ kJ/mol

Enthalpy of hydration $Mg^{2+}(aq) = -1903$ kJ/mol

Enthalpy of hydration of $Cl^-(aq) = -368$ kJ/mol

Melting Ice $CaCl_2$ is often used to melt ice on sidewalks. Could $CaCl_2$ melt ice at − 20°C? Assume that the solubility of $CaCl_2$ at this temperature is 70.1 g of $CaCl_2$/100.0 g of H_2O and that the van 't Hoff factor for a saturated solution of $CaCl_2$ is 2.5.

Making Ice Cream A mixture of table salt and ice is used to chill the contents of hand-operated ice-cream makers. What is the melting point of a mixture of 2.00 lb of NaCl and 12.00 lb of ice if exactly half of the ice melts? Assume that all the NaCl dissolves in the melted ice and that the van 't Hoff factor for the resulting solution is 1.44.

The freezing points of 0.0935 *m* ammonium chloride and 0.0378 *m* ammonium sulfate in water were found to be − 0.322°C and − 0.173°C, respectively. What are the values of the van 't Hoff factors for these salts?

The following data were collected for three compounds in aqueous solution. Determine the value of the van ’t Hoff factor for each salt (K_f for water $= 1.86°C/m$).

Compound	Concentration	Experimentally Measured ΔT_f
LiCl	5.0 g/kg	0.410°C
HCl	5.0 g/kg	0.486°C
NaCl	5.0 g/kg	0.299°C

Physiological Saline A solution of 100 mL of physiological saline (0.92% NaCl by mass) is diluted by the addition of 250.0 mL of water. What is the osmotic pressure of the final solution at 37°C? Assume that NaCl dissociates completely into $Na^+(aq)$ and $Cl^-(aq)$.

What is the osmotic pressure of 100.0 mL of 2.50 m*M* NaCl, 80.0 mL of 3.60 m*M* $MgCl_2$, and the solution that is produced when the first two are blended together at 20°C. Assume that the volumes are additive and that both salts dissociate completely into their component ions.

A solution of 7.50 mg of a small protein in 5.00 mL of aqueous solution has an osmotic pressure of 6.50 torr at 23.1°C. What is the molar mass of the protein?

Kidney Dialysis Hemodialysis, a method of removing waste products from the blood if the kidneys have failed, uses a tube made of a cellulose membrane that is immersed in a large volume of aqueous solution. Blood is pumped through the tube and is then returned to the patient’s vein. The membrane does not allow passage of large protein molecules and cells but does allow small ions, urea, and water to pass through it. Assume that a physician wants to decrease the concentration of sodium ion and urea in a patient’s blood while maintaining the concentration of potassium ion and chloride ion in the blood. What materials must be dissolved in the aqueous solution in which the dialysis tube is immersed? How must the concentrations of ions in the immersion fluid compare with those in blood?

IV Solution Another solution used clinically in the hospital setting for IV administration is Ringer's lactate, a solution of sodium, potassium, and calcium cations and chloride and lactate anions. This solution is isotonic with 0.9% saline and D5W described in Section 11.5. Write a mathematical statement that indicates the relationship between the concentrations of cations and anions in this solution compared with 0.9% saline.

Injections The injection of pharmaceutical solutions that are hypertonic in relation to human plasma can cause considerable pain at the site of injection. Why?

Glossary

Born–Haber cycle	a series of steps with corresponding enthalpy changes that describes the formation of an ionic solid from its constituent elements.
Raoult's law	the principle that the vapor pressure of the solvent in a solution is equal to the vapor pressure of the pure solvent multiplied by the mole fraction of the solvent in the solution.
fractional distillation	a method of separating a mixture of compounds based on their different boiling points.
colligative properties	characteristics of solutions that depend on the concentration and not the identity of particles dissolved in the solvent.
van 't Hoff factor (also called *i*factor)	the ratio of the experimentally measured value of a colligative property to the theoretical value expected for that property if the solute were a nonelectrolyte.
ion pair	a cluster formed when a cation and an anion associate with each other in solution.
osmosis	

the flow of a fluid through a semipermeable membrane to balance the concentration of solutes in solutions on the two sides of the membrane. The solvent particles' flow proceeds from the more dilute solution into the more concentrated one.

osmotic pressure (Π)

the pressure applied across a semipermeable membrane to stop the flow of solvent from the compartment containing pure solvent or a less concentrated solution to the compartment containing a more concentrated solution. The osmotic pressure of a solution increases with solute concentration, M, and with solution temperature, T.

lattice energy (U)

the enthalpy change that occurs when 1 mole of an ionic compound forms from its free ions in the gas phase.

molality (m)

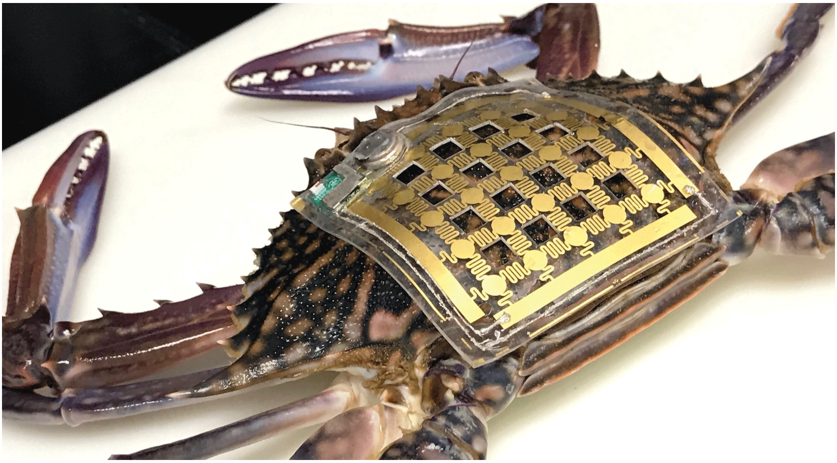
concentration expressed as the number of moles of solute per kilogram of solvent.

enthalpy of solution ($\Delta H_{\text{solution}}$)

the overall change in enthalpy that occurs when a solute dissolves in a solvent.

enthalpy of hydration ($\Delta H_{\text{hydration}}$)

the energy change when gas-phase ions dissolve in water.



CRAB WALK Flexible electronics based on gold circuits printed onto synthetic polymers can be attached to crabs (*Portunis pelagicus*) to allow scientists to collect data on their movements.

Solids
Crystals, Alloys, and Polymers

PARTICULATE REVIEW

Ionic Compounds and Metals

In Chapter 12 we explore the structure and properties of solids. Most metals and ionic compounds are solids at room temperature, including potassium iodide and platinum, whose structures are depicted here.

- Which solid consists of bonds due to delocalized electrons?
- What type of particles experience electrostatic interactions in potassium iodide?
- What type of particles experience electrostatic interactions in platinum?

(Review Sections 8.1 and 11.1 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Three-Dimensional Networks: Structure and Properties

Two allotropes of carbon are depicted, both as three-dimensional networks. As you read Chapter 12, look for ideas that will help you answer these questions:

- Which allotrope has a repeating pattern that is planar? Which allotrope has a repeating pattern that is not planar?
- Which allotrope consists of carbon atoms covalently bonded to one another? Which allotrope has *both* covalent bonds *and* weak interactions between layers?
- One allotrope is used as a lubricant because of its slipperiness. Is it A or B?

Learning Outcomes

- LO1 Identify the differences in packing schemes for atoms in the solid state, including face-centered, body-centered, and simple cubic unit cells, and relate the unit cells to the density and atomic radii of elements

  Sample Exercise 12.1

- LO2 Describe the differences between substitutional and interstitial alloys

  Sample Exercise 12.2

- LO3 Relate the crystalline structures of molecular and ionic compounds to their formulas, particle radii, and densities

Sample Exercises 12.3, 12.4

- LO4 Identify monomers given the structure of a polymer, and determine the structure of a polymer given the structure of a monomer

  Sample Exercises 12.5, 12.7, 12.9

- LO5 Analyze the properties of polymers

  Sample Exercises 12.6, 12.8

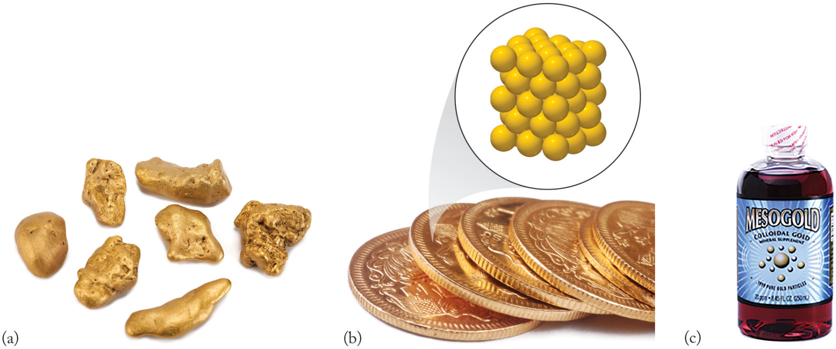

FIGURE 12.1 Different forms of metallic gold include (a) nuggets (the way it is found in nature), (b) coins, and (c) tiny particles suspended in water (touted as elixirs for good health). The gold in each of these forms is the same—an ordered arrangement of gold atoms—even if the colors of gold coins and small gold particles differ.

12.1 The Solid State

People have placed a high value on gold for thousands of years and put gold to many different uses, including jewelry, coinage, and medicine (**Figure 12.1**). Today, research into solid materials is yielding applications that would have been unimaginable as recently as 50 years ago. Nanoparticles of gold (small particles with diameters less than 10^{-7} m) are used in medicine to treat rheumatoid arthritis and to bind drugs (using intermolecular forces) for delivery to specific target cells. Research on other solid elements has resulted in the breakthroughs responsible for miniaturized electronic devices and for the high-molar-mass organic compounds used as sutures and in knee or hip replacement surgery.

Gold is one of the few elements that exists in nature as a pure metal. Because metals are typically shiny, malleable (easily shaped), ductile (easily drawn out), and able to conduct electricity, they have many applications that take advantage of these properties. All metals except mercury exist in the solid state under standard conditions.

Many covalent and ionic compounds are solids at room temperature. Solids may exist as crystalline solids—that is, ordered arrays of atoms, ions, or molecules—or as amorphous solids, which have random or disordered arrangements of particles. There are several types of crystalline solids. Metallic elements generally crystallize as metallic solids consisting of ordered arrays of atoms held together by metallic bonds, whereas most nonmetals crystallize as molecular solids consisting of neutral, covalently bonded molecules held together by intermolecular forces. The noble gases crystallize as atomic solids with only weak dispersion forces between the atoms. A few elements and compounds crystallize as covalent network solids, which consist of extended arrays held together by covalent bonds. Lastly, ionic compounds form crystalline ionic solids in which ions, either monatomic or polyatomic, are held together by ionic bonds. **Table 12.1** summarizes the major classes of solids that we explore in this chapter.

Two solids with different compositions may have very different properties because of the different intermolecular forces between their molecules or different bonds between their atoms or ions. Molecular solids often have lower melting points than ionic solids because the intermolecular forces that hold them together are relatively weak compared to the strength of ionic bonds. The melting points of metallic solids cover a broad range, from gallium at 29.76°C (just above room temperature but below human body temperature) to tungsten, which melts at 3422°C. (Mercury is the one metal that exists as a liquid at room temperature.) Metallic solids are malleable, so they can be bent into a variety of shapes, whereas ionic solids tend to be hard but brittle.

TABLE 12.1 Solid Characteristics and Classification by Particles and Electrostatic Attractions

Class	Particles	Electrostatic Attractions	Physical Properties	Examples
CRYSTALLINE SOLIDS				
Atomic	Atoms	London forces	Low melting point, poor conductor, soft	Metals	Atoms	Metallic bonds	Broad range	
		of melting points, excellent conductor, malleable, ductile, soft to hard	
Covalent network	Covalent bonds	Very high melting point, poor conductor, very hard	Ionic	Cations and anions	High melting point, good conductor (in molten state), hard and brittle	Molecular	London forces Dipole–dipole forces Hydrogen bonds	Low melting point, poor conductor, soft	AMORPHOUS SOLIDS			
Covalent network	Covalent bonds	Properties vary based on composition	
Mixtures of a host metal and one or more other elements are called *alloys*, and more than 500,000 alloys in the solid state have been made and characterized. Some are solid solutions, which means they are homogeneous at the atomic level. Other alloys are heterogeneous mixtures. The purpose of making alloys is to manipulate their properties by varying the proportions of their constituent metals. Alloys of nickel and titanium can be shaped into stents used to prop open arteries in heart patients. Brass, which is an alloy of copper and zinc, is used in hospitals and large kitchens because of its antibacterial properties. The transportation industry uses aluminum alloys that are ideal for making aircraft because they are strong and lighter than steel, resulting in less fuel consumption.

CONNECTION Intermolecular forces are described in Chapter 10.

Polymers, which are discussed in greater detail in Section 12.6, are large solid organic compounds with molar masses up to and exceeding 1,000,000 g/mol. Like metals and alloys, different polymer compositions affect the physical properties of the material. Poly(vinyl chloride), for example, is used to make drainpipes and other building materials (Section 4.2), whereas Teflon is used in nonstick cookware. Abrasion-resistant, ultrahigh-molecular-weight polyethylene is used as a coating on some artificial joints used in hip replacement. A polymer formed by the reaction of glycolic acid and lactic acid is used in dissolving sutures and to support the growth of skin cells for burn victims.

CONNECTION Some physical properties of metals were first described in Chapter 2.

In Chapter 12 we examine the major classes of solid materials and explore the links between their physical properties at the macroscopic level and their structures at the atomic level. Materials science is a fast-changing field, and we are able to discuss only a few of its many applications. The search for new materials and new applications is constant and constantly surprising. We start our exploration of the solid state by looking at the structures of some familiar metals.

Glossary

nanoparticle

an approximately spherical sample of matter with dimensions smaller than 100 nm (1×10^{-7} m).

crystalline solid

a solid made of an ordered array of atoms, ions, or molecules.

amorphous solid

a solid that lacks long-range order for the atoms, ions, or molecules in its structure.

metallic solid

a solid formed by metallic bonds among atoms of metallic elements.

molecular solid

a solid formed by intermolecular attractive forces among neutral, covalently bonded molecules.

atomic solid

a solid formed by weak attractions between noble gas atoms.

covalent network solid

a solid formed by covalent bonds among nonmetal atoms in an extended array.

ionic solid

a solid formed by ionic bonds among monatomic or polyatomic ions.

$$\ell = \frac{4r}{\sqrt{2}} = 2.828r$$

$$\text{Packing efficiency (\%)} = \frac{V_{\text{spheres}}}{V_{\text{unit cell}}} \times 100\% = \frac{\frac{16}{3}\pi r^3}{22.62r^3} \times 100\% = 74.1\%$$

12.2 Structures of Metals

When a metal is heated above its melting point and then slowly allowed to cool, it solidifies into a crystalline solid in which the atoms are arranged in an ordered, repeating, three-dimensional array called a crystal lattice. In many crystal lattices, stacked layers (designated *a*, *b*, *c*, . . .) of particles are packed together as tightly as possible. Each atom in layer *a* touches six others in that layer (**Figure 12.2a**). The atoms in layer *b* nestle into some of the spaces created by the atoms of layer *a* (**Figure 12.2b**), just like oranges in a fruit-stand display or cannonballs at a 16th-century fort (**Figure 12.3**). Similarly, the atoms in a third layer, *c*, nestle among those in layer *b*. However, two different alignments are possible for the atoms in layer *c*. They can align directly above the atoms in layer *a* (**Figure 12.2c**), in which case we label them as layer *a* again, or they can nestle into the atoms of layer *b* in such a way that they are *not* aligned directly above the layer *a* atoms (**Figure 12.2d**). When a fourth layer is nestled into the spaces of layer *c*, the fourth layer atoms lie directly above the layer *a* atoms. In Figure 12.2c, we have an *ababab* . . . stacking pattern throughout the crystal, whereas in Figure 12.2d we have an *abcabc* . . . stacking pattern. As we will see in this and subsequent sections, the pattern in which metal atoms are packed and the available spaces between them affects their physical properties (e.g., their density) and their applications.

Stacking Patterns and Unit Cells

Which of these two patterns do gold atoms adopt? Whether the atoms in a metal like gold are stacked in an *ababab* or an *abcabc* pattern determines the shape of its crystals. The crystal structure of an element or compound specifies the location of the atoms in three-dimensional space in relation to one another. To see how crystal structures are linked to stacking patterns, let's take a closer look at a cluster of atoms held together by the *ababab* stacking pattern (**Figure 12.4a**). This cluster forms a *hexagonal* (six-sided) prism of closely packed atoms. In fact, they are as tightly packed as they can be, so the crystal lattice is called hexagonal closest-packed (hcp). Titanium metal used in surgical repair of fractures is one element that crystallizes in an hcp lattice, forming hexagonal crystals (**Figure 12.5**). As the periodic table in **Figure 12.6** shows, the atoms in 16 metallic elements have an hcp crystal lattice. In these metals, the cluster of atoms in Figure 12.4a serves as an atomic-scale building block—a pattern of atoms repeated over and over again in all three dimensions in the metal.

We call each of these building blocks a unit cell. The example in Figure 12.4a shows a hexagonal unit cell. A unit cell represents the minimum repeating pattern that describes the three-dimensional array of atoms forming the crystal lattice of any crystalline solid, including metals. Think of unit cells as three-dimensional microscopic analogs of the two-dimensional repeating pattern in fabrics, wrapping paper, or even a checkerboard. Look carefully at **Figure 12.7** to confirm that the outlined portion represents the minimum repeating pattern in the checkerboard and in the paper. A unit cell plays the same role in three dimensions in the crystal structure of a solid.

Atoms in solid gold and 11 other metals adopt the *abcabc* stacking pattern when they solidify (Figures 12.1 and 12.6). What is the unit cell in this stacking pattern? Consider what happens when we take the cluster of atoms on the left in **Figure 12.4b**, compact it, rotate the cluster, and tip it 45° to get the orientation shown in the center of Figure 12.4b. The black outline shows that the atoms form a cube: one atom at each of the eight corners of the cube and one at the center of each of the six faces. Atoms at adjacent corners (e.g., atoms 1 and 2, 1 and 4, 2 and 5, or 4 and 5) do *not* touch each other, but the three atoms along the diagonal of any face of the cube (e.g., atoms 2, 3, 4) do touch each other. Because the atoms are stacked together as closely as possible, this crystal lattice is called cubic closest-packed (ccp), and the corresponding unit cell is called a face-centered cubic (fcc) unit cell. The unit cell edges are all of equal length, and the angle between any two edges is 90°.

The two *closest-packed* crystal lattices—hexagonal (hcp) and cubic (ccp)—represent the most efficient ways of arranging solid spheres of equal radius. We can express the packing efficiency as the percentage of the total volume of the unit cell occupied by the spheres:

For both hcp and ccp crystal lattices, the packing efficiency is approximately 74%.

Other crystal lattices have stacking patterns in which the atoms are arranged close together, but not as efficiently as in hcp and ccp lattices. Two of these are shown in **Figure 12.4c and d**. When the atoms are arranged in an *a* layer so that each atom touches just four adjacent atoms in that layer, the arrangement is called *square packing* (Figure 12.4c). If we add a second layer of spheres directly above the first, we create the *aaa* . . . stacking pattern, which is called *cubic packing.* The three-dimensional repeating pattern of this arrangement is called a simple cubic (sc) unit cell. It is the least efficiently packed of the cubic unit cells and is quite rare among metals: only radioactive polonium (Po) forms a simple cubic unit cell.

For crystal lattices in which each atom in a second layer is nestled in the space created by four atoms in a square-packed *a* layer (Figure 12.4d), we have two layers in an *ab* stacking pattern. If the atoms in the third layer are directly above those in the first, then we have an *ababab* . . . stacking pattern based on layers of square-packed atoms. The simplest three-dimensional repeating unit of this pattern is called a body-centered cubic (bcc) unit cell. It consists of portions of nine atoms, one at each of the eight corners of a cube and one in the middle of the cube. All the group 1 metals and many transition metals have bcc unit cells (Figure 12.6). One of those transition metals is tantalum, which is used for wedding rings (**Figure 12.8**) and to coat artificial joints. **Table 12.2** summarizes the different stacking patterns, packing efficiencies, and unit cells described in this section.

CONCEPT TEST

What is the difference between a crystal lattice and a unit cell?

(Answers to Concept Tests are in the back of the book.)

Unit Cell Dimensions

Of all the metallic elements, only Li, Na, and K have densities less than 1 g/cm^3. The densities of the transition metals range from 3 g/cm^3 (Sc) to 22.5 g/cm^3 (Os). The number of atoms in the unit cell of a metallic element, its atomic radius, and its molar mass all contribute to its density. **Figure 12.9** shows whole-atom and cutaway views of sc, fcc, and bcc unit cells. These views make it possible to determine how many atoms are in each type of cubic unit cell.

TABLE 12.2 Summary of Unit Cells, Stacking Patterns, and Packing Efficiencies for Solid Spheres

[illegible]		Number of Nearest Neighbors
[illegible]		Hexagonal closest-packed (hcp)
[illegible]		Cubic closest-packed (ccp)
[illegible]		Body-centered cubic packing
[illegible]		Simple cubic packing

In the simple cubic unit cell (Figure 12.9a), only a fraction of each corner atom is inside the unit cell boundary. In a crystal lattice with this unit cell, each atom is a corner atom in eight unit cells (**Figure 12.10a**). Thus, each atom contributes the equivalent of one-eighth of an atom to the unit cell. A cube has eight corners, so there is a total of

---

This calculation applies to the corner atoms in any type of cubic unit cell. The two corner atoms along each edge in Figure 12.9a touch each other. Therefore, the edge length ℓ in the simple cubic unit cell is equal to twice the atomic radius:

$$\ell = 2r$$

If we can measure the length of the unit cell (ℓ), then we can calculate the atomic radius of an element with this unit cell. For example, an fcc unit cell (Figure 12.9b) has eight corner atoms (just like the sc unit cell) and one atom in the center of each of the six faces (**Figure 12.10b**). Each face atom is shared by the two unit cells that abut each other at that face. Therefore, each unit cell "owns" half of each face atom, making a total of

These three face atoms plus the equivalent of one corner atom means that an fcc unit cell consists of

1 corner atom + 3 face atoms = 4 atoms per fcc unit cell

To relate the size of these atoms to the dimensions of the fcc unit cell, note in the cutaway view of Figure 12.9b that the corner atoms do not touch one another, but adjacent atoms along the face diagonal do touch each other. Therefore, a face diagonal spans the radius r of two corner atoms and the diameter (2 radii = $2r$) of a face atom. The length of a face diagonal, then, is 1 + 2 + 1 = 4 atomic radii = $4r$. A face diagonal connects the ends of two edges and forms a right triangle with those two edges, each of length ℓ (Figure 12.9b). According to the Pythagorean theorem, then, the length of a face diagonal is

As in the case of the simple cubic unit cell, if we know the value of ℓ, we can calculate r by using Equation 12.2.

The bcc unit cell (Figure 12.9c) has one-eighth of an atom at each of the eight corners (just like the sc and fcc unit cells), as well as one atom in the center of the cell that is entirely within the cell (**Figure 12.10c**). This means a bcc unit cell consists of 1 corner atom + 1 center atom = 2 atoms per unit cell.

Relating unit cell edge length ℓ to atomic radius r in a bcc cell is complicated because, in addition to not touching along the edges, adjacent atoms along any face diagonal do not touch each other either. However, each corner atom does touch the atom in the center of the cell, which means that the atoms touch along a *body diagonal*, which runs between opposite corners through the center of the cube. In the cutaway view in Figure 12.9c, the body diagonal runs from the bottom left corner of the front face to the top right corner of the rear face. It spans (1) the radius of the front-face bottom left corner atom, (2) the diameter (2 radii) of the central atom, and (3) the radius of the rear-face top right atom, making the length of the body diagonal equivalent to 4*r*.

A right triangle is formed by an edge (length $= \ell$), a face diagonal $(\text{length} = \ell\sqrt{2})$, and a body diagonal (length $= 4r$) that serves as the hypotenuse of the triangle (Figure 12.9c). Using the Pythagorean theorem again, we find the body diagonal to be:

TABLE 12.3 Contributions of Atoms to Cubic Unit Cells

Atom Position	Contribution to Unit Cell
Center	1 atom
Face	$\frac{1}{2}$ atom
Edge	$\frac{1}{4}$ atom
Corner	$\frac{1}{8}$ atom

Table 12.3 summarizes how atoms in different locations in sc, bcc, and fcc unit cells contribute to the total number of atoms in each unit cell. **Table 12.4** summarizes the number of equivalent atoms and the relationship between *r* and ℓ for the three cubic unit cells.

TABLE 12.4 Summary of Unit Cells, Equivalent Atoms, and the Relationship between Radius of Atoms and Edge Length of Cubic Unit Cells

Unit Cell	Number of Equivalent Atoms per Unit Cell	Relationship between *r* and ℓ
Simple cubic (sc)	1 (8 corners)	$r = \frac{\ell}{2} = 0.5\ell$

Body-centered cubic (bcc)	2 (1 center + 8 corners)	$r = \frac{\ell\sqrt{3}}{4} = 0.4330\ell$
Face-centered cubic (fcc)	4 (6 faces + 8 corners)	$r = \frac{\ell\sqrt{2}}{4} = 0.3536\ell$

SAMPLE EXERCISE 12.1 Calculating Atomic Radius and Density from Unit Cell Dimensions LO1

Tantalum crystallizes with a bcc unit cell as shown in **Figure 12.11**. Its unit cell has an edge length of 330.3 pm. (a) Calculate the radius in picometers of the tantalum atoms. Check your answer against the data in Appendix 3. (b) Calculate the density of tantalum in grams per cubic centimeter at 25°C.

Collect and Organize We are given the unit cell (bcc—see Figure 12.9c) and edge length ($\ell = 330.3$ pm) of tantalum. Together with the molar mass of tantalum (180.95 g/mol), we can calculate both the atomic radius of a Ta atom and the density of Ta metal.

Analyze The tantalum atoms do not touch along the unit cell edges or along any face diagonal, but they do touch along the body diagonals. Table 12.4 gives the relationship between r and ℓ for a bcc unit cell: $r = 0.4330\ell$. We recognize that the radius is a little less than half the edge length ($\ell/2$), so with $\ell = 330$ pm, we expect a value less than 165 pm for r.

We assume that the density of the unit cell is the same as the density of solid Ta. The density of the Ta bcc unit cell is the mass of two Ta atoms divided by the volume of the cell. We can calculate the mass of two Ta atoms from the molar mass, which is 180.95 g/mol. The conversion includes dividing by the Avogadro constant to calculate the mass of each Ta atom in grams. The formula for the volume of a cube of edge length ℓ is $V = \ell^3$.

Solve

1. Substituting the edge length into the formula for r from Table 12.4:

   $$r = 0.4330 \times 330.3 \text{ pm} = 143.0 \text{ pm}$$

This is close to the reference value of 146 pm for Ta (Table A3.1).

2. We first calculate the mass *m* of two Ta atoms:

$$m = \frac{180.95\ \text{g Ta}}{1\ \cancel{\text{mol Ta}}} \times \frac{1\ \cancel{\text{mol Ta}}}{6.022 \times 10^{23}\ \cancel{\text{atoms Ta}}} \times 2\ \cancel{\text{atoms Ta}} = 6.010 \times 10^{-22}\ \text{g Ta}$$

The volume of the cell in cubic centimeters is

$$V = \ell^3 = (330.3\ \cancel{\text{pm}})^3 \times \frac{(10^{-10}\ \text{cm})^3}{1\ \cancel{\text{pm}}^3} = 3.604 \times 10^{-23}\ \text{cm}^3$$

The density is

$$d = \frac{m}{V} = \frac{6.010 \times 10^{-22}\ \text{g}}{3.604 \times 10^{-23}\ \text{cm}^3} = 16.68\ \text{g/cm}^3$$

Think About It The value of *r* is indeed less than half the value of the edge length, as predicted. If the calculated density is correct, then it should match the measured density in Table A3.2. The reported density of tantalum is 16.65 g/mL, so the result of our calculation (16.68 g/cm^3) is reasonable.

Practice Exercise Silver and gold both crystallize in face-centered cubic unit cells with edge lengths of 407.7 and 407.0 pm, respectively. Calculate the atomic radius and density of each metal, and compare your answers with the data listed in Appendix 3.

(Answers to Practice Exercises are in the back of the book.)

Earlier in this section we mentioned that ccp and hcp are the most efficient packing schemes for spheres. Now that we know more about the fcc unit cell, let’s take another look at the calculation of packing efficiency by using Equation 12.1. The unit cell for a ccp arrangement of solid spheres of radius r is an fcc unit cell that contains four equivalent spheres. The volume occupied by these four spheres is

From Table 12.4, the unit cell edge (ℓ) is $r = (\ell\sqrt{2})/4$, in which case

This equation enables us to express the volume of the unit cell in terms of r:

$$V_{\text{unit cell}} = \ell^3 = (2.828r)^3 = 22.62r^3$$

Substituting V_{spheres} and $V_{\text{unit cell}}$ into Equation 12.1:

This means that the most efficient packing of spheres results in about 26% of the total volume being empty.

Glossary

crystal lattice

a three-dimensional repeating array of particles (atoms, ions, or molecules) in a crystalline solid.

crystal structure

a particular arrangement in three-dimensional space that specifies the positions of the particles (atoms, ions, or molecules) in relation to one another in a crystalline solid.

hexagonal closest-packed (hcp)

a crystal lattice in which the layers of atoms or ions in hexagonal unit cells have an *ababab* . . . stacking pattern.

unit cell

the repeating unit of the arrangement of atoms, ions, or molecules in a crystal lattice.

hexagonal unit cell

an array of closest-packed particles that includes parts of four particles on the top and four on the bottom faces of a hexagonal prism and one particle in a middle layer.

cubic closest-packed (ccp)

a crystal lattice in which the layers of atoms or ions in face-centered cubic unit cells have an *abcabc* . . . stacking pattern.

face-centered cubic (fcc) unit cell

an array of closest-packed particles that has one particle at each of the eight corners of a cube and one more at the center of each face of the cube.

packing efficiency

the percentage of the total volume of a unit cell occupied by the atoms, ions, or molecules.

simple cubic (sc) unit cell

an array of atoms or molecules with one particle at the eight corners of a cube.

body-centered cubic (bcc) unit cell

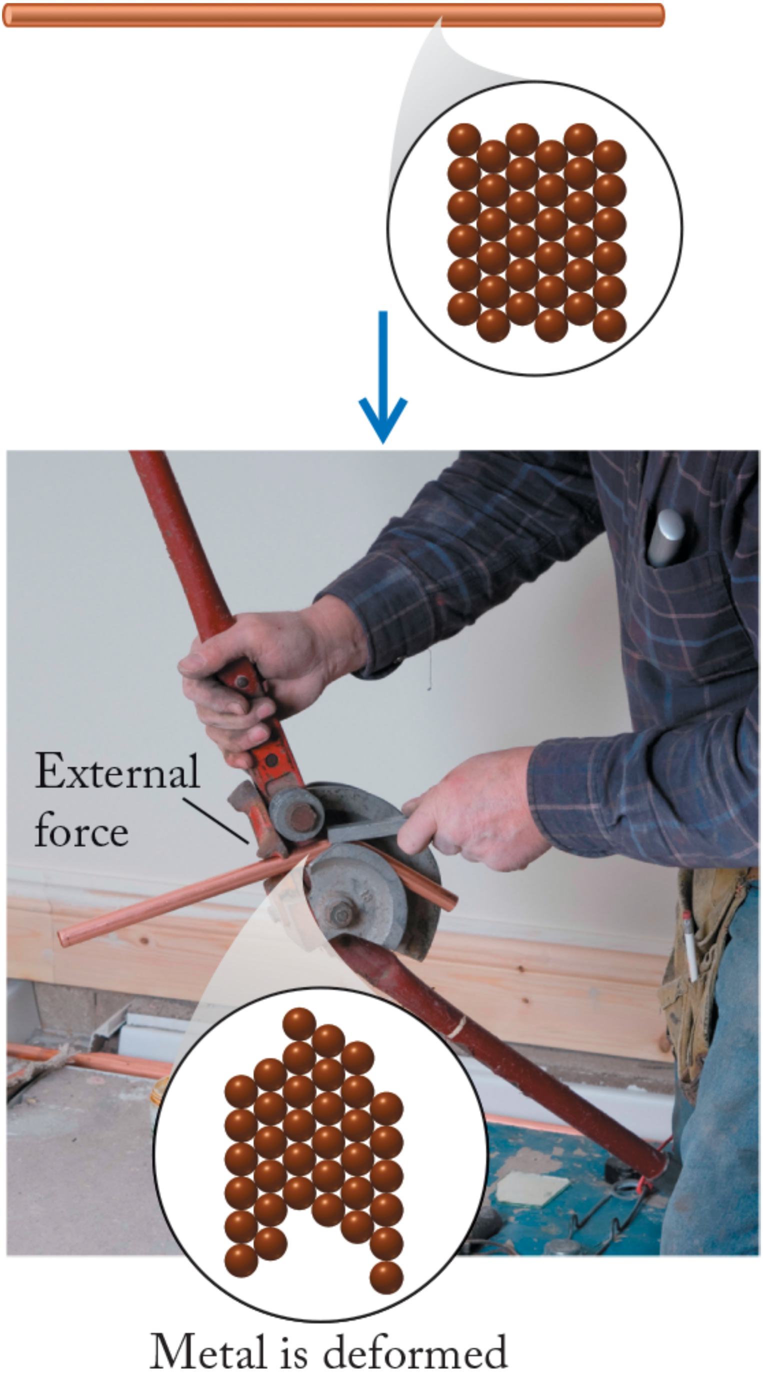
an array of atoms or molecules with one particle at each of the eight corners of a cube and one at the center of the cell.

Learning Objectives

Identify the differences in packing schemes for atoms in the solid state, including face-centered, body-centered, and simple cubic unit cells, and relate the unit cells to the density and atomic radii of elements **Return to Sample Exercise 12.1**

(a) (b)

FIGURE 12.12 (a) Brass and (b) bronze are alloys of copper containing zinc and tin (up to 30% by mass), respectively. Both alloys have antibacterial properties, making them desirable coatings for fixtures in hospitals and restaurant kitchens.



External force
Metal is deformed

FIGURE 12.13 Copper and other metals are malleable because their atoms

are stacked in layers that can slip past each other under stress. Slippage is possible because of the diffuse nature of metallic bonds and the relatively weak interactions between pairs of atoms in adjoining layers.

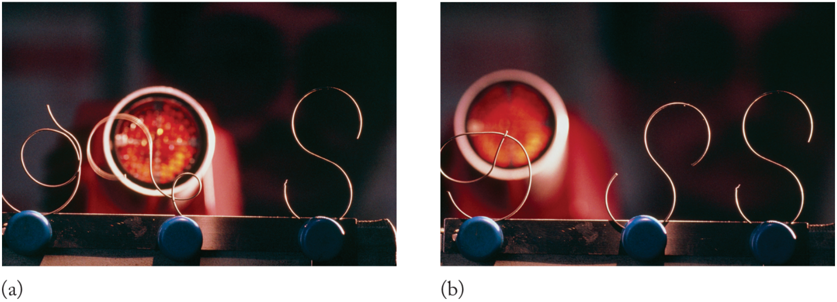


FIGURE 12.14 Shape memory alloys are used in stents for heart patients. This figure illustrates how shape memory alloys work. (a) The S shape on the right is the desired final shape of the wire. The left and middle wires have been coiled to take up less space. The white circle in the background is a hair dryer heating the wires. (b) When the wire in the middle is heated, it returns to its original shape, while the wire on the left is in the process of unraveling.

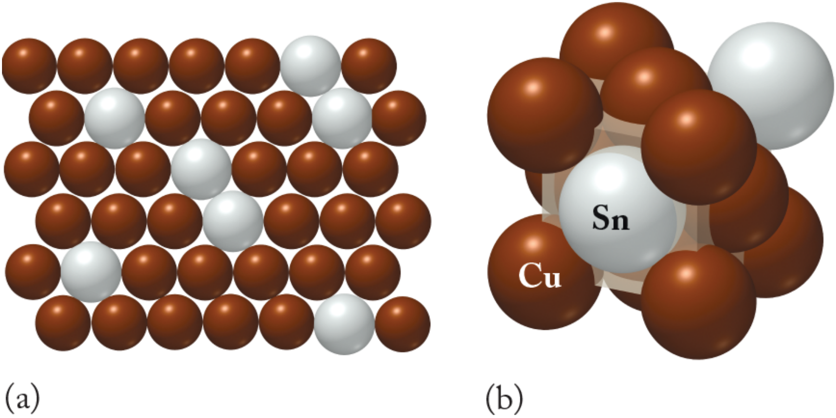

FIGURE 12.15 Two atomic-scale views of one type of bronze, a substitutional alloy. (a) A layer of close-packed copper (Cu) atoms interspersed with a few atoms of tin (Sn). (b) One possible unit cell for bronze. In this case, tin atoms have replaced one corner Cu atom and one face Cu atom.

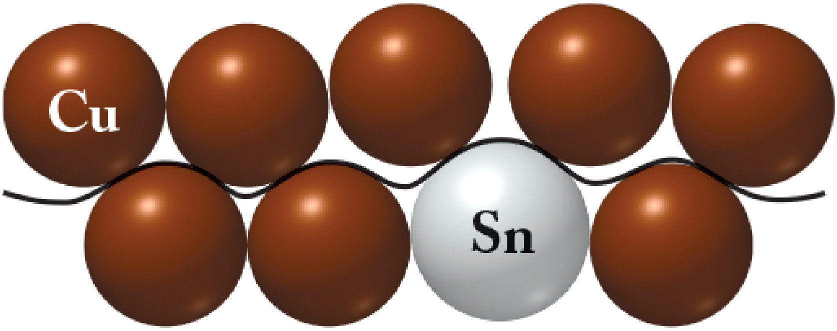

FIGURE 12.16 The larger Sn atoms in bronze disturb the Cu crystal lattice, producing atomic-scale bumps in the slip plane (wavy line) between layers of Cu atoms. These bumps make it more difficult for Cu atoms to slide past each other when an external force is applied.

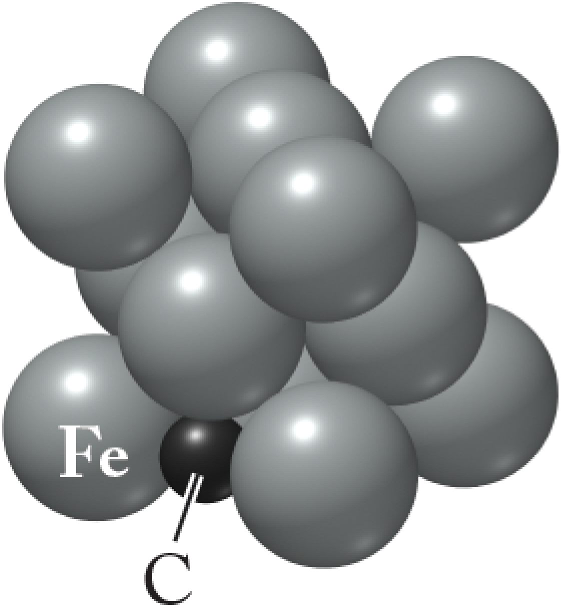

FIGURE 12.17 Carbon steel is an interstitial alloy of carbon in iron. The fcc form of iron (austenite) that forms at high temperatures can accommodate carbon atoms in its octahedral holes.

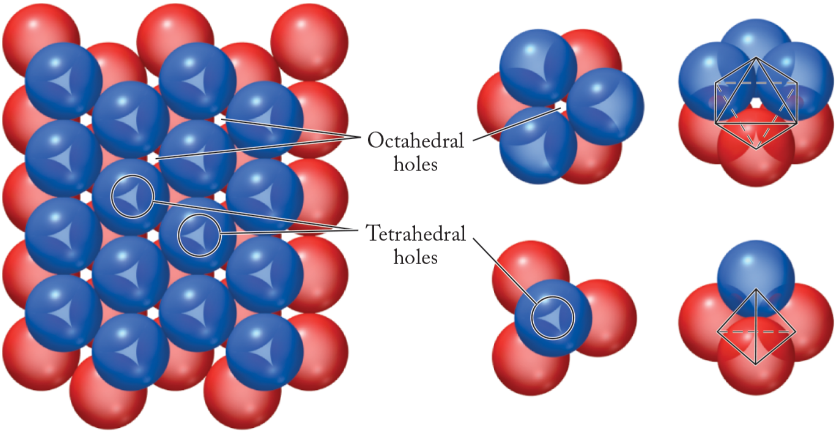

FIGURE 12.18 Close-packed atoms in adjacent layers of a crystal lattice produce octahedral holes surrounded by six host atoms and tetrahedral holes surrounded by four host atoms. Octahedral holes are larger than tetrahedral holes and so can accommodate larger nonhost atoms in interstitial alloys. All of the atoms are identical here; the colors are used only to distinguish one layer of atoms from another.

$$r_{\text{nonhost}}/r_{\text{host}} = \frac{139\ \cancel{\text{pm}}}{144\ \cancel{\text{pm}}} = 0.965$$

12.3 Alloys and Medicine

The antibacterial properties of copper metal are attractive for coating surfaces in hospitals and in food service kitchens where an infection can prove deadly (**Figure 12.12**). However, pure copper has two disadvantages: it is both relatively soft and very malleable, which means that pure copper objects are easily bent and damaged. We can explain the malleability of Au, Cu, and other metals in terms of the relatively weak bonds between the atoms in their cubic closest-packed crystal structure. This arrangement gives the atoms in one layer the ability, under stress, to slip past atoms in an adjacent layer (**Figure 12.13**), but the overall crystal structure is still cubic closest-packed. The ease with which copper atoms slip past each other makes it easy to bend copper pipes used in plumbing, but it also makes them susceptible to damage. Additionally, copper reacts with air to produce blue-green copper hydroxides and carbonates.

The physical and chemical properties of copper change when mixed with zinc or tin to produce mixtures known as brass and bronze, respectively. Brass and bronze are stronger than pure copper and have improved resistance to reactions with air or moisture while retaining the antibacterial properties of pure copper. A mixture of two metals represents an alloy: a metallic material made when a host metal is blended with one or more other elements, which may or may not be metals, thereby changing the properties of the host metal. Like the mixtures discussed in Chapter 1, alloys can be classified according to their composition as homogeneous or heterogeneous mixtures. Brass and bronze are both *homogeneous alloys*, solid solutions in which the atoms of the added elements (in this case tin or zinc) are randomly but uniformly distributed among the atoms of the host (copper). *Heterogeneous alloys* consist of matrices of atoms of host metals interspersed with small "islands" made up of individual atoms of other elements. For example, the different unit cells of lead and tin give solder its properties because it is a heterogeneous alloy. In both cases, the compositions may vary over a limited range.

CONNECTION The classification of homogeneous and heterogeneous mixtures and the difference between compounds and mixtures are described in Chapter 1.

Every year thousands of patients suffering from cardiovascular disease undergo a procedure called balloon angioplasty to open clogged arteries. This surgery involves the insertion of small metal supports called stents to prop open the artery. Increasingly, stents are manufactured from an alloy containing nickel and titanium. The alloy NiTi (nitinol) is an example of an *intermetallic compound,* a substance that has a reproducible stoichiometry and constant composition (just like chemical compounds). Intermetallic compounds are still commonly referred to as alloys and are considered to be a subgroup within homogeneous alloys. What makes nickel–titanium alloys particularly useful is that they demonstrate shape memory (**Figure 12.14**). A piece of NiTi wire is heated and formed into the desired shape for the stent. On cooling, the NiTi undergoes a phase change to a different structure. The structural change allows the stent to be easily straightened for insertion into an artery. After insertion, the coiled stent is heated, and it springs back into its original shape as it rapidly reverts to the high-temperature form.

Substitutional Alloys

If alloys are mixtures of metals, and pure metals have crystal lattices as described in Section 12.2, how are the metal atoms arranged in the crystal lattices and unit cells of alloys? How does the structure of NiTi memory metal change as a function of temperature? The answer to these questions gives rise to another classification system: a substitutional alloy is one in which atoms of the nonhost metal replace host atoms in the crystal lattice. Bronze and nitinol are both examples of *homogeneous, substitutional alloys*. Substitutional alloys may form between metals that have the same crystal lattice and atomic radii that are within about 15% of each other.

CONCEPT TEST

Is it accurate to call bronze a *solution* of tin *dissolved* in copper? Explain why or why not.

Why is an alloy more difficult to bend than a pure metal? **Figure 12.15** illustrates one layer of the crystal lattice of bronze. The radii of copper and tin atoms are similar—128 pm and 140 pm, respectively. Inserting the slightly larger Sn atoms in the cubic closest-packed Cu crystal lattice disturbs the structure a little, making the planes of copper atoms “bumpy” instead of uniform (**Figure 12.16**), and making it more difficult for the copper atoms to slip past one another. Less slippage makes bronze less malleable than copper, but being less malleable also means that bronze is harder and stronger.

Alloys with good strength and corrosion resistance are essential for the manufacture of surgical tools and biomedical implants. One family of such alloys is the stainless steels, and its high-grade medical version is considered “surgical steel.” Steel is an alloy of iron, and stainless steel owes its useful properties to chromium; surgical steel contains 13%–16.5% chromium and 0.4%–0.6% carbon by mass. When atoms of Cr on the surface of a piece of stainless steel combine with oxygen, they form a layer of Cr_2O_3 that tightly bonds to the surface and protects the metallic material beneath from further oxidation. This resistance to surface discoloration from corrosion means that the surfaces of these alloys “stain less” than a surface of pure iron.

Interstitial Alloys

The major difference between iron and any kind of steel is the presence of carbon in steel. Molten iron produced in a blast furnace to which hot carbon has been added may contain up to 5% carbon. When the molten iron cools to its melting point of 1538°C, it crystallizes in a body-centered cubic structure before undergoing a phase transition at around 1390°C to austenite, a form of solid iron made up of face-centered cubic unit cells. The spaces, or *holes*, between iron atoms in austenite can accommodate carbon atoms, forming an interstitial alloy (**Figure 12.17**), so named because the carbon atoms occupy spaces, or *interstices*, between the iron atoms.

CONCEPT TEST

Is a substitutional alloy a homogeneous or a heterogeneous alloy, or could it be both? Is an interstitial alloy a homogeneous or a heterogeneous alloy, or could it be both?

Not all interstices in a crystal lattice are equivalent, however. Indeed, holes of two different sizes occur between the atoms in any closest-packed crystal lattice (**Figure 12.18**). The larger holes are surrounded by clusters of six host atoms in the shape of an octahedron and are called *octahedral holes.* The smaller holes are located between clusters of four host atoms and are called *tetrahedral holes.* The data in **Table 12.5** show which holes are more likely to be occupied based on the relative sizes of nonhost and host atoms. The atomic radii of C and Fe are 77 and 126 pm, respectively (see Appendix 3). According to Table 12.5, the ratio 77/126 = 0.61 means that C atoms should fit in the octahedral holes of austenite, but not in the tetrahedral holes.

TABLE 12.5 Atomic Radius Ratios and Location of Nonhost Atoms in Unit Cells of Interstitial Alloys

Atomic Radius Ratio $r_{\text{nonhost}}/r_{\text{host}}$[a]	**Hole Type**	[illegible]
0.22–0.41	Tetrahedral	[illegible]
0.41–0.73	Octahedral	[illegible]
0.73–1.00	Cubic packing	

As austenite (an fcc unit cell) cools to room temperature, it changes into the crystalline solid form of iron called ferrite, which is body-centered cubic. The octahedral holes in ferrite are smaller than those in austenite, and they are too small to accommodate carbon atoms. As a result, much of the carbon precipitates as clusters of carbon atoms, or it may react with iron to form iron carbide (Fe_3C). The clusters of carbon and Fe_3C disrupt ferrite's body-centered cubic lattice and inhibit the host iron atoms from slipping past each other when a stress is applied. This resistance to slippage, which is much like that experienced by the copper atoms in bronze (Figure 12.16), makes steel much harder and stronger than pure iron. In general, the greater the carbon concentration, the stronger the steel. However, there is a trade-off in this relationship; increased strength and hardness come at the cost of increased brittleness (**Table 12.6**).

TABLE 12.6 Effect of Carbon Content on the Properties of Steel

Carbon Content (%)	**Description**	**Properties**	**Uses**
[illegible]	**Mild**	[illegible] ductile	[illegible]
[illegible]	[illegible]	[illegible]	[illegible] girders
[illegible]	[illegible]	[illegible] brittle	[illegible]

SAMPLE EXERCISE 12.2 Predicting the Crystal Structure of a Two-Element Alloy LO2

Gold nanoparticles containing 10%–50% platinum show enhanced antibiotic properties in comparison with pure gold or pure platinum nanoparticles. Both elements form cubic closest-packed crystal lattices with face-centered cubic unit cells. Are these gold–platinum alloys substitutional or interstitial alloys?

Collect, Organize, and Analyze Atoms of two or more elements form a substitutional alloy when all the atoms are of similar size (within 15%). The highest $r_{\text{nonhost}}/r_{\text{host}}$ ratio in Table 12.5 for a ccp lattice, 0.73, means that an interstitial alloy can form only when the radius of the nonhost atoms is *less* than 73% of the radius of the host atoms. The atomic radii given in Appendix 3 are 144 pm for Au and 139 pm for Pt.

Solve The ratio of the atomic radii of Pt to Au is

Based on this $r_{\text{nonhost}}/r_{\text{host}}$ ratio, the platinum atoms are too big to fit into interstices in the lattice of gold atoms, regardless of whether the holes are tetrahedral or octahedral, so an *interstitial* alloy is impossible. Instead, atoms of Pt can *substitute* for atoms of Au in the Au ccp lattice with some room to spare. Both elements form fcc unit cells (see Figure 12.6), so little disruption to the Au lattice should result from incorporating Pt atoms. Thus, gold and platinum form a *substitutional* alloy.

Think About It Substitution of one sphere for another in the fcc unit cell in Figure 12.9bis least disruptive to the packing of the spheres when the atoms are similar in size, that is, with atomic radii that are within 15% of each other. The radii of Au and Pt are nearly the same size, differing by only 3.5%, so we would expect gold and platinum to form a substitutional alloy.

Practice Exercise The potential for allergic reactions to nickel in nitinol shape memory alloys has spurred the exploration of titanium and niobium alloys. Would you expect niobium (atomic radius 146 pm) to form a substitutional alloy with titanium (atomic radius 147 pm)? With molybdenum (atomic radius 139 pm)?

Glossary

alloy

a blend of a host metal and one or more other elements, which may or may not be metals, that are added to change the properties of the host metal.

substitutional alloy

an alloy in which atoms of the nonhost metal replace host atoms in the crystal lattice.

interstitial alloy

an alloy in which atoms of the added element occupy the spaces between atoms of the host.

Endnotes

- Radius ratios as predictors of the crystal lattice in crystalline solids are of limited value because atoms are not truly solid spheres with a constant radius; given that the radius of an atom may differ in different compounds, these ranges are approximate.Return to reference a

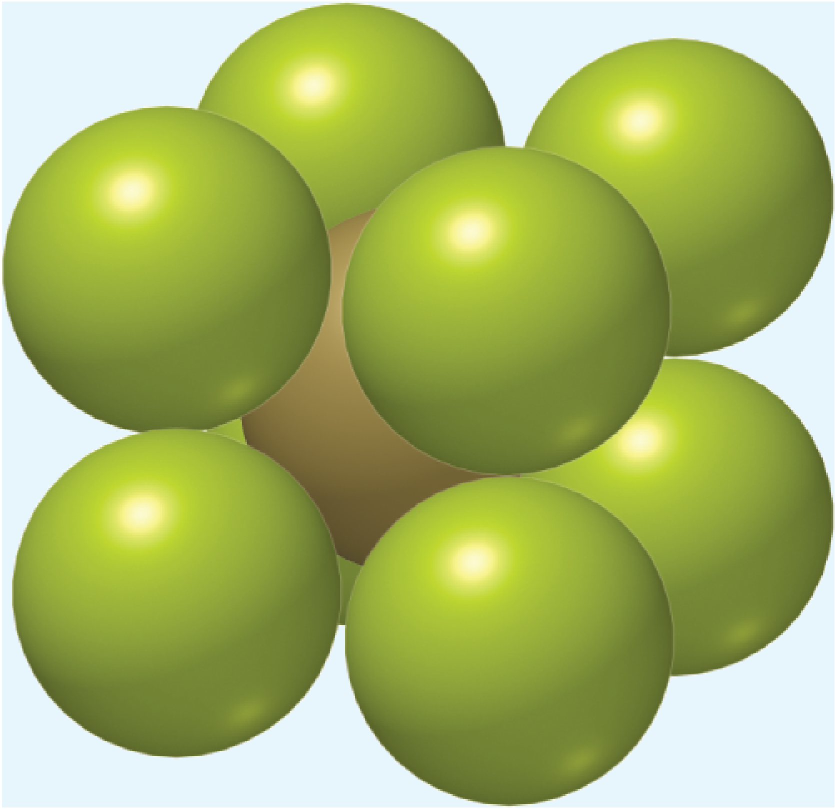

FIGURE 12.20 The unit cell of CsCl with Cs^+ in the cubic hole formed by eight Cl^- anions.

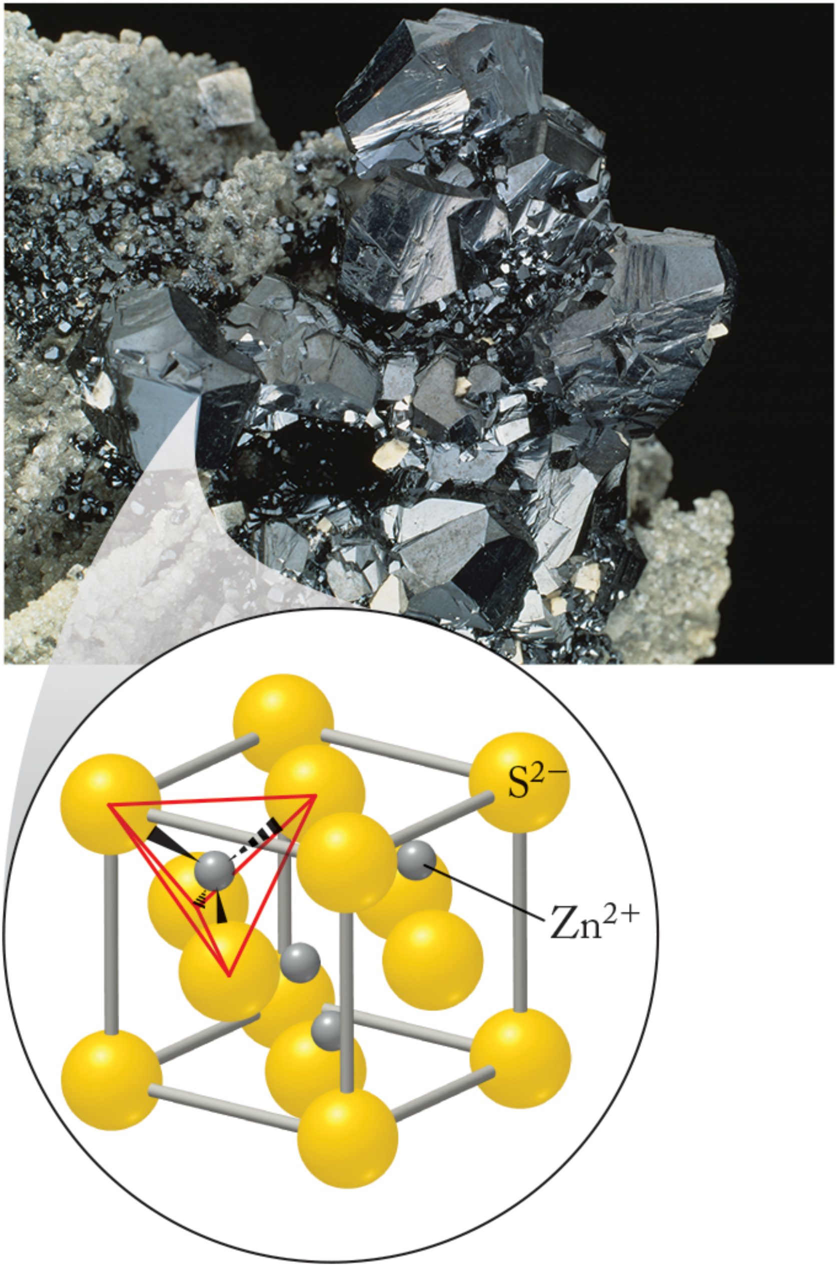

FIGURE 12.21 Many crystals of the mineral sphalerite (ZnS), like the largest ones in this photograph, have a tetrahedral shape. The crystal lattice of sphalerite is based on an fcc unit cell of S^{2-} ions with Zn^{2+} ions in four of the eight tetrahedral holes. In the

expanded view of the sphalerite unit cell, each Zn^{2+} ion is in a tetrahedral hole formed by one corner S^{2-} ion and three face-centered S^{2-} ions.

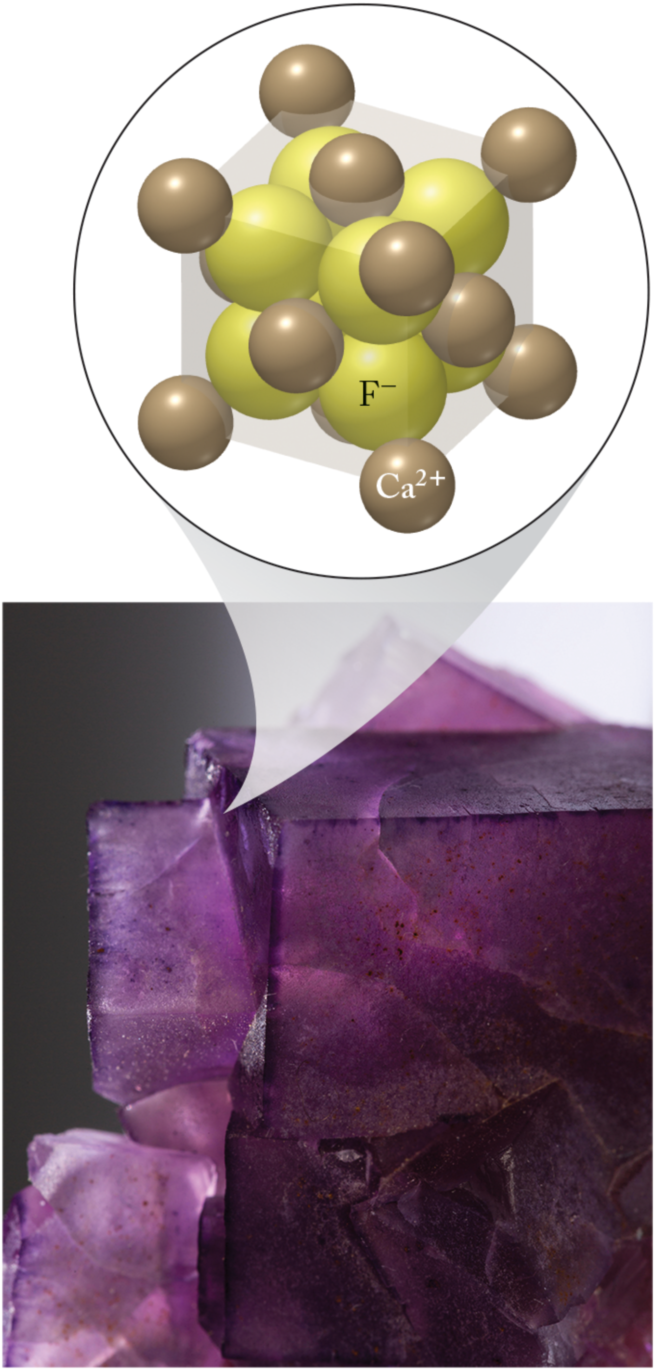

FIGURE 12.22

The mineral fluorite (CaF_2) forms cubic crystals. The crystal lattice of CaF_2 is based on an fcc array of Ca^{2+} ions, with F^- ions occupying all eight tetrahedral holes. Because they are bigger than Ca^{2+} ions, the F^- ions do not fit in the tetrahedral holes of a cubic closest-packed array of Ca^{2+} ions. Instead, the Ca^{2+} ions, while maintaining the fcc unit cell arrangement, spread out to accommodate the larger F^- ions. Note how adjacent Ca^{2+} ions along any face diagonal do *not* touch each other the way they do in the ideal fcc unit cell in Figure 12.9b.

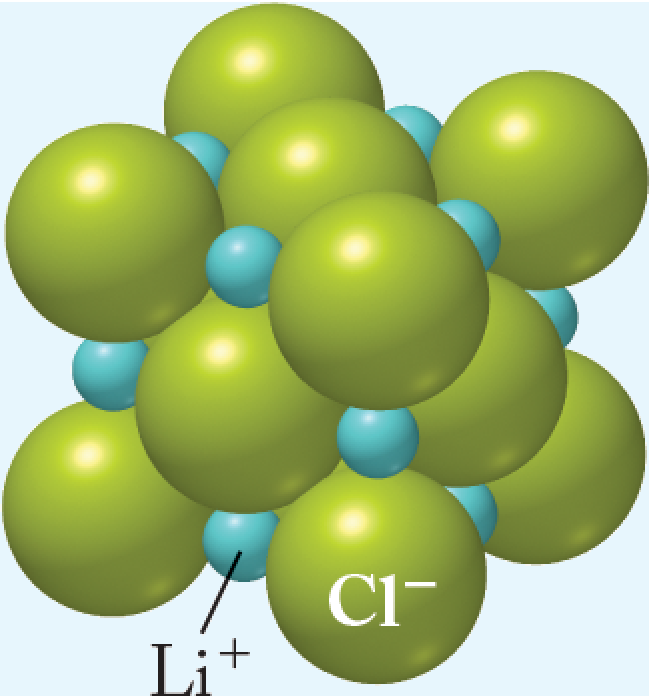

FIGURE 12.23

The face-centered cubic unit cell of LiCl.

12.4 Ionic Solids and Salt Crystals

Most of Earth's crust is composed of ionic solids, which consist of monatomic or polyatomic ions held together by ionic bonds. Most of these solids are crystalline. The simplest crystal structures are those of binary salts, such as NaCl (**Figure 12.19**). The cubic shape of large NaCl crystals results from the cubic shape of the NaCl unit cell. We can describe the unit cell of NaCl (Figure 12.19b, c) as a face-centered cubic arrangement of Cl^- ions at the corners and in the center of each face, with the smaller Na^+ ions occupying the 12 octahedral holes along the edges of the unit cell and the single octahedral hole in the middle of the cell. The ordered arrangement in Figure 12.19 maximizes the coulombic forces of attraction between oppositely charged particles and minimizes the repulsions between similarly charged ions. As a result, the potential energy of the crystal structure is minimized.

In Section 12.3 we used atomic radius ratios to determine the location of atoms in a crystal lattice. The same ratios that applied to interstitial alloys guide us in understanding the structures of binary ionic compounds. Rather than examine the ratio of nonhost radii to host radii, however, we consider the ratio of the smaller ion to the larger ion. In the unit cell of NaCl (Figure 12.19b), for example, the smaller Na^+ cations occupy the interstices in the cubic closest-packed lattice of Cl^- anions. The Na^+ ions fit better into the octahedral holes because the radius ratio of Na^+ to Cl^- is

---

The radius ratio 0.564 is too large for Na^+ to occupy a tetrahedral hole but well within the range for occupying an octahedral hole.

CONNECTION Periodic trends in atomic radii are discussed in Section 7.10, and the sizes of common cations and anions are compared to their neutral parent atoms in Figure 11.1.

Let’s take an inventory of the ions in a unit cell of NaCl. Like the metal atoms in the fcc unit cell in Figure 12.9b, an isolated unit cell contains portions of 14 Cl^- ions: one at each corner and one in each of the six faces of the cube. Therefore, accounting for partial ions gives us a total of four Cl^- ions in the unit cell in Figure 12.19c. To count the Na^+ ions, note that one Na^+ ion occupies the central octahedral hole, and one Na^+ ion fits into each of the 12 octahedral holes along the edges of the cell. Because each Na^+ ion along an edge is shared by four unit cells, only one-fourth of each Na^+ ion on an edge is in each cell (see Figure 12.10d). Only the Na^+ in the center belongs completely to the unit cell. As a result, the total number of Na^+ ions in the unit cell is

The ratio of Na^+ to Cl^- ions in the unit cell is 4:4, consistent with the chemical formula NaCl. Because the four Na^+ ions occupy all the octahedral holes in the unit cell, the result of this calculation also means that each fcc unit cell contains the equivalent of four octahedral holes.

CONNECTION Electrostatic attractions, ion–ion forces, and potential energy in ionic compounds are discussed in Section 8.1.

Note in Figure 12.19 that adjacent Cl^- ions along any face diagonal do *not* touch each other the way they do in Figure 12.9b because the Cl^- ions have to spread out a little to accommodate the Na^+ ions in the octahedral holes. Sodium ions and chloride ions touch along each edge of the unit cell, however, which means that each Na^+ ion touches six Cl^- ions and each Cl^- ion touches six Na^+ ions. This arrangement of positive and negative ions is common enough among binary ionic compounds to be assigned its own name: the *rock salt structure*.

SAMPLE EXERCISE 12.3 Determining the Formula of a Compound from Its Unit Cell LO3

Cesium chloride has the solid state structure shown in **Figure 12.20**, which is called the *cesium chloride* structure. The cation and anion have ionic radii of 170 and 181 pm, respectively. (a) Show that the structure in Figure 12.20 is consistent with the empirical formula of cesium chloride and (b) determine which type of hole the cation is found in.

Collect and Organize We are asked to determine the empirical formula of cesium chloride from its crystal structure using the information in Table 12.3. We are given the ionic radii of both ions and asked to assign the cation to one of the three types of holes identified in Table 12.5.

Analyze The empiricial formula of cesium chloride is CsCl. According to Figure 12.20, CsCl has a simple cubic unit cell that contains eight corner ions (chloride) arranged with the cesium ion in the center. The unit cell for CsCl resembles a bcc unit cell (e.g., tantalum in Figure 12.8) except that Cs^+ is found in the center of the unit cell rather than Cl^-. To determine the empirical formula of cesium chloride, we use Table 12.3 to calculate the contribution each ion makes to the unit cell. The radius ratios applied in Section 12.3 to metal alloys can be used here to identify the type of hole in the simple cubic lattice of chloride ions suitable for the cation.

Solve

1. Table 12.3 indicates that particles (atoms or ions) on the corners of a cubic unit cell each contribute $\frac{1}{8}$ to the unit cell. The cesium ion lies in the middle of the unit cell and only touches eight corner atoms. Therefore, the unit cell consists of $\frac{1}{8}$(8 corner ions) = 1 Cl^- ion and 1 Cs^+ ion, which gives the empirical formula CsCl.
2. The cation:anion ratio for CsCl is

$$\frac{r_{\text{cation}}}{r_{\text{anion}}} = \frac{170\ \cancel{\text{pm}}}{181\ \cancel{\text{pm}}} = 0.939$$

Table 12.5 indicates that Cs^+ occupies a cubic hole in a simple cubic lattice of chloride ions.

Think About It From Section 2.6 we know that the empirical formula of cesium chloride is CsCl, so the formula of any unit cell for this salt must contain a 1:1 ratio of equivalent cations and anion. Cesium chloride contains the same ratio of cations to anions as sodium chloride (NaCl), but it adopts a different crystal structure because Cs^+ ions are 67% bigger than Na^+ ions and no longer fit into the octahedral holes in an fcc lattice of Cl^- ions. Only the cubic hole is big enough to accommodate the larger cation. The cesium chloride structure is not the same as a body-centered cubic unit cell because it does not contain identical particles.

Practice Exercise Thallium and bromine form two binary compounds, $TlBr_3$ and TlBr. Which compound crystallizes with the CsCl structure? Why doesn't this compound crystallize in the rock salt structure? The ionic radii of Tl^+ and Tl^{3+} are 159 and 89 pm, respectively.

In other binary ionic solids, the smaller ion is small enough to fit into the tetrahedral holes formed by the larger ions. In the unit cell of the mineral sphalerite (zinc sulfide), for example, the S^{2-} anions (ionic radius 184 pm) are arranged in an fcc lattice (**Figure 12.21**), and half of the eight tetrahedral holes inside the cell are occupied by Zn^{2+} cations (74 pm). Therefore, the unit cell contains four Zn^{2+} ions that balance the charges on the four S^{2-} ions. This pattern of half-filled tetrahedral holes in an fcc unit cell is sometimes called the *sphalerite structure.* Compounds containing zinc, cadmium, or mercury cations with a 2+ charge and heavier anions of the group 16 elements with a 2− charge (i.e., S^{2-}, Se^{2-}, and Te^{2-}) also have a sphalerite structure.

The crystal structure of the mineral fluorite (CaF_2), shown in **Figure 12.22**, is based on an fcc unit cell of smaller Ca^{2+} ions at the eight cube corners and six face centers, with all eight tetrahedral holes formed by neighboring Ca^{2+} ions filled by larger F^-ions. Because the unit cell has a total of four Ca^{2+} ions and the eight F^-ions are all completely inside the cell, this arrangement satisfies the 1:2 mole ratio of Ca^{2+} ions to F^-ions. This structure is so common that it too has its own name: the *fluorite structure*. Other compounds having this structure are SrF_2, $BaCl_2$, and PbF_2.

Some compounds in which the cation-to-anion mole ratio is 2:1 have an *antifluorite structure.* In the crystal lattices of these compounds, which include Li_2O and K_2S, the smaller cations occupy the tetrahedral holes in an fcc unit cell formed by cubic closest packing of the larger anions.

SAMPLE EXERCISE 12.4 Calculating an Ionic Radius and Density from a Unit Cell Dimension LO3

The unit cell of lithium chloride (LiCl) contains an fcc arrangement of Cl^- ions (**Figure 12.23**). In LiCl, the Li^+ cations (radius 76 pm) are small enough to allow adjacent Cl^- ions to touch along any face diagonal.

---

1. If the edge length (ℓ) of the LiCl fcc cell is 513 pm, what is the radius of the Cl^- ion?
2. Use that value to predict the type of hole the Li^+ ion occupies.
3. What is the density of LiCl at 25°C?

Collect and Organize We are given the edge length (513 pm), the radius of the Li^+ cation (76 pm), and the type of unit cell for LiCl (fcc). We are asked to calculate the ionic radius of the Cl^- ion, predict in which type of hole the Li^+ is found, and calculate the density of LiCl.

Analyze (a) The unit cell is an fcc array of Cl^- ions that touch along the face diagonal. Equation 12.2 relates the edge length (ℓ) of an fcc cell to the radius (r) of the atoms or ions that touch along its diagonals: $r = 0.3536\ell$. (b) Once we know the radius of the Cl^- ion, the radius ratio of Li^+ to Cl^- ions and Table 12.5 allow us to predict which type of hole Li^+ occupies. (c) LiCl has an fcc unit cell, which means that there are four Cl^- ions and four Li^+ ions in the cell. The molar masses of these ions are 35.45 and 6.941 g/mol, respectively. As in Sample Exercise 12.1, we need to convert from molar masses to the masses of individual particles by dividing by Avogadro's number. Density is the ratio of mass to volume, and the volume of a cubic cell is the cube of its edge length: $V = \ell^3$.

Solve

1. Substituting the edge length into Equation 12.2, we calculate the radius of Cl^-:

   $$r = 0.3536 \times 513\ \text{pm} = 181\ \text{pm}$$

2. The ratio of the radius of a Li^+ ion to the radius of a Cl^- ion is

   76 pm/181 pm = 0.42

   According to Table 12.5, the Li^+ cations occupy octahedral holes in the lattice formed by the larger Cl^- anions.

3. Calculating the mass of four Cl^- ions:

$$m = \frac{35.45\text{ g Cl}^-}{1\ \cancel{\text{mol Cl}^-}} \times \frac{1\ \cancel{\text{mol Cl}^-}}{6.022 \times 10^{23}\ \cancel{\text{ions Cl}^-}} \times 4\ \cancel{\text{ions Cl}^-}$$
$$= 2.355 \times 10^{-22}\text{ g Cl}^-$$

The mass of four Li^+ ions is

$$m = \frac{6.941\text{ g Li}^+}{1\ \cancel{\text{mol Li}^+}} \times \frac{1\ \cancel{\text{mol Li}^+}}{6.022 \times 10^{23}\ \cancel{\text{ions Li}^+}} \times 4\ \cancel{\text{ions Li}^+}$$
$$= 0.4610 \times 10^{-22}\text{ g Li}^+$$

Combining the masses of the two kinds of ions in the unit cell:

$$2.355 \times 10^{-22}\text{ g} + 0.4610 \times 10^{-22}\text{ g} = 2.816 \times 10^{-22}\text{ g}$$

The volume of the cell in cubic centimeters is

$$V = \ell^3 = (513\ \cancel{\text{pm}})^3 \times \frac{(10^{-10}\text{ cm})^3}{(1\ \cancel{\text{pm}})^3} = 1.35 \times 10^{-22}\text{ cm}^3$$

Taking the ratio of mass to volume, we have

$$d = \frac{m}{V} = \frac{2.816 \times 10^{-22}\text{ g}}{1.35 \times 10^{-22}\text{ cm}^3} = 2.09\text{ g/cm}^3$$

Think About It The average ionic radius value in Figure 11.1 for Cl^- ions is 181 pm, so our calculation is correct. Figure 12.23 shows the structure of LiCl to be similar to the rock salt structure of NaCl in Figure 12.19b. The calculated density for LiCl is consistent with the measured density, $d = 2.068\ \text{g/cm}^3$, and the observation that most minerals are more dense than water but less dense than common metals.

Practice Exercise Assuming the Cl^- radius in NaCl is also 181 pm, what is the radius of the Na^+ ion in NaCl if the edge length of the NaCl unit cell is 564 pm but the anions do *not* touch along any face diagonal? What is the density of NaCl?

(a) Diamond
(b) Graphite
(c) Graphene

FIGURE 12.24 Two of carbon's three allotropes. (a) Diamond is a three-dimensional covalent network solid made of carbon atoms, each connected by σ bonds to four adjacent carbon atoms. (b) Graphite is a collection of layers of carbon atoms connected by σ bonds and delocalized π bonds. (c) Graphene is a single layer of C atoms arranged as the atoms are in a layer of graphite.

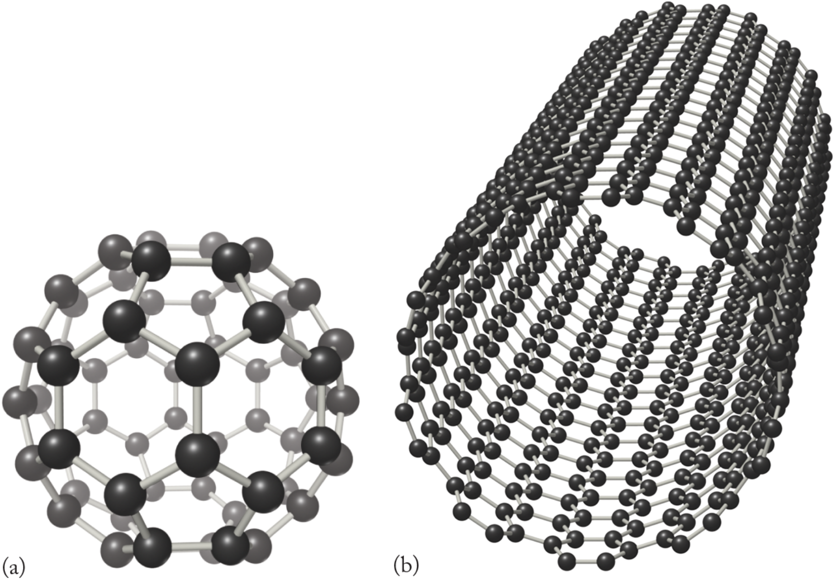

FIGURE 12.25 Some solids are described as clusters, a category between covalent network solids and molecular solids. Fullerenes,

the third allotrope of carbon, are clusters. (a) One of them, buckminsterfullerene (C_{60}), is made up of 60 sp^2-hybridized carbon atoms. Both five- and six-membered rings are required to construct the nearly spherical molecule. (b) Nanotubes have diameters approximately equal to the diameter of a buckyball.

12.5 Allotropes of Carbon

According to the periodic table in Figure 12.6, the unit cells of silicon, germanium, and tin are “diamond.” Carbon is a nonmetal, but the specific arrangement of carbon atoms in diamond (**Figure 12.24a**) is also found in some metallic materials. In addition, some diamonds may include metal impurities in the crystal lattice that give rise to distinctive colors.

CONNECTION Allotropes are structurally different forms of the same physical state of an element (Section 8.4).

Diamond is one of three allotropes of carbon, the other two being graphite (**Figure 12.24b**) and fullerenes (**Figure 12.25**). Diamond is classified as a crystalline covalent network solid because it consists of an extended three-dimensional network of atoms joined by covalent bonds. Each carbon atom in diamond bonds by overlapping one of its sp^3 hybrid orbitals with an sp^3 hybrid orbital in each of four neighboring carbon atoms, creating a network of carbon tetrahedra. The atoms in these tetrahedra are connected by localized σ bonds, making diamond a poor electrical conductor. The σ-bond network is extremely rigid, making diamond the hardest natural material known. The atoms of other group 14 elements, particularly silicon, germanium, and tin, also form covalent network solids based on the diamond crystal lattice.

CONNECTION Hybridization and σ bonds are described in Section 9.4.

Natural diamond forms from graphite under intense heat (> 1700 K) and pressure ($> 50{,}000$ atm) deep in Earth. Industrial diamonds are synthesized at high temperatures and pressures from graphite or any other source rich in carbon. Synthetic diamonds are used as abrasives and for coating the tips and edges of cutting tools. Diamond has the highest thermal conductivity of any natural substance (five times higher than copper and silver, the most thermally conductive metals), so tools made from diamond do not become overheated. Thin diamond films grown from methane (CH_4) and hydrogen have been used to reduce wear and extend the lifetime of prosthetic implants.

CONNECTION We introduced dispersion forces between molecules in Section 10.2. We discussed semiconductors in Section 9.6.

Graphite is by far the most abundant allotrope of carbon. It is a covalent network solid, too, which is frequently the principal ingredient in soot and smoke and is used to make pencils, lubricants, and gunpowder. Graphite contains sheets of carbon atoms in which each atom is connected by sp^2 orbitals to a like orbital in each of three neighboring carbon atoms, forming a two-dimensional covalent network of six-membered rings (Figure 12.24b). Each carbon–carbon bond is 142 pm, which is shorter than the C—C σ bond in diamond (154 pm). Overlapping unhybridized *p* orbitals on the carbon atoms form a network of π bonds that are delocalized across the plane defined by the rings. The mobility of these delocalized electrons makes graphite a conductor of electricity.

As shown in Figure 12.24b, the two-dimensional sheets in graphite are 335 pm apart. This distance is much too long to be a covalent bonding distance. Instead, the sheets are held together by dispersion forces only. These relatively weak interactions allow adjacent sheets to slide past each other, making graphite soft, flexible, and a good lubricant. In 2004, researchers in the United Kingdom and Russia found that they could isolate just a single layer of carbon atoms from graphite with a piece of adhesive tape. This material, called graphene (**Figure 12.24c**), behaves as a semiconductor.

CONCEPT TEST

The diamond form of carbon is a semiconductor with a much larger band gap than that of silicon. With what elements might you choose to dope diamonds to form an n-type semiconductor?

The third allotrope of carbon was discovered in the 1980s. Networks of five- and six-atom carbon rings form molecules of 60, 70, or more carbon atoms that look like miniature soccer balls (Figure 12.25a). They are called *fullerenes* because their shape resembles the geodesic domes designed by the American architect R. Buckminster Fuller (1895–1983). Many chemists call them *buckyballs* for the same reason. In terms of both size and properties, buckyballs are too small to be classified as covalent network solids but too large to be molecular solids (discussed below). They fall in an ambiguous zone between small molecules and large networks and are classified as *clusters*. The 70–100 pm diameter of fullerenes means that they can fit into the three-dimensional structure of enzymes like HIV protease, inhibiting its activity. The surface of fullerenes can also be chemically modified to transport drug molecules into cells. Some fullerenes stretch the meaning of the word cluster. These include structures known as nanotubes, so named because they are 1–2 nm in diameter (Figure 12.25b). Nanotubes have been fabricated that are 20 cm long. Like graphene, carbon nanotubes exhibit semiconductor properties, but they are also extremely strong and have been used to strengthen fibers in sports gear.

FIGURE 12.26 Items made of synthetic polymers are ubiquitous in modern society. They are also ubiquitous in our trash as shown in this photo of the Great Pacific Garbage Patch of waste plastic of all kinds that circulates with the currents in the Pacific Ocean.

12.6 Polymers

As part of our discussion of covalent bonding in Chapters 8 and 9, we studied small organic compounds containing carbon, hydrogen, nitrogen, and oxygen. These compounds had molar masses less than 1000 g/mol. Much larger organic compounds, with molar masses up to and exceeding 1,000,000 g/mol, represent a category of materials called polymers. The use of polymers in consumer products is underscored by the Great Pacific Garbage Patch (**Figure 12.26**), a vast field of largely nonbiodegradable debris that circulates in response to ocean currents. In between small molecules and polymers (also called macromolecules) are midsize molecules called *oligomers*. The root word *meros* is Greek for “part” or “unit,” so *polymer* literally means “many units” and *oligomer* means “a few units.” An example of a polymer from Chapter 4 is poly(vinyl chloride), used to make drain pipes and other building materials.

CONNECTION We introduced many organic molecules in Chapters 4 through 11. These included acetic acid; methane, ethane, and other hydrocarbon fuels; acetylene used in welding; and ethanol and other alcohols.

Polymers are composed of small structural units called monomers. Polymers may be formed from more than one type of monomer unit, they may have more than one functional group, and they may have shapes other than long chains. However, the single feature that distinguishes them as a class is their large size. In Section 12.6 we explore the preparation and properties of polymers, focusing on materials with biomedical applications.

Polymers of Alkenes

Some widely used polymeric alkanes are produced industrially from small alkenes. The alkene polymer with the simplest structure is linear polyethylene (PE), produced from ethylene at high temperature and pressure:

Polyethylene is a homopolymer, which means it is composed of only one type of monomer. Its condensed structure is $CH_3(CH_2)_nCH_3$, but there are so many more methylene groups than methyl groups that the structure is frequently written as $[\text{—}CH_2CH_2]\text{—}_n$ to highlight the structure and composition of the monomer. Polyethylene is also an example of an addition polymer because it is synthesized by adding many molecules together to form the polymer chain without the loss of any atoms or molecules. Correspondingly, the individual reactions that create an addition polymer are called addition reactions, in which two reactants combine to form one product.

CONNECTION The molecular structure and bonding in ethylene ($CH_2=CH_2$) is described in Section 9.5.

In most products made of polyethylene, *n* is a very large number, ranging from 1000 to almost 1 million. Polyethylene has a wide range of properties that depend on the value of *n* and on whether the polymer chains are straight or branched. In low-density polyethylene (LDPE)—a stretchable, soft plastic used in films and wrappers—*n* ranges from 350 to 3500 and the chains are branched (**Figure 12.27**). When the bagger at the grocery store asks, “Paper or plastic?” the plastic in question is LDPE.

When the molar mass of a PE polymer is between 100,000 and 500,000 and the chains are straight, the polymer has physical properties that differ from those of LDPE grocery bags. This straight-chain polymer—a rigid, translucent solid called high-density polyethylene (HDPE)—is used in milk containers, electrical insulation, and toys.

Why are the properties of straight-chain HDPE (rigid, tough) so different from those of branched-chain LDPE (stretchable, soft)? Think of the branched polymer (Figure 12.27) as a tree branch with lots of smaller branches attached to it. The polymer has three dimensions, so it can have branches that come out of the plane of the paper. In contrast, the straight-chain polymer is like a long, straight pole. Suppose you had a pile of 100 tree branches and a pile of 100 poles, and your task was to stack each pile into the smallest possible volume to fit into a truck. You can certainly pile the branches on top of one another, but they will not fit together neatly, and probably the best you can do is to make the pile a bit more compact. In contrast, you can stack the poles into a very compact pile.

CONNECTION The carbon-skeleton structures used to illustrate large molecules like those in Figure 12.27 were described in Section 9.5.

The same situation arises with the branched and linear molecules of polyethylene. Branched-chain LDPE has a low density because the molecules do not line up neatly and so they stack less efficiently than do the molecules of HDPE. This makes LDPE more deformable and softer, whereas HDPE is more rigid and even has some regions that are crystalline because the packing is so uniform. Ultrahigh molecular weight polyethylene (UHMWPE; $n > 100{,}000$) is an even tougher material, because not only are the molecules straight, but they are also significantly *larger* than the molecules in HDPE. UHMWPE is used as a coating on some artificial ball-and-socket joints (**Figure 12.28**) because it is extremely resistant to abrasion and makes the joints last longer. The different forms of polyethylene illustrate how the size and shape of its molecules affect the physical properties of a material. The ethylene used to make polyethylene has traditionally come from petroleum but the availability of ethanol derived from biomass allows for a renewable source of this valuable monomer.

CONCEPT TEST

During recycling, articles made from LDPE are separated from those made from HDPE (**Figure 12.29**). Why?

Chemical composition also plays a role in determining physical properties. If the hydrogen atoms in PE are all replaced with fluorine atoms, the resultant polymer is chemically very unreactive, can withstand high temperatures, and has a very low coefficient of friction, which means other things do not stick to it. This polymer is Teflon, $[\text{—}CF_2CF_2]\text{—}_n$ (**Figure 12.30**), most familiar for its use as a nonstick surface in cookware. However, Teflon tubing is also used in the grafts inserted into small-diameter blood vessels during vascular surgery on limbs.

SAMPLE EXERCISE 12.5 Identifying Monomers LO4

Polypropylene, $[\text{—}CH_2CH(CH_3)]\text{—}_n$, is an addition polymer used in the manufacture of fabrics, ropes, and other materials (**Figure 12.31**). Draw the condensed molecular structure of the monomer used to prepare polypropylene.

Collect and Organize We are given a condensed structure of a polymer and asked to identify the monomer used in its preparation. We know that polypropylene is an addition polymer, so the monomer must be an alkene.

Analyze To understand the relationship between the polymer and the monomer from which it is made, let's look at Equation 12.5, which is Equation 12.4 in the reverse direction:

Breaking the blue bonds in Equation 12.5 and making the red carbon–carbon single bond a double bond illustrates the relationship between polyethylene and ethylene, the alkene monomer. We need to apply a similar analysis to polypropylene.

Solve The relationship between polypropylene and its monomer is illustrated by Equation 12.6:

Breaking the two blue bonds and making the red C—C bond a C□C double bond yields the alkene shown in **Figure 12.32**. This three-carbon alkene has the name propene.

Think About It The structural difference between polypropylene and polyethylene is the presence of a $–CH_3$ group bonded to one of the two sp^3 C atoms in polypropylene instead of an H atom in polyethylene. The $–CH_3$ group appears in a similar location in the propene monomer rather than in the polymer backbone making our answer reasonable.

Practice Exercise Draw the condensed molecular structure of the monomer used to make poly(methyl methacrylate) (PMMA), a polymer used in shatterproof transparent plastic that can be used in place of glass:

Polymers Containing Aromatic Rings

Benzene rings are flat molecules (see Figure 9.35 in Section 9.5). Replacing one hydrogen atom in benzene with a vinyl group, the $CH_2{=}CH$– subunit, produces styrene. Polymerizing styrene produces polystyrene (PS) (**Figure 12.33**). Polystyrene molecules tend to stack neatly (**Figure 12.34**), which gives rise to useful properties in materials that incorporate benzene rings and other aromatic compounds.

Solid PS is a transparent, colorless, hard, inflexible plastic. In this form it is used for the handles of some disposable razors and plastic cutlery. A more common form of PS, however, is the *expanded solid* made by blowing carbon dioxide gas or pentane gas into molten polystyrene, which then expands and retains voids in its structure when it solidifies. One form of this expanded PS is the familiar material of coffee cups and takeout food containers (**Figure 12.35**).

CONNECTION The molecular structure and bonding in benzene (C_6H_6) was introduced in Section 8.4. We explored its shape and defined it as an aromatic compound in Section 9.5.

The difference in properties between transparent, colorless, inflexible nonexpanded PS and the opaque, white, pliable material can be explained by considering the role of the aromatic ring in aligning the polymer chains. Branches in the chains have the same effect that we saw in polyethylene, but the aromatic rings and their tendency to stack (Figure 12.34) provide additional interactions that make chain alignment more favorable energetically. The aromatic rings along two neighboring chains can stack, and this stacking makes nonexpanded PS rigid. When the chains are blown apart by a gas, the stacking is disrupted and the chains open to form cavities that fill with air, making expanded PS a good thermal insulator and packing material (Figure 12.35).

Polymers of Alcohols and Ethers

More than 400,000 tons of the addition polymer poly(vinyl alcohol) (PVAL) are produced annually in the United States. It is used in fibers, adhesives, and materials known as sizing, which changes the surface properties of textiles and paper to make them smooth, less porous, and less able to absorb liquids. Because the polymer chains in PVAL are studded with –OH groups (**Figure 12.36a**), the surface of the polymer chains in PVAL is very polar and very water-like, and hydrocarbon solvents that are not soluble in water do not penetrate PVAL barriers. PVAL is the material of choice for laboratory gloves that are resistant to organic solvents.

PVAL is also impenetrable to carbon dioxide, and this property has led to its use in soda bottles, in which it is blended with the polymer poly(ethylene terephthalate) (PETE; **Figure 12.36b**). The two polymers do not mix but rather separate into layers (**Figure 12.36c**). The PETE makes the bottle strong enough to bear pressure changes that result from temperature changes and survive the impact of falling off tables. Also, CO_2, the dissolved gas that makes soda fizz, passes readily through PETE but not through the PVAL layers, with the result that the soda does not go flat. Polymers with different properties are frequently combined in this way to create new materials with desired properties.

The blend of PVAL and PETE in early soda bottles was a physical mixture of the two polymers. New materials can also be made by reacting different monomer units in one polymer molecule. This type of molecule is called a copolymer when two different monomers are reacted and a heteropolymer when three or more different monomers are reacted. One example of an addition copolymer is a material called EVAL, made from ethylene and vinyl acetate (**Figure 12.37**). EVAL is used in food wrappings when the preservation of aroma and flavor is required. Food usually deteriorates in the presence of oxygen, and packages made of EVAL provide an excellent barrier to the entry of oxygen while retaining the flavor and fragrance of the packaged food.

Commercially important polymers made from ethers include poly(ethylene glycol) (PEG) and poly(ethylene oxide) (PEO), which contain the same subunit (**Figure 12.38**). PEG is a low-molar-mass liquid made from ethylene glycol, whereas PEO is a higher-molar-mass solid made from ethylene oxide. As a polyether, PEG has properties closely related to those of diethyl ether, in that it is soluble in both polar and nonpolar liquids. It is a common component in toothpaste because it interacts both with water and with the water-insoluble materials in the paste, so it keeps the toothpaste uniform both in the tube and during use. PEGs of many lengths are finding increasing use as attachments to pharmaceutical agents to improve their solubility and biodistribution: the enhanced circulation in the blood results from increased solubility. Like ethylene, the feedstock for PEG can now be prepared from ethanol obtained from plant-based sources relieving the demands on limited supplies of petroleum.

CONNECTION Alcohols are organic molecules with the general formula R—OH (Section 2.8). Some properties of alcohols are further investigated in Chapter 10.

SAMPLE EXERCISE 12.6 Analyzing Properties of Polymers LO5

PEG (Figure 12.38) is used to blend materials that are typically insoluble in one another. PEG is soluble in both water (a polar solvent) and benzene (a nonpolar solvent). Describe the structural features of PEG that make it soluble in these two liquids of very different polarities.

Collect, Organize, and Analyze The relationship between structure and the solubility of compounds, first discussed in Chapter 10, can be expressed as “like dissolves like.” That is, polar substances will dissolve in polar solvents, because they both experience dipole–dipole interactions, and nonpolar substances will dissolve in nonpolar solvents as a result of dispersion forces. We need to describe the intermolecular forces in PEG and see whether one part is compatible with water and another part with benzene. Water is a polar molecule and benzene is a nonpolar molecule, so we predict that PEG must contain both polar and nonpolar regions in order to be soluble in both substances.

Solve The structure of PEG consists of $–CH_2CH_2–$ groups connected by oxygen atoms. The oxygen atoms can form hydrogen bonds with water molecules, so the hydrogen bonds provide the attractive force between PEG and water. Benzene is nonpolar and is attracted to the $–CH_2CH_2–$ groups in the polymer. Nonpolar groups interact via dispersion forces, so dispersion forces must be responsible for the solubility of PEG in nonpolar benzene.

Think About It As predicted, PEG contains both polar and nonpolar regions, allowing it to be solvated by both polar solvents such as water and nonpolar solvents such as benzene.

Practice Exercise When PEG is added to soft drinks it keeps CO_2, responsible for the fizz in soda, in solution longer when the soda is poured. What intermolecular attractive forces between PEG and CO_2 might make this application possible?

CONCEPT TEST

A polymer chemist decides to make a series of derivatives of PEG by using the following alcohols in place of ethylene glycol:

What effect will this have on the solubility of the resulting polymer in water?

Polyesters and Polyamides

Prior to this point, the polymers we have examined have been prepared from *monofunctional* monomers, in which the monomers have only one functional group. A wide range of polymers are derived from *difunctional* molecules, which contain two functional groups. Several classes of polymers are derived from difunctional carboxylic acids, but we consider only two of them here: polyesters and polyamides.

An ester is prepared by the *esterification* of a carboxylic acid with an alcohol. In esters, the –OH group of the acid is replaced by –OR, where R can be any organic group (**Figure 12.39**). Esterification is not an addition reaction but rather a condensation reaction—that is, two molecules react to create a larger molecule while a small molecule (typically water, hence “condensation reaction”) is also formed. In Figure 12.39, the –COOH group of butyric acid reacts with the –OH group of ethanol to form a carbon–oxygen single bond in the resulting ester (ethyl butyrate) and releases a molecule of water.

What do you think happens at the molecular level when we have a single compound that contains a carboxylic acid functional group at one end and an alcohol functional group at the other (**Figure 12.40**)? The carboxylic acid group of one molecule can react with the alcohol group of another molecule in a condensation reaction to generate a molecule that has a carboxylic acid group at one end, an alcohol at the other end, and an ester linkage between them. If this reaction takes place repeatedly, a monomer containing one carboxylic acid and one hydroxyl group (a hydroxy acid) polymerizes, as shown in Figure 12.40, to form a *polyester*, a condensation polymer. We have already encountered one condensation polymer, PETE. In general, condensation polymers are formed by the reaction of monomers yielding a polymer and water as a by-product of the reaction. In addition to its use in plastic soda bottles, PETE is used extensively in medicine. Artificial heart valves and grafts for arteries are also made from PETE.

CONNECTION The carboxylic acid functional group (–COOH) was first described in Section 4.5.

A copolymer formed by the reaction of glycolic acid and lactic acid (**Figure 12.41**) is used to support the growth of skin cells for burn victims. The polymer in Figure 12.41 is also used to make dissolving sutures. Esterification reactions used to make polyesters can be reversed by the addition of water, breaking their ester linkages and forming alcohol and acid functional groups.

SAMPLE EXERCISE 12.7 Making a Polyester LO4

Show how a polyester can be synthesized from the difunctional alcohol $HO(CH_2)_3OH$ and the difunctional carboxylic acid $HOOC(CH_2)_3COOH$.

Collect, Organize, and Analyze An ester is the product of a reaction between a carboxylic acid and an alcohol. A polyester is a polymer with a repeating unit containing an ester functional group. We are given an alcohol and a carboxylic acid to react to make the ester repeating monomer unit. Because the starting materials are difunctional, the alcohol can react with two molecules of carboxylic acid, and the acid can react with two molecules of alcohol.

Solve The reaction is

The two –OH groups shown in blue react to form an ester at one end of the carboxylic acid. The product molecule has an alcohol group on one end (shown in red) that can react with another molecule of carboxylic acid and has a carboxylic acid group (green) on the other end that can react with another molecule of alcohol. Continuing these condensation reactions results in the formation of a polymer whose repeating unit is

Think About It The repeating unit in the polyester is reasonable because it contains one section that came from the alcohol and a second section that came from the carboxylic acid, and esters are formed from alcohols and acids.

Practice Exercise A difunctional molecule may contain two different functional groups, such as this one with an alcohol group and a carboxylic acid group:

Draw the repeating unit of the polyester made from this molecule.

SAMPLE EXERCISE 12.8 Comparing Properties of Polymers LO5

Clothes made from the polyester fabric known as Dacron can be less comfortable in hot weather than clothes made of cotton (also a polymer) because Dacron does not absorb perspiration as effectively as cotton. On the basis of the repeating units of these two polymers (**Figure 12.42**), suggest a structural reason why cotton absorbs perspiration (water) better than Dacron.

Collect, Organize, and Analyze Cotton and Dacron are polymers that differ in the functional groups in their repeating units. The absorption of water by a polymer depends on the intermolecular forces present. Water is a polar molecule and is attracted to polar groups. We need to compare the different functional groups in each monomer to see which has the greatest number of polar functional groups or atoms that can form hydrogen bonds. This will be the polymer more likely to absorb water.

Solve Each monomer unit in cotton has three –OH groups attached to it, all polar and capable of hydrogen bond formation, which means they are likely to interact with the water in perspiration and thereby draw it away from the body. The monomer unit in Dacron has oxygen atoms in it, but no –OH groups. Although regions in the Dacron monomer are polar, they are not nearly as polar as the –OH groups in the cotton monomer unit.

Think About It The principle of like interacting with like which works for small molecules in Chapter 11 also applies to polymers. The more polar groups on the polymer (cotton), the greater the interaction with polar molecules like water.

Practice Exercise Gloves made of a woven blend of cotton and polyester fibers protect the hands from exposure to oil and grease and are comfortable to wear because they “breathe”—they allow perspiration to evaporate and pass through them, thereby cooling the skin. Suggest how these gloves work at the molecular level.

Combining difunctional molecules in a condensation reaction can be used to make *polyamides*, another class of very useful synthetic polymers. The functional groups are a carboxylic acid and an amine. The difunctional monomer units can be identical (**Figure 12.43a**), each containing one carboxylic acid group and one amine group, or they can be different (**Figure 12.43b**), with one monomer containing two carboxylic acid groups (a dicarboxylic acid) and the other containing two amine groups (a diamine). Some of these monomers, such as adipic acid, are now available from renewable bio-based sources.

In amides, the –OH group of a carboxylic acid is replaced by an amine group, which can be $-NH_2$, –NHR, or $-NR_2$ (**Figure 12.44**). Amides are polar and can form intermolecular hydrogen bonds. The hydrogen atoms on the $-NH_2$ group can form hydrogen bonds with the oxygen atom in the carbonyl group of an adjacent molecule. This causes the boiling points of amides to be considerably higher than those of esters of comparable size. Although amines are bases, amides are actually weakly acidic. The carbonyl group pulls electron density away from the nitrogen, making it less favorable for the nitrogen to behave like a Brønsted–Lowry base and pick up a proton. It is actually more favorable for an amide to donate a proton and function as an acid.

Nylon-6,6 is a polyamide made from the monomers shown in Figure 12.43b. Each monomer contains six carbon atoms, which is what the numbers in the name represent.

SAMPLE EXERCISE 12.9 Identifying Monomers LO4

Another form of nylon is nylon-6, with the single 6 indicating that the polymer is made from the reaction of a series of identical six-carbon monomers. By analogy with the polyester in Sample Exercise 12.7 and the accompanying practice exercise, draw the condensed structure of a compound that could polymerize to make nylon-6.

Collect, Organize, and Analyze We are asked to draw the condensed structure for a monomer that contains both functional groups that react to form an amide and that could react with identical monomers to form a polyamide with a repeating unit six carbon atoms long. By analogy to Sample Exercise 12.7 and its accompanying practice exercise, we should suggest a difunctional molecule that has a carboxylic acid on one end and an amine on the other because these are the two functional groups that react to form the amide linkage.

Solve We can build the required monomer by starting with one of the functional groups. It doesn't matter which one, so let's begin with the amine:

We then add a chain of five –CH_2– units because the name nylon-6 indicates that six carbon atoms separate the ends of the repeating unit. Finally, we add the carboxylic acid functional group as the second functional group and the sixth carbon atom in the chain.

Think About It Our monomer includes two different functional groups; an amine and a carboxylic acid, consistent with our strategy for solving this exercise. The five –CH_2– units together with the carbon in the CO_2H group results in nylon-6, a polymer with a six-carbon repeating unit.

Practice Exercise Draw the carbon-skeleton structures of two monomers that could react with each other to make nylon-5,4. Draw the carbon-skeleton structure of the repeating unit in the polymer. (*Note*: The first number refers to the carboxylic acid monomer; the second refers to the amine monomer.)

Polymers of nylon make long, straight fibers that are quite strong and excellent for weaving into fabrics. Nylon is flexible and stretchable because the hydrocarbon chains can bend and curl, much like a telephone cord or a Slinky spring toy. To produce an even stronger nylon, researchers recognized they had to find some way to reduce the ability of the chains to form coils. They discovered this could be done by using monomer units containing functional groups that made it difficult for the chains to bend. One product of this work was a polyamide called Kevlar, invented by Stephanie Kwolek (**Figure 12.45**) at DuPont in 1965. Kevlar is formed from a dicarboxylic acid of benzene and a diamine of benzene (**Figure 12.46**). When these two monomers polymerize, the flat, rigid aromatic rings keep the chains straight.

Two additional intermolecular interactions orient the chains and hold them together very tightly (**Figure 12.47**). First, the –NH hydrogen atoms form hydrogen bonds with the oxygen atoms of carbonyl groups on adjacent chains. Second, the rings stack on top of one another (just as in polystyrene) and provide additional interactions that hold the chains together in parallel arrays. The result is a fiber that is very strong but still flexible. Fabrics and helmets made of Kevlar resist puncture, even when bullets (**Figure 12.48**) and hockey pucks are fired at them. They are resistant to flames and reactive chemicals, too.

In this section we have discussed many polymers and mentioned their uses in common products. The classification of these polymeric materials as addition or condensation polymers is summarized in **Table 12.7**. Table 12.7 also identifies the polymers by their distinctive functional groups and mentions some common uses in our lives.

TABLE 12.7 Summary of Common Polymers and Their Uses

[illegible]	Abbreviation	Functional Group	[illegible]
Addition Polymers			
Polyethylene	PE	Alkene	Plastic bags and films
Poly(tetrafluoroethylene)	[illegible]	[illegible]	[illegible]
Poly(1,1-dichloroethylene)	Saran	[illegible]	[illegible]
Poly(vinyl chloride)	PVC	[illegible]	[illegible]
Poly(methyl methacrylate)	PMMA	[illegible]	[illegible] (e.g., Plexiglas, Lucite)
Polystyrene	PS	[illegible]	[illegible] dishes, insulation
Poly(vinyl alcohol)	PVA	Alcohol	[illegible] bottles
Condensation Polymers			
Poly(ethylene glycol)	PEG	[illegible]	[illegible] consumer products
Poly(ethylene oxide)	PEO	[illegible]	Same as for PEG
Poly(ethylene terephthalate)	PET	[illegible]	Plastic bottles
[illegible]		[illegible]	Clothing
Kevlar		Amide	Protective equipment
[illegible]		Ester	Clothing

SAMPLE EXERCISE 12.10 Integrating Concepts: Glowing Lantern Mantles

The mantles in camping lanterns contain the mineral thorite, an oxide of thorium. Thorite crystallizes with the fluorite structure and contains 87.88% thorium and 12.12% oxygen (**Figure 12.49**). The unit cell edge for thorite was measured as $\ell = 560$ nm.

1. Determine the empirical formula of thorite.
2. Calculate the density of thorite. Does the calculated density match the measured density of 9.86 g/cm^3?
3. The ionic radii of Th^{4+} and O^{2-} ions are 102 pm and 140 pm, respectively. If thorite were to crystallize with the rock salt structure, why would the Th^{4+} ions most likely occupy octahedral rather than tetrahedral holes?

4. Calculate the density of the rock salt polymorph of thorite by using the same unit cell edge length as in part (b). Compare the value with the observed and calculated values in part (b).

Collect and Organize We are given the percent composition and density of a thorium mineral. We are asked to determine the empirical formula of thorite and to calculate the density of thorite in two possible crystal structures—the fluorite (observed) and rock salt (hypothetical) structures. Methods for determining empirical formulas were described in Chapter 3. We will also make use of the information presented in Section 12.4.

Analyze Thorite contains only Th and O with the general formula Th_xO_y because the sum of the %Th and %O equals 100%, so we know the masses of each element in thorite. We can convert the masses to the equivalent number of moles and determine the simplest whole-number ratio of the moles of the elements. In the fluorite structure of thorite, the unit cell consists of a face-centered arrangement of Th ions with oxide ions in all of the tetrahedral holes. Following the procedure in Sample Exercise 12.4, we can calculate the density of thorite. If thorite were to crystallize in a ccp rock salt structure, the Th^{4+} ions are more likely to occupy a hole based on the cation:anion radius ratio.

Solve

1. A 100.00 g sample of thorite contains 87.88 g of Th and 12.12 g of O. Converting these masses to moles:

$$87.88\ \cancel{\text{g Th}} \times \frac{1\ \text{mol Th}}{232.04\ \cancel{\text{g Th}}} = 0.3787\ \text{mol Th}$$

$$12.12\ \cancel{\text{g O}} \times \frac{1\ \text{mol O}}{16.00\ \cancel{\text{g O}}} = 0.7575\ \text{mol O}$$

Dividing by the smallest number of moles gives us the empirical formula: ThO_2.

2. In the fluorite structure of ThO_2, the Th^{4+} ions adopt an fcc unit cell with O^{2-} ions in all the tetrahedral holes. The equivalent of four Th^{4+} and eight O^{2-} are in the unit cell.

The mass of the ions in the unit cell is

$$\begin{aligned} m &= \frac{232.04 \text{ g Th}^{4+}}{1 \cancel{\text{mol Th}^{4+}}} \times \frac{1 \cancel{\text{mol Th}^{4+}}}{6.022 \times 10^{23} \cancel{\text{ions Th}^{4+}}} \times 4 \cancel{\text{ions Th}^{4+}} \\ &= 1.541 \times 10^{-21} \text{ g Th}^{4+} \end{aligned}$$

$$\begin{aligned} m &= \frac{16.00 \text{ g O}^{2-}}{1 \cancel{\text{mol O}^{2-}}} \times \frac{1 \cancel{\text{mol O}^{2-}}}{6.022 \times 10^{23} \cancel{\text{ions O}^{2-}}} \times 8 \cancel{\text{ions O}^{2-}} \\ &= 0.2126 \times 10^{-21} \text{ g O}^{2-} \end{aligned}$$

Total mass of ions = 1.541×10^{-21} g Th^{4+} + 0.2126×10^{-21} g O^{2-} = 1.754×10^{-21} g

Using the unit cell edge length, ℓ = 560 nm, the volume of the unit cell is

$$V = \ell^3 = (560 \cancel{\text{pm}})^3 \times \frac{(10^{-10} \text{ cm})^3}{(1 \cancel{\text{pm}})^3} = 1.756 \times 10^{-22} \text{ cm}^3$$

and the calculated density of ThO_2 is

$$d = \frac{m}{V} = \frac{1.754 \times 10^{-21} \text{ g}}{1.756 \times 10^{-22} \text{ cm}^3} = 9.99 \text{ g/cm}^3$$

The calculated density differs from the observed density of 9.86 g/cm^3 by less than 2%.

3. In a hypothetical rock salt structure of ThO_2, the lattice would be composed of fcc O^{2-} ions with Th^{4+} in holes. The radius ratio of Th^{4+} to O^{2-} would be

$$\frac{r_{\text{cation}}}{r_{\text{anion}}} = \frac{102 \cancel{\text{pm}}}{140 \cancel{\text{pm}}} = 0.729$$

From data in Table 12.5, the radius ratio indicates that Th^{4+} ions will fit in octahedral holes but not in tetrahedral holes. The four Th^{4+} ions would occupy one-half of the octahedral holes.

4. By analogy to part (b), the density of ThO_2 in a hypothetical rock salt structure would be

$$m = \frac{232.04\ \text{g Th}^{4+}}{1\ \cancel{\text{mol Th}^{4+}}} \times \frac{1\ \cancel{\text{mol Th}^{4+}}}{6.022 \times 10^{23}\ \cancel{\text{ions Th}^{4+}}} \times 2\ \cancel{\text{ions Th}^{4+}}$$
$$= 7.706 \times 10^{-22}\ \text{g Th}^{4+}$$

$$m = \frac{16.00\ \text{g O}^{2-}}{1\ \cancel{\text{mol O}^{2-}}} \times \frac{1\ \cancel{\text{mol O}^{2-}}}{6.022 \times 10^{23}\ \cancel{\text{ions O}^{2-}}} \times 4\ \cancel{\text{ions O}^{2-}}$$
$$= 1.063 \times 10^{-22}\ \text{g O}^{2-}$$

Total mass of ions = 7.706×10^{-22} g Th^{4+} + 1.063×10^{-22} g O^{-2} = 8.769×10^{-22} g ions

The volume of the unit cell is the same as in part (b): $V = 1.756 \times 10^{-22}$ cm^3. Substituting into the equation for density:

$$d = \frac{m}{V} = \frac{8.769 \times 10^{-22}\ \text{g}}{1.756 \times 10^{-22}\ \text{cm}^3} = 4.99\ \text{g/cm}^3$$

The calculated density for ThO_2 in a rock salt structure would be about half of the observed value, and it is about half of the calculated value based on the fluorite structure.

Think About It By analogy to the fluorite structure shown in Figure 12.22, the larger oxide ions occupy the tetrahedral holes. The calculated value for the density of ThO_2 is very close to the observed value, supporting the assignment of the fluorite structure for ThO_2. The rock salt structure, where the smaller Th^{4+} ions occupy octahedral holes in the fcc lattice of the larger O^{2-} ions, can be ruled out because the calculated density is very different from the observed density.

Glossary

polymer (or macromolecule)

a very large molecule with high molar mass formed by bonding many small molecules of low molecular mass.

polymer (or macromolecule)

a very large molecule with high molar mass formed by bonding many small molecules of low molecular mass.

monomer

a small molecule that bonds with others like it to form polymers.

homopolymer

a polymer composed of only one kind of monomer.

addition polymer

a polymer formed by an addition reaction.

addition reaction

a reaction in which two reactants couple to form one product without the loss of any atoms or molecules.

vinyl group

the subgroup CH_2□CH–.

copolymer

a polymer formed from the chemical reaction of two different monomers.

heteropolymer

a polymer made of three or more different monomer units.

ester

an organic compound in which the –OH of a carboxylic acid group is replaced by –OR, where R can be any organic group.

condensation reaction

a reaction in which two molecules combine to form a larger molecule and a small molecule, typically water.

condensation polymer

a polymer formed by a condensation reaction.

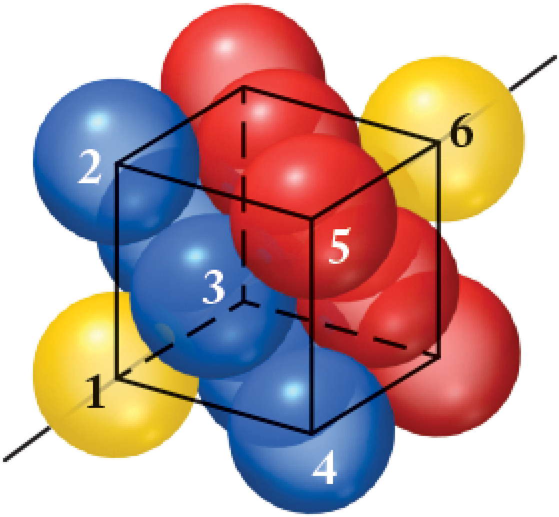
amide

an organic compound in which the same carbon atom is single bonded to a nitrogen atom and double bonded to an oxygen atom.

Learning Objectives

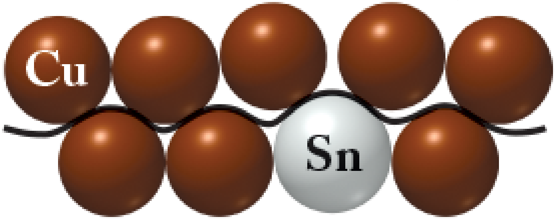
- Identify monomers given the structure of a polymer, and

determine the structure of a polymer given the structure of a monomer **Return to Sample Exercises 12.5, 12.7, 12.9**
- Analyze the properties of polymers **Return to Sample Exercises 12.6, 12.8**
- Identify monomers given the structure of a polymer, and determine the structure of a polymer given the structure of a monomer **Return to Sample Exercises 12.5, 12.7, 12.9**
- Analyze the properties of polymers **Return to Sample Exercises 12.6, 12.8**
- Identify monomers given the structure of a polymer, and determine the structure of a polymer given the structure of a monomer **Return to Sample Exercises 12.5, 12.7, 12.9**

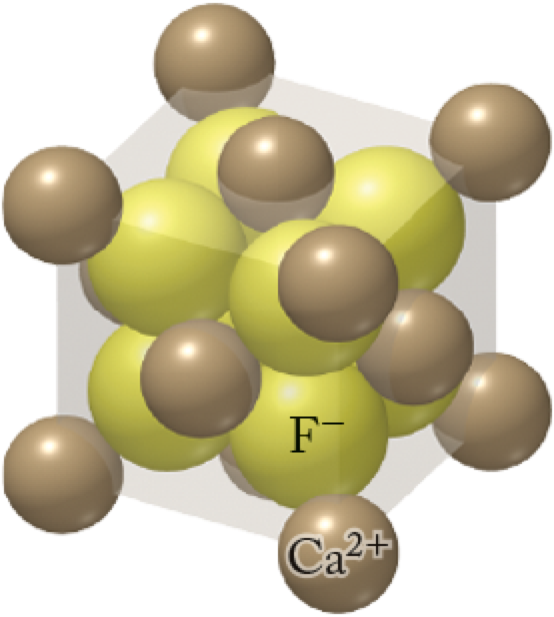


SUMMARY

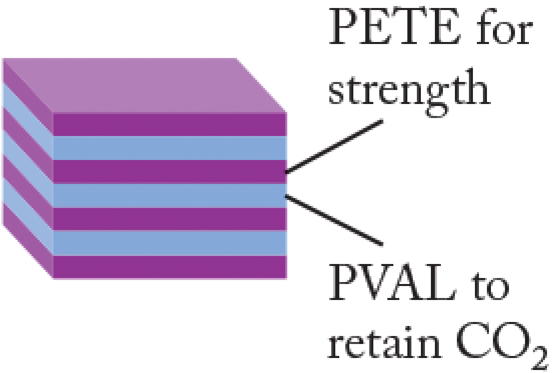
LO1 Many metallic crystals are based on crystal lattices of the cubic closest-packed (ccp) and hexagonal closest-packed (hcp) types, which are the two most efficient ways of packing atoms in a solid. Crystalline solids contain repeating unit cells, which can be simple cubic (sc), body-centered cubic (bcc), or face-centered cubic (fcc). The dimensions of the unit cell in a crystalline lattice can be used to determine the radius of the atoms or ions and to predict density. (Sections 12.1 and 12.2)



- LO2Alloys are blends of a host metal and one or more other elements (which may or may not be metals) added to enhance the properties of the host, including strength, hardness, and corrosion resistance. In substitutional alloys, atoms of the added elements replace atoms of the host metal in the crystal lattice. In interstitial alloys, atoms of added elements are located in the tetrahedral holes, in the octahedral holes of the host metal, or both. (Section 12.3)



- LO3 Many ionic solids consist of crystals with some number of either cations or anions forming the unit cell with the opposite ion occupying cubic, octahedral, and tetrahedral holes in the unit cell. The unit cell edge lengths of ionic solids can be used to calculate ionic radii and to predict densities. Two allotropes of carbon are the covalent network solids graphite and diamond. (Sections 12.1, 12.4, and 12.5)
- LO4 Alkenes undergo addition reactions to form homopolymers known as addition polymers. Monomer units derived from alcohols or ethers can be chemically reacted to make heteropolymers or copolymers. Condensation reactions of carboxylic acids and amines are used to prepare condensation polymers such as polyesters and polyamides. (Section 12.6)



- LO5 Properties of polymers depend on the identity and arrangement of the monomer units in the polymer. (Section 12.6)

PARTICULATE PREVIEW WRAP-UP

Each carbon atom in allotrope A is covalently bonded to four other carbon atoms in a tetrahedral geometry, so the pattern is nonplanar. Each carbon atom in allotrope B is covalently bonded to three other carbon atoms in a trigonal planar geometry and is attracted to the planar layers above and below through dispersion forces. The pattern in allotope B is planar. Allotrope A (diamond) is very hard and resists compression, whereas allotrope B (graphite) can be used as a lubricant because the planar layers can slide past one another.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts and Equations	Sample Exercises
Calculating atomic or ionic radii and density from unit cell dimensions	Determine the length of the unit cell edge, face diagonal, or body diagonal along which adjacent atoms touch. Use the relationship between edge length ℓ and the atomic radius r to calculate the value of r: $r = 0.5\ell$ for sc unit cells, $r = 0.3536\ell$ for fcc unit cells, and $r = 0.4330\ell$ for bcc unit cells. Determine the mass of the atoms in the unit cell from the molar mass and the volume of the unit cell from the unit cell edge length; then calculate the density:	12.1, 12.4

$$d = \frac{m}{V}$$

Predicting the crystal structure of two-element alloys	[illegible]	Compare the radii of the elements. Similarly sized radii (within 15%) suggest a substitutional alloy. When the radius of the smaller atom in a hcp or ccp lattice is $<$ 73% of the radius of the larger atom, an interstitial alloy forms.
Predicting the location of ions in ionic compounds	12.3, 12.4	Determine the ratio of the radii of the ion and the host to predict whether the ion is more likely to reside in an octahedral or tetrahedral hole.
Identifying monomers in polymers	12.5, 12.9	Identify the smallest portion of the polymer that is repeated.
Analyzing the properties of polymers	12.6, 12.8	Identify the functional groups in the polymer, and assess the relative importance of all types of intermolecular forces possible in the molecules.
Making a polyester	12.7	Combine monomers with alcohol functional groups (ROH) and carboxylic acid functional groups (RCOOH) to form water (H_2O) and ester groups (RCOOR).

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

Which drawings in Figure P12.1 are analogous to crystalline solids, and which are analogous to amorphous solids?

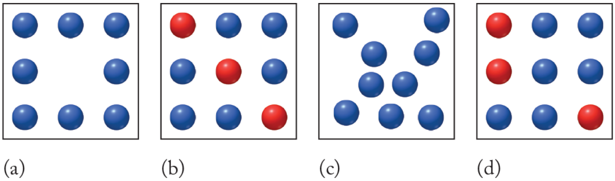


FIGURE P12.1

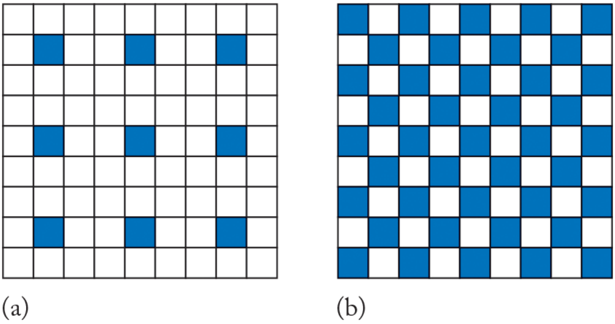
The unit cells in Figure P12.2 continue infinitely in two dimensions. Draw a box around a unit cell in each pattern. How many light squares and how many dark squares are in each unit cell?



(a) (b) **FIGURE P12.2**

The pattern in Figure P12.3 continues indefinitely in three dimensions. Draw a box around a unit cell. If the red spheres represent element A and the blue spheres represent element B, what is the chemical formula of the compound?

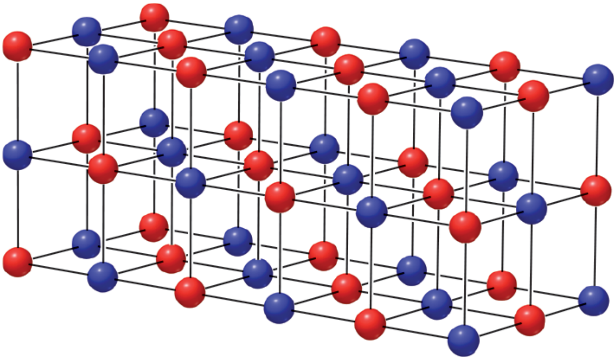


FIGURE P12.3

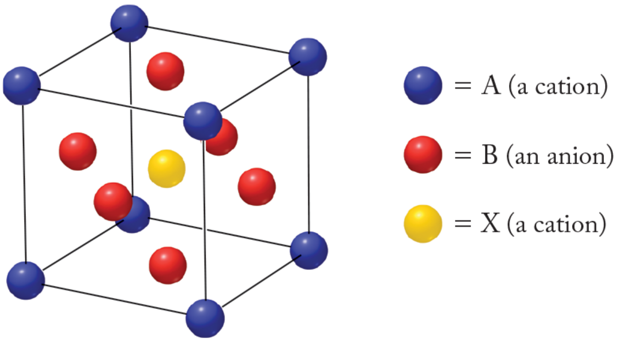
The unit cell of an ionic compound is shown in Figure P12.4. What is the chemical formula of the ionic compound, if A and X are cations and B is an anion?



= A (a cation)
= B (an anion)
= X (a cation)

FIGURE P12.4

What is the formula of the compound that crystallizes in the cubic closest-packed arrangement of A atoms (silver) shown in Figure P12.5? The B atoms (red) occupy half of the octahedral holes and the C atoms (blue) occupy one-eighth of the tetrahedral holes.

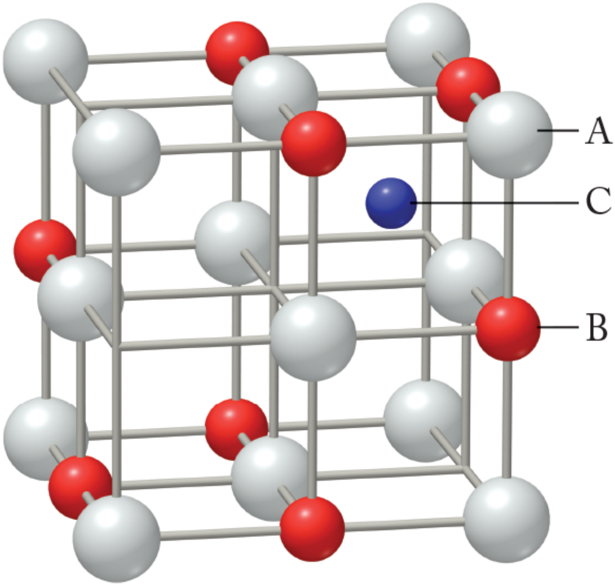


FIGURE P12.5

What is the formula of the compound that crystallizes with copper ions (the small spheres in Figure P12.6) occupying half of the tetrahedral holes in a cubic closest-packed arrangement of chloride ions?

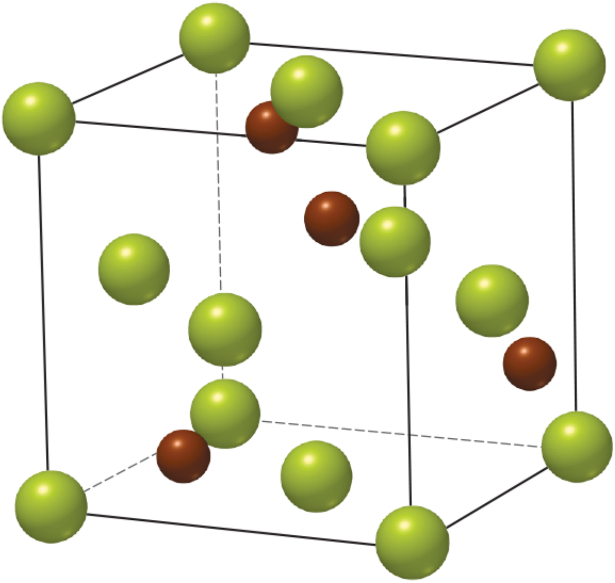

FIGURE P12.6

What is the formula of the compound that crystallizes with lithium ions occupying all of the tetrahedral holes in the cubic closest-packed arrangement of sulfide ions shown in Figure P12.7?

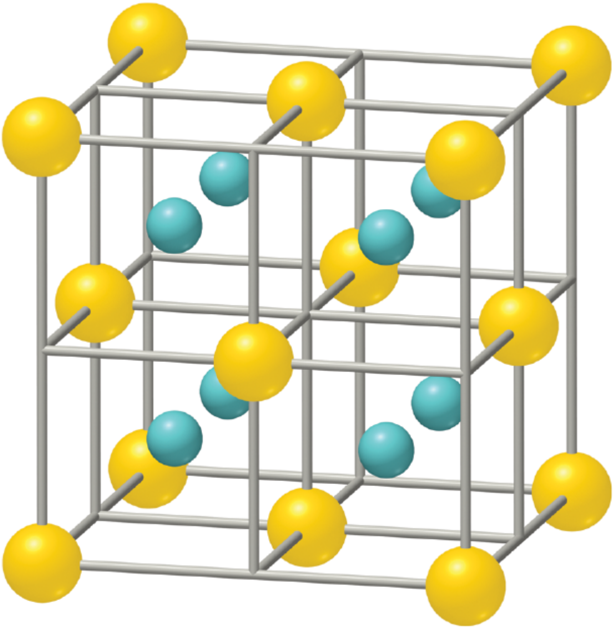

FIGURE P12.7

Figure P12.8 shows the unit cell of CsCl. From the information shown and given that the radius of the chloride (corner) ions is 181 pm, calculate the radius of Cs^+ ions.

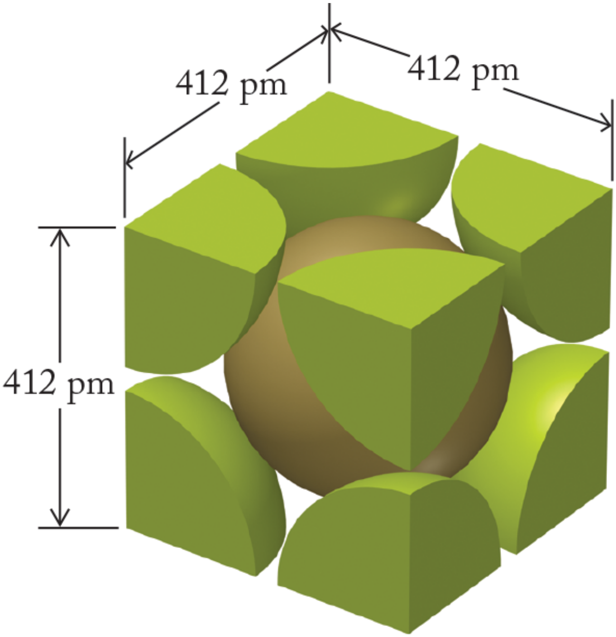

FIGURE
P12.8

Calculate the empirical formula and density of nitinol, the memory alloy composed of nickel and titanium with the unit cell shown in Figure P12.9. The atomic radii of Ni and Ti are 124 and 147 pm, respectively.

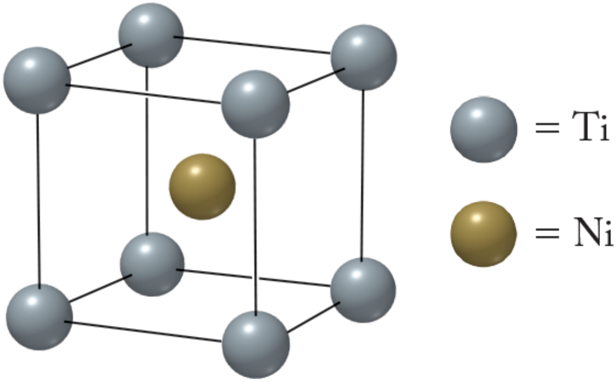

FIGURE
P12.9

Calculate the empirical formula and density of a rose gold alloy composed of 25% Cu and 75% Au given the unit cell in Figure P12.10. The atomic radii of Cu and Au are 128 and 144 pm, respectively.

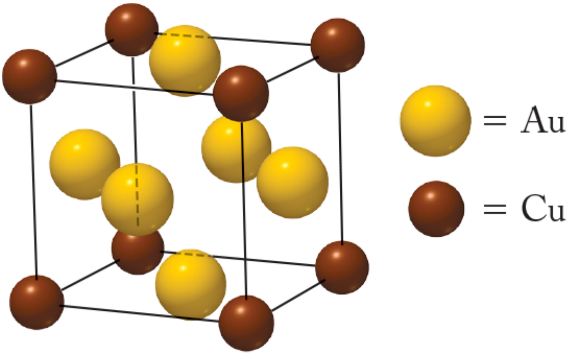

FIGURE P12.10

Superconducting Materials I In 2000, magnesium boride was observed to behave as a superconductor. Its unit cell is shown in Figure P12.11. What is the formula of magnesium boride? A boron atom is in the center of the unit cell (on the left), which is part of the hexagonal closest-packed crystal structure (right).

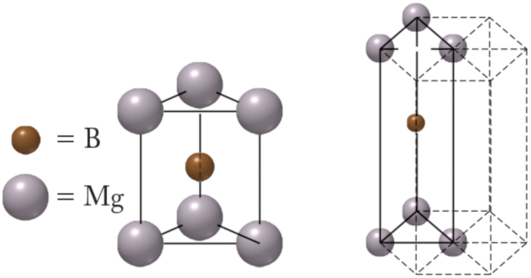

FIGURE P12.11

Superconducting Materials II The 1987 Nobel Prize in Physics was awarded to J. G. Bednorz and K. A. Müller for their discovery of superconducting ceramic materials such as $YBa_2Cu_3O_7$. Figure P12.12 shows the unit cell of another yttrium–barium–copper oxide.

1. What is the chemical formula of this compound?
2. Eight oxygen atoms must be removed from the unit cell shown here to produce the unit cell of $YBa_2Cu_3O_7$. Does it make a difference which oxygen atoms are removed?

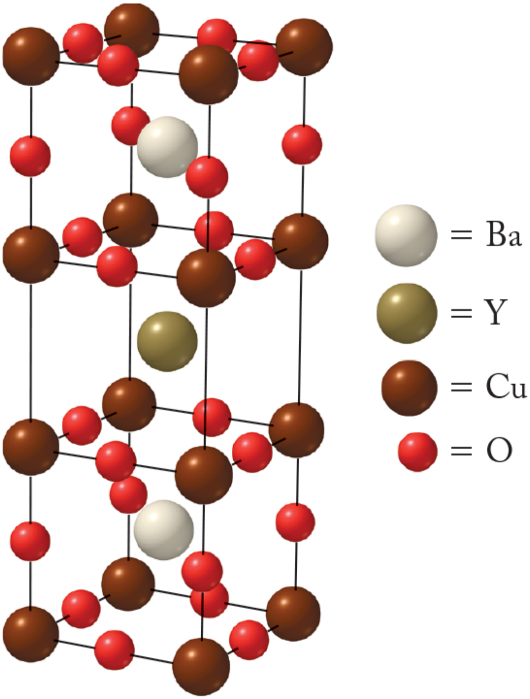

FIGURE P12.12

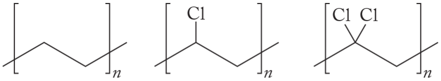
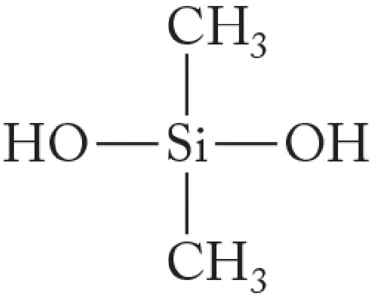
The three polymers shown in Figure P12.13 are widely used in the plastics industry. In which of them are the intermolecular forces per mole of monomer the strongest?



(a) Polyethylene (b) Poly(vinyl chloride) (c) Poly(1,1-dichloroethylene) **FIGURE P12.13**

Silly Putty Silly Putty is a condensation polymer of dihydroxydimethylsilane (Figure P12.14). Draw the condensed structure of the repeating monomer unit in Silly Putty.



$$HO-\overset{\displaystyle CH_3}{\underset{\displaystyle CH_3}{Si}}-OH$$

Dihydroxydimethylsilane **FIGURE P12.14**

Spider Silk Polymer chemists have long sought to mimic the physical properties of spider silk, a remarkably strong but flexible material. The structure of spider silk is illustrated in Figure P12.15.

1. What are the intermolecular forces between the strands?
2. The strands are formed during a condensation reaction. What functional group is present along each strand? What two functional groups reacted to form this functional group?

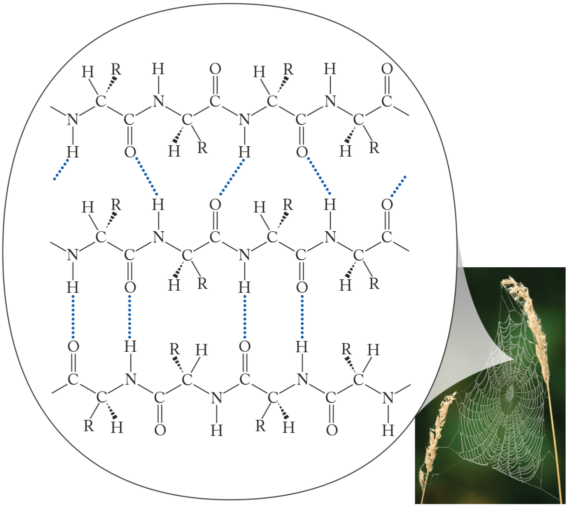


FIGURE P12.15

Use representations [A] through [I] in Figure P12.16 to answer questions (a)–(f).

1. Two forms of iron are ferrite and austenite. One has a body-centered cubic structure, whereas the other has a face-centered cubic structure. Which representations depict these common lattices for iron?
2. Which representation depicts an ionic compound?
3. Which representation depicts an interstitial alloy?
4. Which polymers were formed by an addition polymerization process? Which polymers were formed by a condensation polymerization process?
5. Which polymer structures are likely to result in rigid, hard materials?
6. Which polymer structures are likely to result in flexible, stretchable, soft materials?

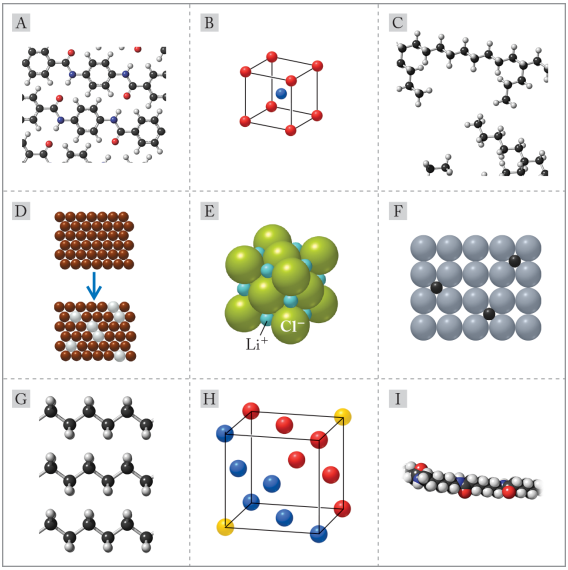

FIGURE P12.16

QUESTIONS AND PROBLEMS

Structures of Metals

Concept Review

Explain the difference between cubic closest-packed and hexagonal closest-packed arrangements of identical spheres.

Describe the features of simple cubic, body-centered cubic, and face-centered cubic crystal structures and rank these structures by decreasing packing efficiency.

Which unit cell has the greater packing efficiency, simple cubic or body-centered cubic?

Use Figure 12.9 to predict which unit cell has the greater packing efficiency: body-centered cubic or face-centered cubic.

The unit cell in iron metal is either fcc or bcc, depending on temperature. Are the fcc form of iron and the bcc form allotropes? Explain your answer.

At low temperatures, the unit cell of calcium metal is found to be fcc, a closest-packed crystal lattice. At higher temperatures, the unit cell of calcium metal is found to be bcc, a crystal lattice that is *not* a closest-packed structure. What might be a reason for this difference?

Problems

Europium crystallizes in a crystal lattice built on bcc unit cells, with a unit cell edge of 240.6 pm. Calculate the radius of a europium atom.

Nickel has an fcc unit cell with an edge length of 350.7 pm. Calculate the radius of a nickel atom.

What is the length of an edge of the unit cell when barium (atomic radius 222 pm) crystallizes in a crystal lattice of bcc unit cells?

What is the length of an edge of the unit cell when aluminum (atomic radius 143 pm) crystallizes in a crystal lattice of fcc unit cells?

A crystalline form of copper has a density of 8.95 g/cm^3. If the radius of copper atoms is 127.8 pm, is the copper unit cell (a) simple cubic, (b) body-centered cubic, or (c) face-centered cubic?

A crystalline form of molybdenum has a density of 10.28 g/cm^3 at a temperature at which the radius of a molybdenum atom is 139 pm. Which unit cell is consistent with these data? (a) simple cubic; (b) body-centered cubic; (c) face-centered cubic

Sodium metal crystallizes with a body-centered cubic structure at normal atmospheric pressure. The atomic radius of a sodium atom is 186 pm and the density of Na is 0.971 g/cm^3. At 613,000 atm (9 million psi) the structure of Na metal becomes fcc. Assuming the radius of Na is unchanged, what is the density of the fcc form of Na?

Calcium metal undergoes two phase changes under pressure. At atmospheric pressure, Ca crystallizes in an fcc unit cell that changes to a bcc unit cell above 20 GPa and to a simple cubic structure above 32 GPa.

1. If the radius of Ca remains unchanged, calculate the density of the simple cubic phase.
2. Calculate the radius of a Ca atom in the simple cubic structure if the density of the sc and fcc phases is the same.

The unit cell for hcp Ti is shown in Figure P12.31. Given the unit cell dimensions, calculate the density of titanium (atomic radius 147 pm).

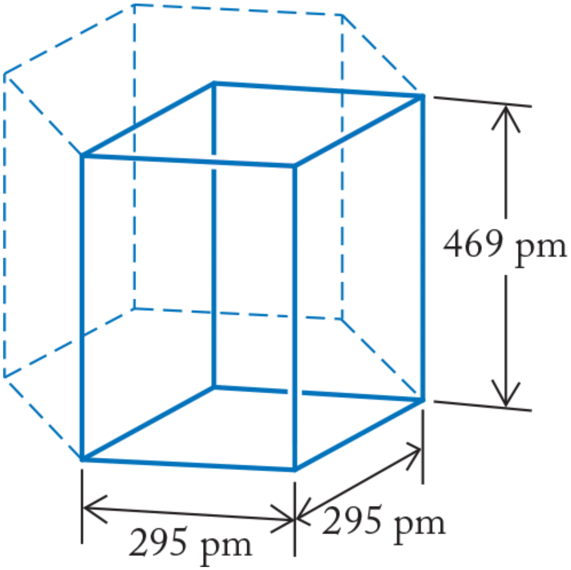

FIGURE P12.31

Cobalt crystallizes with the same unit cell as titanium (Figure P12.31). The edge length (251 pm) and height (407 pm) are both shorter than for titanium. Is cobalt denser than titanium? Explain your answer.

Alloys and Medicine

Concept Review

Describe the structural differences between substitutional and interstitial alloys and give an example of each alloy.

Describe how homogeneous alloys and intermetallic compounds are similar and how they are different.

What effect does the substitution of Ni for Ti in the center of a bcc unit cell of Ti have on the unit cell edge length?

White gold was originally developed to give the appearance of platinum. One formulation of white gold contains 25%

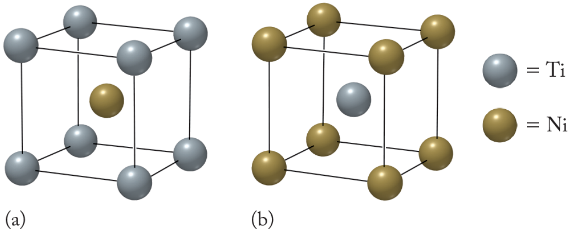
nickel and 75% gold. Which is more malleable, white gold or pure gold? Explain your answer.

Magnesium and hafnium have nearly the same atomic radius (within 1 pm). Does substitution of 25% of the magnesium by hafnium in an alloy increase or decrease the density of the alloy in comparison with pure magnesium? Explain your answer.

Why are the alloys that second-row nonmetals—such as B, C, and N—form with transition metals more likely to be interstitial than substitutional?

Problems

The unit cell of NiTi in Figure P12.39a shows a bcc arrangement of Ti atoms with Ni in the middle. Could we also draw the unit cell of NiTi as a bcc arrangement of Ni atoms with Ti in the middle as shown in Figure P12.39b? Explain why or why not.



(a) (b)

FIGURE P12.39

Can both of the unit cells in Figure P12.40 represent the same substitutional alloy? Explain why or why not.

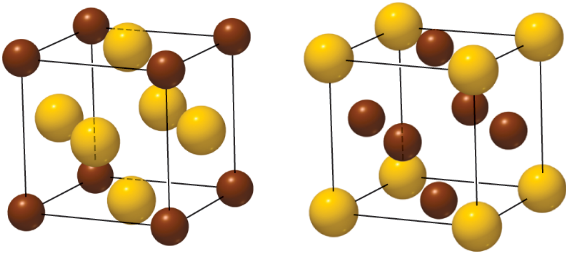


FIGURE P12.40

Hydrogen Storage Hydrogen is an attractive alternative fuel to hydrocarbons because it has a high fuel value and does not produce carbon dioxide when burned. One challenge to developing a hydrogen economy is storing hydrogen. Many transition metals absorb hydrogen by breaking the H—H bond and storing H atoms in the interstices between the metal atoms.

1. What is the minimum radius for the host metal for a H atom (radius 37 pm) to fit in a tetrahedral hole of an fcc unit cell?
2. Suppose the H is present as a hydride ion, H^- (ionic radius = 146 pm). Is the hydrogen then more likely to be found as an interstitial alloy in a tetrahedral or octahedral hole or as a substitutional alloy? *Hint*: Consult Appendix 3 for atomic radii of metals.

Metal borides MB_x exist for many transition metals.

1. What is the minimum radius for the host metal for a B atom (radius 88 pm) to fit in an octahedral hole of an fcc unit cell?
2. What is the value of x if an average of one octahedral hole is occupied per unit cell?

Dental Fillings Dental fillings are mixtures of several alloys, including one with the formula Ag_3Sn. Silver (radius 144 pm) and tin (140 pm) both crystallize in an fcc unit cell.

1. Is this alloy likely to be a substitutional alloy or an interstitial alloy?
2. Draw an fcc unit cell for Ag_3Sn that corresponds to an *intermetallic* alloy of silver and tin.

Joint Replacement A titanium–gold alloy discovered in 2016 is four times harder than pure titanium, making the new material attractive for use in knee and hip replacements.

1. Is this titanium–gold alloy more likely to be a substitutional or an interstitial alloy?
2. The structure of the alloy can be described as a bcc arrangement of Au atoms with two Ti atoms on each face. What is the formula of this alloy?

What is the formula of vanadium carbide if the vanadium atoms have a cubic closest-packed structure and two of the octahedral holes are occupied by C atoms?

What is the formula of manganese nitride if the manganese atoms have an fcc unit cell and one of the tetrahedral holes is occupied by a N atom?

When a metallurgist allows a molten mixture of 96 mg molybdenum and 184 mg of tungsten to cool to 25°C, it forms a crystalline alloy.

1. The unit cell of the alloy contains eight Mo atoms on the corners and one tungsten atom in the center. What is the empirical formula of the alloy?
2. Is the unit cell consistent with the masses of the metals used in the reaction?
3. Calculate the density of the alloy given that the atomic radii of both metals are 139 pm.

Building on the success described in Problem 12.47, the metallurgist halved the amount of molybdenum and increased the amount of tungsten in the mixture 1.5 times to obtain a different alloy.

1. The unit cell of this alloy contains four W atoms on alternate corners and one tungsten atom in the center. Molybdenum atoms occupy the remaining four corners in the unit cell. What is the empirical formula of the alloy?
2. Calculate the density of the alloy given that the atomic radii of both metals are 139 pm.
3. Would the density of the alloy change if the four tungsten and four molybdenum atoms in the unit cell were randomly distributed among all available sites in the lattice?

One of the many alloys of copper and zinc has the unit cell shown in Figure P12.49.

1. What type of crystal structure does this alloy have?
2. What are the proportions of copper and zinc in the alloy?

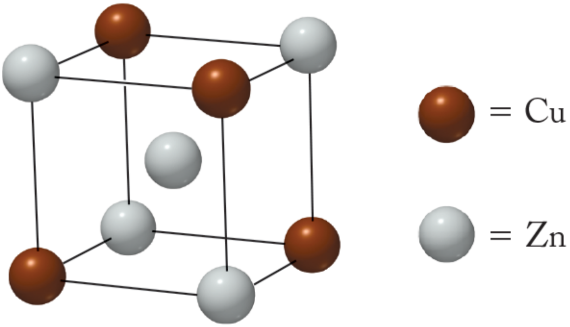

FIGURE P12.49

The unit cell of an iron–aluminum alloy is shown in Figure P12.50. (*Hint*: Consult Figure 12.6 for help in identifying the atoms.)

1. Is this alloy substitutional or interstitial?

2. What is the composition of this alloy?

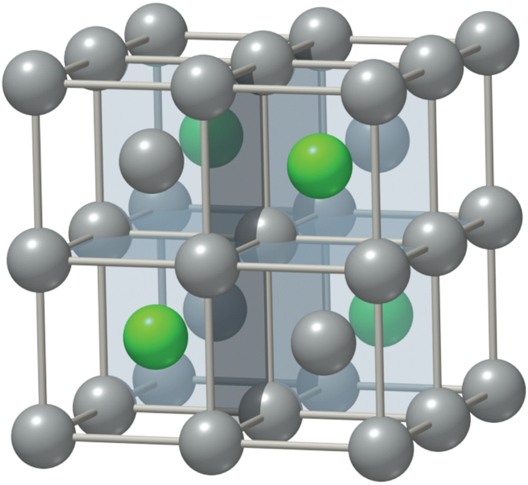

FIGURE P12.50

If the unit cell of a substitutional alloy of copper and tin has the same unit cell edge as the unit cell of copper, will the alloy have a greater density than copper? Explain your answer.

If the unit cell of an interstitial alloy of vanadium and carbon has the same unit cell edge as the unit cell of vanadium, will the alloy have a greater density than vanadium? Explain your answer.

Ionic Solids and Salt Crystals

Concept Review

Crystals of both LiCl and KCl have the rock salt structure. In the unit cell of LiCl, adjacent Cl^- ions touch each other. In KCl, they don't. Why?

Does the absolute size of an octahedral hole in an fcc lattice of halide ions change as we move down group 17 from fluoride to iodide?

In some books the unit cell of CsCl is described as being body-centered cubic (Figure P12.55); in others, as simple cubic (see Figure 12.9a). Explain how CsCl crystals might be described by either unit cell type.

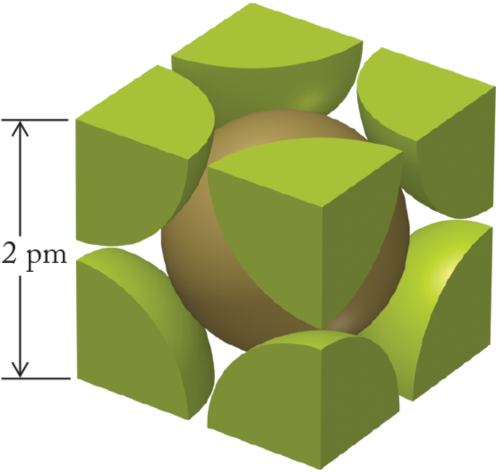

FIGURE P12.55

If some of the sulfide ions in zinc sulfide are replaced by selenide ions, will the selenide ions occupy the same sites as the sulfide ions?

Why can’t calcium chloride have a rock salt structure?

Why can’t sodium fluoride have exactly the same structure as calcium fluoride?

If the cation–anion radius ratio increases for an ionic compound with the rock salt crystal structure, is the calculated density more likely to be greater than or less than the measured value?

If the cation–anion radius ratio increases for an ionic compound with the rock salt crystal structure, is the length of the unit cell edge calculated from ionic radii likely to be greater than or less than the observed unit cell edge length?

Problems

What is the formula of the oxide that crystallizes with Fe^{3+} ions in one-fourth of the octahedral holes, Fe^{3+} ions in one-eighth of the tetrahedral holes, and Mg^{2+} in one-fourth of the octahedral holes of a cubic closest-packed arrangement of oxide ions (O^{2-})?

What is the chemical formula of the compound that crystallizes in a simple cubic arrangement of fluoride ions with Ba^{2+} ions occupying half of the cubic holes?

The Vinland Map At Yale University there is a map, believed to date from the 1400s, of a landmass labeled “Vinland” (Figure P12.63). The map is thought to be evidence of early Viking exploration of North America. Debate over the map’s authenticity centers on yellow stains on the map paralleling the black ink lines. One analysis suggests the yellow color is from the mineral anatase, a form of TiO_2 that was not used in 15th-century inks.

1. The crystal structure of anatase is approximated by a ccp arrangement of oxide ions with titanium(IV) ions in holes. Which type of hole are Ti^{4+} ions likely to occupy? The radius of Ti^{4+} is 60.5 pm.
2. What fraction of these holes is likely to be occupied?

FIGURE P12.63

The crystal structure of olivine—M_2SiO_4 (where M = Mg or Fe)—can be viewed as a ccp arrangement of oxide ions with silicon(IV) in tetrahedral holes and the metal ions in octahedral holes.

1. What fraction of each type of hole is occupied?
2. The unit cell volumes of Mg_2SiO_4 and Fe_2SiO_4 are 2.91×10^{-26} cm^3 and 3.08×10^{-26} cm^3, respectively. Why is the unit cell volume of Fe_2SiO_4 larger?

The rock salt structure (Figure 12.19) of magnesium selenide (MgSe) at atmospheric pressure changes to a cesium chloride structure (Figure P12.55) under pressure.

1. How do these structures differ?
2. Explain how both structures are consistent with the observed stoichiometry of MgSe.

The sphalerite structure of ZnS changes to a rock salt structure above 15 GPa.

1. Describe the differences between these two structures.
2. Explain how both structures are consistent with the observed stoichiometry of ZnS.

The unit cell of rhenium trioxide (ReO_3) consists of a cube with rhenium atoms at the corners and an oxygen atom on each of the 12 edges. The atoms touch along the edge of the unit cell. The radii of Re and O atoms in ReO_3 are 137 and 73 pm, respectively.

1. Draw the unit cell of ReO_3 and show that it is consistent with the empirical formula.
2. Calculate the density of ReO_3.

New Forms of Salt Sodium chloride is the prototypical example of the rock salt structure. In 2013, though, researchers discovered a new compound containing sodium and chlorine. Under high pressure, NaCl reacts with excess sodium metal to produce the compound shown in Figure P12.68.

1. What is the empirical formula of this compound?
2. Calculate the density of this compound if the atoms touch along the edges, using the atomic radii for the sodium and chlorine.

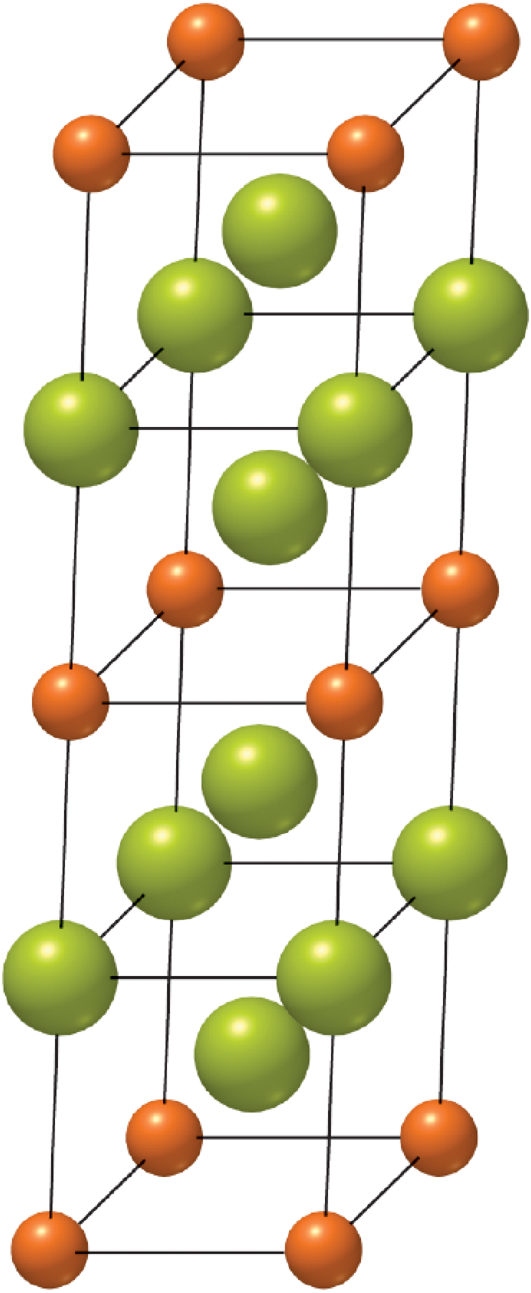

FIGURE P12.68

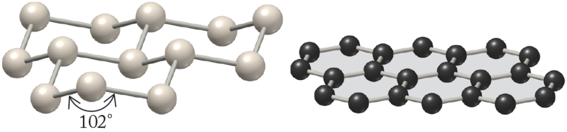
Magnesium oxide crystallizes in the rock salt structure. Its density is 3.60 g/cm^3. What is the edge length of the fcc unit cell of MgO?

Crystalline potassium bromide (KBr) has a rock salt structure and a density of 2.75 g/cm^3. Calculate its unit cell edge length.

Allotropes of Carbon

Concept Review

When amorphous red phosphorus is heated at high pressure, it is transformed into the allotrope black phosphorus, which can exist in one of several forms. One form consists of six-membered rings of phosphorus atoms (Figure P12.71a). Why are the six-atom rings in black phosphorus puckered, whereas the six-atom rings in graphene (Figure P12.71b) are planar?



(a) Black phosphorus (b) Graphene

FIGURE P12.71

If the carbon atoms in graphite are replaced by alternating B and N atoms, would the resulting structure contain puckered rings like black phosphorus or flat ones like graphite (see Figure P12.71)?

Problems

In the fullerene known as buckminsterfullerene (C_{60}), molecules of C_{60} form a cubic closest-packed array of spheres with a unit cell edge length of 1410 pm.

1. What is the density of crystalline C_{60}?
2. If we treat each C_{60} molecule as a sphere of 60 carbon atoms,

what is the radius of the C_{60} molecule?

C_{60} reacts with alkali metals to form M_3C_{60} (where M = Na or K). The crystal structure of M_3C_{60} contains cubic closest-packed spheres of C_{60} with metal ions in holes. (Use the radius for C_{60} that you calculated in Problem 12.73.)

1. If the radius of a K^+ ion is 138 pm, which type of hole is a K^+ ion likely to occupy? What fraction of the holes will be occupied?
2. Under certain conditions, a different substance, K_6C_{60}, can be formed in which the C_{60} molecules have a bcc unit cell. Calculate the density of a crystal of K_6C_{60}.

Semiconducting Phosphorus A cubic form of phosphorus is drawing renewed interest as a semiconductor. The distance between atoms in this cubic form of phosphorus is 238 pm (Figure P12.75).

1. Calculate the density of this form of phosphorus.
2. Is the cubic hole in cubic P large enough to hold either a silicon or a boron atom?
3. Would the material(s) from part (b) behave as n-type or p-type semiconductors?

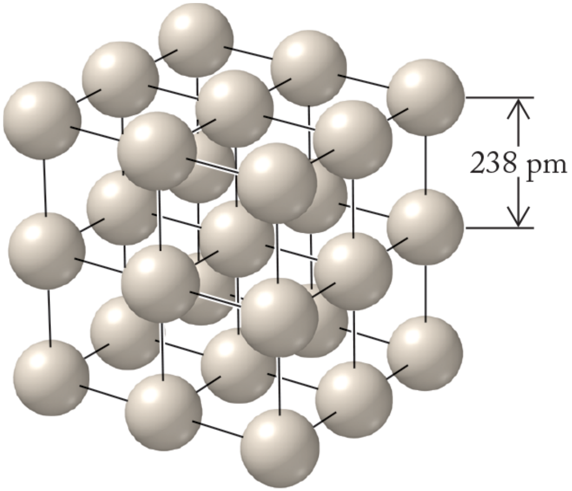


FIGURE P12.75

Ice under Pressure Kurt Vonnegut's novel *Cat's Cradle* describes an imaginary, high-pressure form of ice called "ice-nine." With the assumption that ice-nine has a cubic closest-packed arrangement of oxygen atoms with hydrogen atoms in the appropriate holes, what type of hole will accommodate the H atoms?

Polymers

Concept Review

Can a polymer be composed of more than one type of monomer? Explain why or why not.

Body Wash Personal care products such as body wash contain molecules like cetyl alcohol and glycol stearate (Figure P12.78). Are these two molecules considered to be polymers?

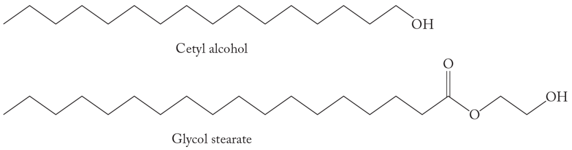

FIGURE P12.78

Compare the large hydrocarbon $C_{24}H_{50}$ with polyethylene. What structural feature(s) do they share in common? How do the structures of these compounds differ?

The 2000 Nobel Prize in Chemistry was awarded for research on the electrically conductive polymer polyacetylene, an addition polymer that is prepared from the monomer acetylene (HC ≡ CH). How does polyacetylene differ from polyethylene?

Problems

Polyethylene is prepared from the monomer ethylene (C_2H_4). About how many monomers are needed to make a polymer with a molar mass of 100,000 g/mol?

Synthetic rubber is prepared from butadiene (C_4H_6). About how many monomers are needed to make a polymer with a molar mass of 100,000 g/mol?

Making Glue Wood glue, or “carpenter’s glue,” is made of poly(vinyl acetate). Draw the carbon-skeleton structure of this polymer. The monomer is shown in Figure P12.83.

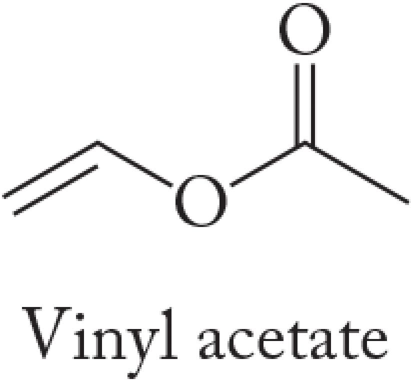

FIGURE P12.83

Cross-linked polymers based on boronic acids (Figure P12.84) show promise as a recyclable plastic. What is the other product of the reaction? Is this an addition or a condensation polymer?

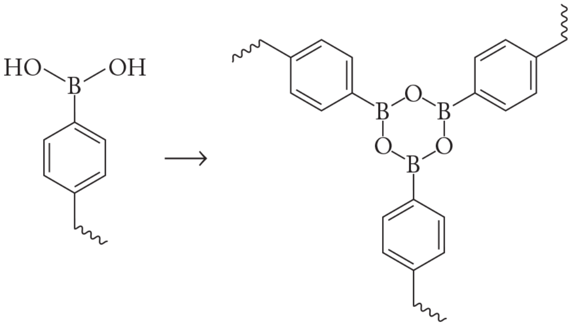

FIGURE P12.84

Soap One of the first chemical syntheses ever carried out was the making of soap. This same reaction is still carried out by modern-day manufacturers. The reaction is called saponification, and it is the reverse of esterification: an ester is taken apart to produce its component acid and alcohol. A compound called a glyceride, which is a fat, is reacted with an aqueous base (usually NaOH). The ester bonds are broken to yield glycerol (an alcohol) and the sodium salt of a fatty acid, which is then used as soap. Given the glyceride shown in Figure P12.85, draw the structures of the alcohol and the fatty acids that result when it is saponified.

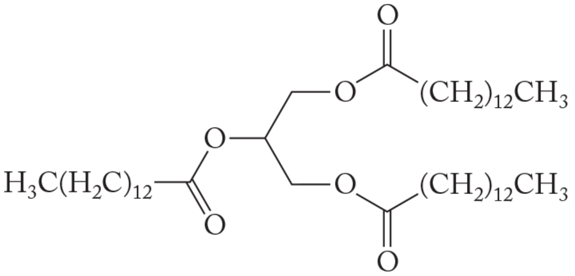

FIGURE P12.85

Reactions between 1,6-diaminohexane, $H_2N(CH_2)_6NH_2$, and different dicarboxylic acids, $HOOC(CH_2)_nCOOH$, are used to prepare polymers that have a structure similar to that of nylon. How many carbon atoms (n) were in the dicarboxylic acids used to prepare the polymers with the repeating units shown in Figure P12.86?

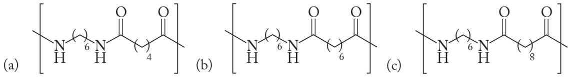

FIGURE P12.86

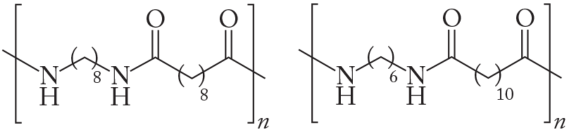
The two polymers in Figure P12.87 have the same empirical formula.

1. What pairs of monomers could be used to make each of them?
2. How might the physical properties of these two polymers differ?

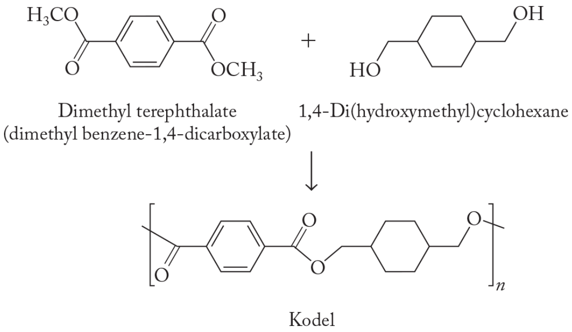


Polymer I
Polymer II

FIGURE P12.87

The polyester called Kodel is made with polymeric strands prepared by the reaction of dimethyl terephthalate with 1,4-di(hydroxymethyl)cyclohexane (Figure P12.88).

1. Is Kodel a condensation polymer or an addition polymer? What is the other product of the reaction?
2. Dacron (see Sample Exercise 12.8) is made from dimethyl terephthalate and ethylene glycol. What properties of Kodel fibers might make them better than Dacron as a clothing material?



Dimethyl terephthalate
(dimethyl benzene-1,4-dicarboxylate)
1,4-Di(hydroxymethyl)cyclohexane
Kodel

FIGURE P12.88

Lexan is a polymer belonging to the class of materials called polycarbonates. Figure P12.89 shows the polymerization reaction for Lexan.

1. What other compound is formed in the polymerization

reaction?

2. Why is Lexan called a “polycarbonate”?

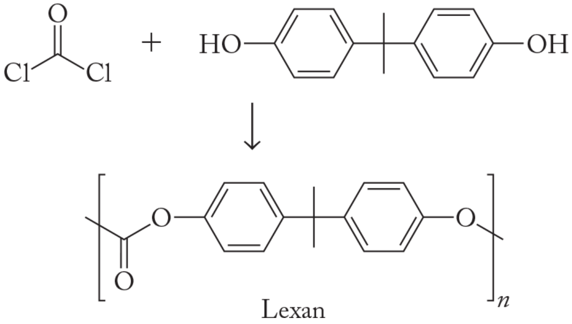


FIGURE P12.89

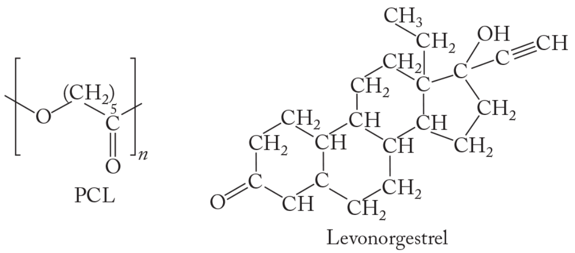
Nonbiodegradable Polymers Biodegradable polymers are important in applications such as dissolving sutures, but biocompatible polymers that resist degradation can serve as drug delivery systems in implanted devices. Poly(caprolactone) (PCL; Figure P12.90) degrades slowly in the human body but is very permeable to the contraceptive levonorgestrel. This combination is used in implantable contraceptive devices that are effective for many years.

1. Why is levonorgestrel soluble in PCL?
2. PCL does eventually degrade by reacting with water. What are the products of biodegradation?
3. Is PCL an addition or a condensation polymer?



FIGURE

P12.90

Additional Problems

A unit cell consists of a cube that has an ion of element X at each corner, an ion of element Y at the center of the cube, and an ion of element Z at the center of each face. What is the formula of the compound?

The unit cell of an oxide of uranium consists of cubic closest-packed uranium ions with oxide ions in all the tetrahedral holes. What is the formula of the oxide?

The phase diagram for titanium is shown in Figure P12.93.

1. Which structure does Ti metal have at 1500 K and 6 GPa of pressure?
2. How many phase changes does Ti metal undergo as pressure is increased at 725°C?

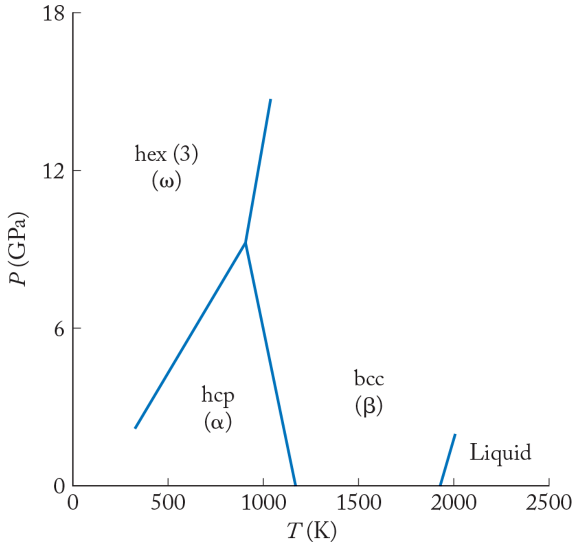


FIGURE P12.93

The phase diagram of thallium metal is shown in Figure P12.94.

1. At what temperature and pressure are all three solid phases of thallium metal present?
2. Does the melting point of thallium increase or decrease with increasing pressure?

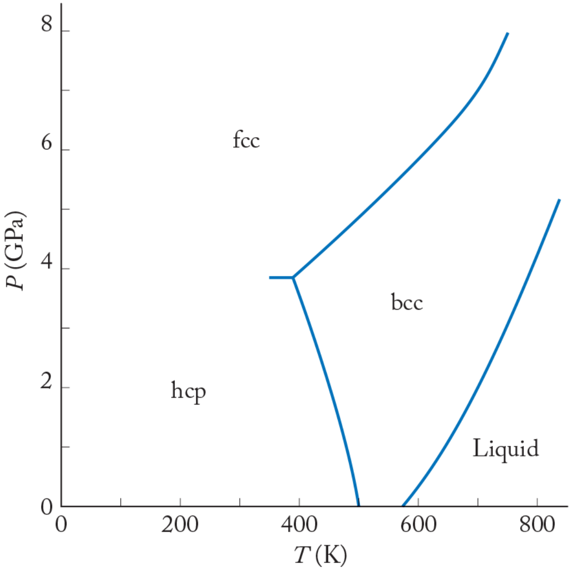

FIGURE P12.94

Silver nanoparticles are embedded in clothing fabric to kill odor-causing bacteria. Silver crystallizes in an fcc unit cell.

1. How many unit cells are present in a cubic silver particle with an edge length of 25 nm?
2. How many silver atoms are there in this particle?
3. If there are 1360 μg of silver per sock, how many of these particles does this mass correspond to?

In 2011, researchers at Duke University reported on the use of cylindrical gold particles called “nanorods” to image brain tumors (Figure P12.96).

1. If the nanorods have a diameter of 32 nm and a height of 67 nm, approximately how many gold atoms are in each nanorod?
2. How many unit cells does this correspond to?
3. What is the mass of each nanorod?

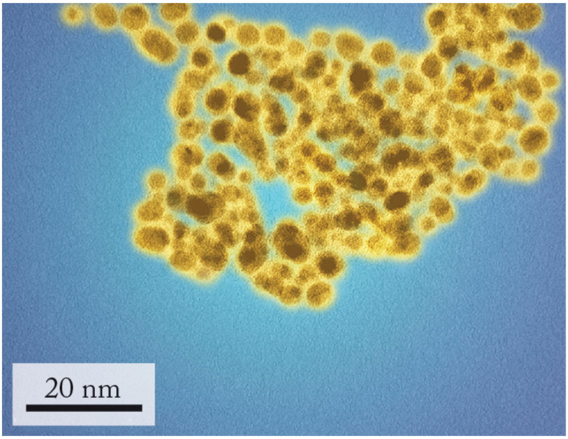

FIGURE P12.96

The center of Earth is composed of a solid iron core within a molten iron outer core. When molten iron cools, it crystallizes in different ways depending on pressure—in a bcc unit cell at low pressure and in a hexagonal unit cell at high pressures like those at Earth's center.

1. Calculate the density of bcc iron given that the radius of an iron atom is 126 pm.
2. Calculate the density of hexagonal iron given a unit cell volume of 5.414×10^{-23} cm^3.
3. Seismic studies suggest that the density of Earth's solid core is only about 90% of that of hexagonal Fe. Laboratory studies have shown that up to 4% by mass of Si can be substituted for Fe without changing the hcp crystal structure built on hexagonal unit cells.

Calculate the density of such a crystal.

The unit cell of an alloy with a 1:1 ratio of magnesium and strontium is identical to the unit cell of CsCl. The unit cell edge of MgSr is 390 pm. What is the density of MgSr?

In the structure of LiCl in Figure 12.23 we treat the particles as Li$^+$ and Cl$^-$ ions and use the corresponding ionic radii to calculate the density of LiCl as 2.09 g/cm^3.

1. How would the structure change if we treated the particles as neutral atoms? Assume an fcc lattice composed of one type of atom with the other atoms in holes.
2. Calculate the density of LiCl if we treated the particles as atoms rather than ions.

Figure P12.100 shows four identical layers of atoms in an *aaaa* . . . pattern. Using the yellow triangle as a guide, how many nearest-neighbor atoms does any one hole between the layers have? Are there any other kinds of holes in this structure?

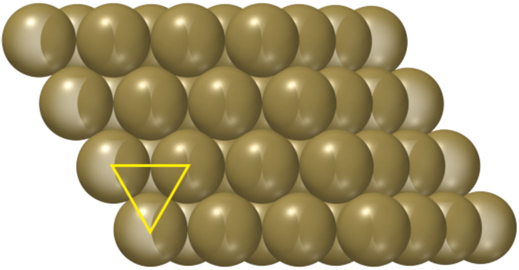

FIGURE P12.100

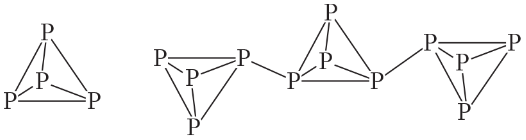
Forms of Phosphorus White phosphorus is a highly reactive material consisting of independent P_4 tetrahedra (Figure P12.101a). Red phosphorus is much less reactive with a structure consisting of linked P_4 tetrahedra (Figure P12.101b). What is the maximum-sized particle that could fit inside a P_4 tetrahedron? Is there any element that fits this criterion?



(a) (b) **FIGURE P12.101**

Aluminum forms alloys with lithium (LiAl), gold ($AuAl_2$), and titanium (Al_3Ti). On the basis of their crystal lattices, each of these alloys is considered a substitutional alloy.

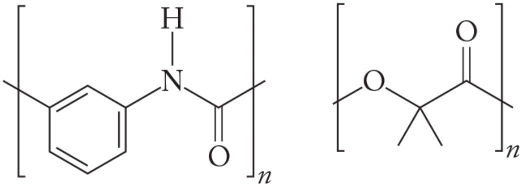
1. Do these alloys fit the general size requirements for substitutional alloys? The atomic radii for Li, Al, Au, and Ti are 152, 143, 144, and 147 pm, respectively.
2. If the unit cell of LiAl is bcc, what is the density of LiAl?

The aluminum alloy Cu_3Al crystallizes in a bcc unit cell. Propose a way that the Cu and Al atoms could be allocated between bcc unit cells that is consistent with the formula of the alloy.

Light-Emitting Diodes The colored lights on many electronic devices are light-emitting diodes (LEDs). One of the compounds used to make them is aluminum phosphide (AlP), which crystallizes in a sphalerite crystal structure.

1. If AlP were an ionic compound, would the ionic radii of Al^{3+} and P^{3-} be consistent with the size requirements of the ions in a sphalerite crystal structure?
2. If AlP were a covalent compound, would the atomic radii of Al and P be consistent with the size requirements of atoms in a sphalerite crystal structure?

Identify the reactants in the polymerization reactions that produce the two polymers shown in Figure P12.105.



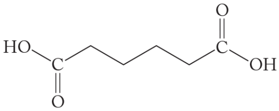
(a) (b) **FIGURE P12.105**

Raincoats “Waterproof” nylon garments have a coating to prevent water from penetrating the hydrophilic fibers. Which functional groups in the nylon molecule make it hydrophilic?

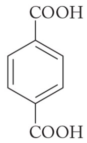
Draw the carbon-skeleton structure of the condensation polymer of $H_2N(CH_2)_6COOH$. How does this polymer compare with nylon-6?

Putrescine, $H_2N(CH_2)_4NH_2$, is one of the compounds that form in rotting meat.

1. Draw the carbon-skeleton structures of all the trimers (a molecule formed from three monomers) that can be formed from putrescine, adipic acid, and terephthalic acid (Figure P12.108). The three monomers forming the trimer do not have to be different from one another.
2. A chemist wants to make a putrescine polymer containing a 1:1 ratio of adipic acid to terephthalic acid. What should be the mole ratio of the three reactants?



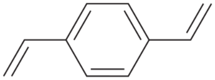
Adipic acid



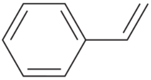
Terephthalic acid
(benzene-1,4-dicarboxylic acid)

FIGURE P12.108

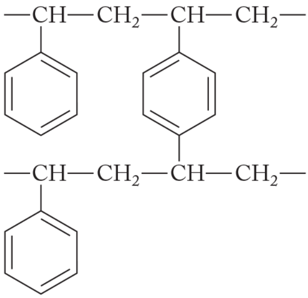
Polymer chemists can modify the physical properties of polystyrene by copolymerizing divinylbenzene with styrene (Figure P12.109). The resulting polymer has strands of polystyrene cross-linked with divinylbenzene. Predict how the physical properties of the copolymer might differ from those of 100% polystyrene.



Divinylbenzene (DVB)



Styrene (S)



S cross-linked with DVB

FIGURE P12.109

Maleic anhydride and styrene (Figure P12.110) form a polymer with alternating units of each monomer.

1. Draw two repeating monomer units of the polymer.
2. From the structure of the copolymer, predict how its physical properties might differ from those of polystyrene.

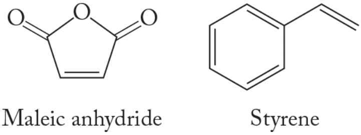


FIGURE P12.110

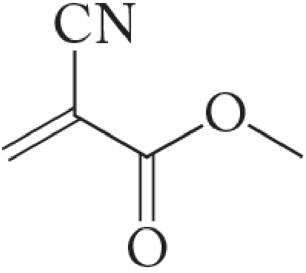
Superglue The active ingredient in superglue is methyl 2-cyanoacrylate (Figure P12.111). The liquid glue hardens rapidly when methyl 2-cyanoacrylate polymerizes. This happens when it contacts a surface containing traces of water or other compounds containing –OH or –NH– groups. Draw the carbon-skeleton structure of two repeating monomer units of poly(methyl 2-cyanoacrylate).



Methyl 2-cyanoacrylate **FIGURE P12.111**

Silicones are polymeric materials with the formula $[R_2SiO]_n$ (Figure P12.112). They are prepared by reaction of R_2SiCl_2 with water, yielding the polymer and aqueous HCl. Consider this reaction as taking place in two steps: (1) water reacts with 1 mole of R_2SiCl_2 to produce a new monomer and 1 mole of HCl(*aq*); (2) one new monomer molecule reacts with another new monomer molecule to eliminate one molecule of H_2O and make a dimer with a Si—O—Si bond.

1. Suggest two balanced equations that describe these reactions that occur over and over again to produce a silicone polymer.
2. Why are silicones water repellent?

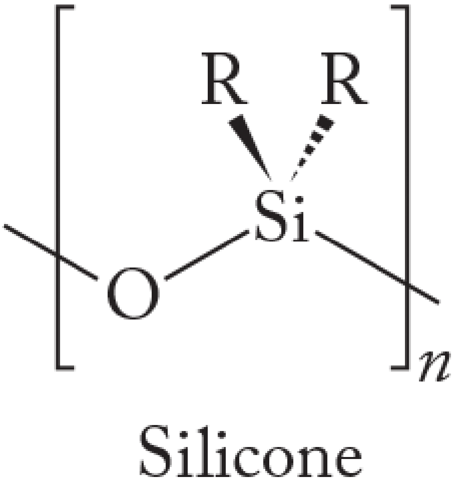


FIGURE P12.112

Glossary

crystal lattice

a three-dimensional repeating array of particles (atoms, ions, or molecules) in a crystalline solid.

cubic closest-packed (ccp)

a crystal lattice in which the layers of atoms or ions in face-centered cubic unit cells have an *abcabc* . . . stacking pattern.

hexagonal closest-packed (hcp)

a crystal lattice in which the layers of atoms or ions in hexagonal unit cells have an *ababab* . . . stacking pattern.

crystalline solid

a solid made of an ordered array of atoms, ions, or molecules.

unit cell
the repeating unit of the arrangement of atoms, ions, or molecules in a crystal lattice.

alloy
a blend of a host metal and one or more other elements, which may or may not be metals, that are added to change the properties of the host metal.

substitutional alloy
an alloy in which atoms of the nonhost metal replace host atoms in the crystal lattice.

interstitial alloy
an alloy in which atoms of the added element occupy the spaces between atoms of the host.

ionic solid
a solid formed by ionic bonds among monatomic or polyatomic ions.

covalent network solid
a solid formed by covalent bonds among nonmetal atoms in an extended array.

addition reaction
a reaction in which two reactants couple to form one product without the loss of any atoms or molecules.

homopolymer
a polymer composed of only one kind of monomer.

addition polymer
a polymer formed by an addition reaction.

heteropolymer
a polymer made of three or more different monomer units.

copolymer
a polymer formed from the chemical reaction of two different monomers.

condensation reaction
a reaction in which two molecules combine to form a larger molecule and a small molecule, typically water.

condensation polymer
a polymer formed by a condensation reaction.

simple cubic (sc) unit cell
an array of atoms or molecules with one particle at the eight corners of a cube.

body-centered cubic (bcc) unit cell

an array of atoms or molecules with one particle at each of the eight corners of a cube and one at the center of the cell.

face-centered cubic (fcc) unit cell

an array of closest-packed particles that has one particle at each of the eight corners of a cube and one more at the center of each face of the cube.

AIR QUALITY On a smoggy day, this iconic building in Tiananmen Square in Beijing is nearly invisible.

Chemical Kinetics

Reactions in the Atmosphere

PARTICULATE REVIEW

Concentration and Solutions

In Chapter 13 we explore how the rates of reactions depend on variables such as concentration and temperature. The image shows two graduated cylinders that contain aqueous solutions of copper(II) nitrate. Cylinder 1 has a concentration of 0.01 *M*.

Which cylinder contains the more concentrated solution?
- What is the concentration of the solution in cylinder 2?
- Which cylinder contains more dissolved solute?

(Review Section 4.2 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Collisions and Reactions

The images represent three samples of nitrogen dioxide, which is a component of the atmospheric pollution shown in the opening photograph of this chapter. At high temperatures, nitrogen dioxide decomposes to nitrogen monoxide and oxygen gas. As you read Chapter 13, look for ideas that will help you answer these questions:

- Assuming the temperature of all three NO_2 samples is the same, in which one do the NO_2 molecules collide most frequently?

- In which sample do the NO_2 molecules collide four times more frequently than they do in sample (c)?
- In which of the three samples does the decomposition of NO_2 proceed the most rapidly?

Learning Outcomes

- LO1 Relate the rates of change in the concentrations of reactants and products to each other and to reaction rate, reaction order, and rate constant units

  Sample Exercises 13.1, 13.2

- LO2 Determine average and instantaneous reaction rates from experimental data

  Sample Exercise 13.3

- LO3 Derive rate laws from initial reaction rate data

  Sample Exercise 13.4

- LO4 Use integrated rate laws to identify zero-, first-, and second-order reactions and to determine rate constants for such reactions

  Sample Exercises 13.5, 13.8

- LO5 Use rate laws to relate the half-lives of zero-, first-, and second-order reactions to reactant concentrations

  Sample Exercises 13.6, 13.7

- LO6 Relate the activation energy of a reaction and the effect of temperature on rate constants

  Sample Exercises 13.9, 13.10

- LO7 Relate a reaction mechanism (i.e., how a reaction occurs at the particle level) to its molecularity and overall rate law

Sample Exercises 13.11, 13.12

- LO8 Describe catalysts and explain how they alter reaction mechanisms in ways that increase reaction rates

  Sample Exercise 13.13

FIGURE 13.1 A London policeman uses a torch so that drivers will see his traffic directions during the Great Smog of 1952.

$$N_2(g) + O_2(g) \rightarrow 2\ NO(g) \qquad (13.1)$$

$$2\ NO(g) + O_2(g) \rightarrow 2\ NO_2(g) \qquad (13.2)$$

$$NO_2(g) \xrightarrow{\text{sunlight}} NO(g) + O(g) \qquad (13.3)$$

$$O(g) + H_2O(g) \rightarrow 2\ OH(g) \qquad (13.4)$$

$$O(g) + O_2(g) \rightarrow O_3(g) \qquad (13.5)$$

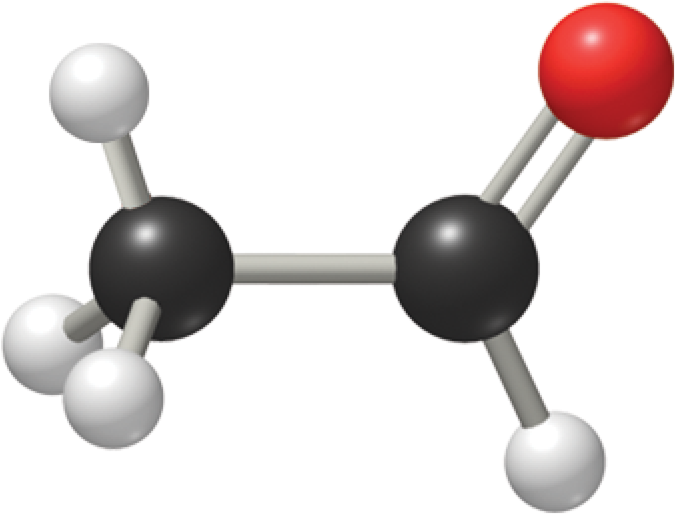

FIGURE 13.2 Acetaldehyde.

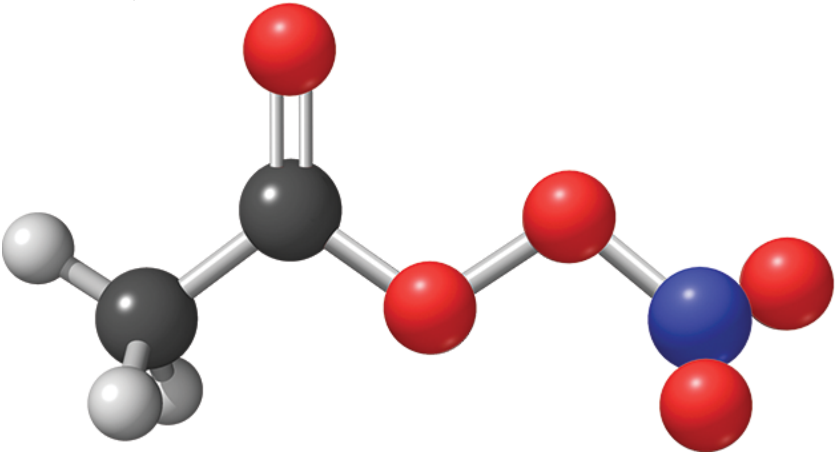

FIGURE 13.3 Peroxyacetyl nitrate (PAN).

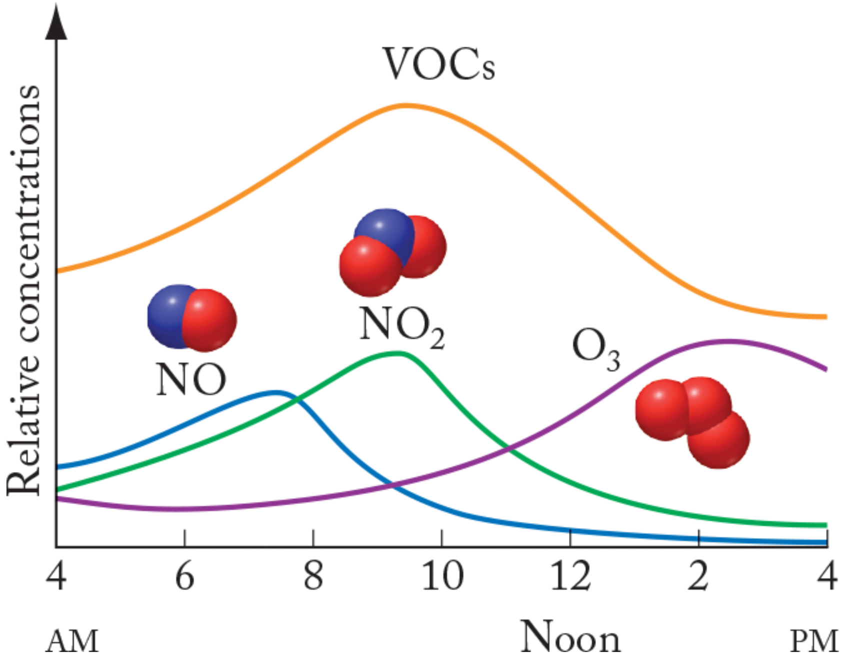

FIGURE 13.4 The concentrations of these components of photochemical smog reach their maxima in the atmosphere at different times as they are produced and then consumed in the many reactions that contribute to smog formation.

13.1 Cars, Trucks, and Air Quality

The common name for the haze hanging over the city in the chapter-opening photograph is *smog*, a name first used over a century ago to describe the air pollution that blanketed some cities during the winter when smoke from coal-fired stoves and furnaces combined with natural fog to produce air that had the appearance of pea soup. This greenish-yellow form of smog contained high concentrations of volatile sulfur compounds that combined with atmospheric moisture, forming highly acidic aerosols (suspended particles). Breathing in these pollutants can cause severe respiratory distress. During one particularly intense smog event in London, England, in December of 1952 (**Figure 13.1**), more than 100,000 people were sickened and about 12,000—mostly elderly or very young children—died from impaired lung function caused by the smog. In response to this environmental disaster, Parliament passed the Clean Air Act of 1956, which banned the use of high-sulfur coal for heating homes in cities and towns across the United Kingdom.

The smog in the chapter-opening photograph is different from the pea-soup variety that covered London. It is called photochemical smog because some of the gases in it form in the atmosphere when solar radiation interacts with gases produced in the internal combustion engines that power most cars and trucks. The high temperatures inside the engines in these vehicles allow N_2 and O_2 to combine, producing nitrogen monoxide:

When the NO in engine exhaust enters the atmosphere, it slowly reacts with more oxygen, producing nitrogen dioxide:

which is the ingredient that often gives photochemical smog a brown color. Sunlight can break the bonds in NO_2, producing NO and very reactive oxygen atoms:

These atoms of oxygen may react with molecules of water vapor, producing hydroxyl radicals,

or they may combine with molecules of O_2, forming ozone,

CONNECTION A free radical (Section 8.6), also called just a “radical,” is a molecule with an odd number of electrons, which makes it chemically reactive.

Even trace concentrations of O_3 in the air can irritate your eyes and respiratory system. In addition, O_3 and OH radicals react with volatile organic compounds (VOCs) in the atmosphere, converting them to compounds containing C□O double bonds, such as acetaldehyde (**Figure 13.2**).

Acetaldehyde undergoes further oxidation and combines with nitrogen dioxide, forming a compound with the common name peroxyacetyl nitrate (PAN; **Figure 13.3**). PAN is an extremely potent eye and respiratory irritant and a principal contributor to the watery eyes, runny noses, sore throats, and difficulty breathing that many people experience during photochemical smog events.

The chemical reactions in Equations 13.1 to 13.5 are linked: the products of the early reactions in the sequence are reactants in later reactions. These relations are the reason why the atmospheric concentrations of different smog components reach their maximum values at different times during the day (**Figure 13.4**). Also, the *rates* of the reactions—that is, the rates at which reactants are consumed and products are formed—control the atmospheric concentrations of the components, including when they form and how long they last.

The formation of NO from N_2 and O_2 (Equation 13.1), for example, is an endothermic reaction ($\Delta H^\circ = 180.6$ kJ/mol) that proceeds only at extremely high temperatures. However, the gases in the combustion chamber of an automobile engine experience such temperatures for only a tiny fraction of a second before they flow into the car's exhaust system. Therefore, NO forms only if the rate of its formation reaction is very rapid. Unfortunately, the reaction is quite rapid.

To further explore the impact of reaction rates on smog formation, let's return to Figure 13.4 and see how NO emitted by vehicles during a morning rush hour affects air quality on a sunny day with little wind over a large urban area. Heavy traffic and exhaust emissions increase the concentration of NO, which reaches a maximum in the atmosphere early in the morning—near the height of traffic. By mid-morning, NO levels start to fall and NO_2 levels start to rise as NO combines with atmospheric O_2. By noon, the concentration of NO_2 is falling as it undergoes photodecomposition, releasing O atoms that combine with O_2, forming O_3. Ozone concentrations reach their maximum in mid-afternoon and then fall as this highly reactive allotrope of oxygen combines with VOCs and nitrogen oxides. A principal source of VOCs in urban air is unburnt hydrocarbons from car and truck fossil fuels. Their peak concentration also tracks with the morning rush hour. If we were to extend the graph in Figure 13.4, we would see a second maximum in VOC concentration after the evening rush hour.

Smog conditions and ozone concentrations that posed a threat to human health were a worsening environmental crisis during the 1950s and 1960s in many American cities, particularly in metropolitan Los Angeles. In fact, the expression “brown L.A. haze” became so common it found its way into the lyrics of a popular song.[1] To combat smog pollution, exhaust systems of automobiles sold in the United States since the 1975 model year have been equipped with devices called *catalytic converters*, which reduce the concentrations of NO in the exhaust gases.

CONNECTION Kinetic molecular theory, introduced in Section 5.8, is a model that describes the behavior of gases.

In this chapter we explore how catalytic converters accelerate the rates of chemical reactions that turn NO and other pollutants into nonpolluting products. To understand this process, we need to investigate the factors that influence the rates of chemical reactions, but before we do that, we need to learn how to measure reaction rates and to express the results of those measurements. All of these concepts are part of chemical kinetics, the study of the rates of chemical reactions and the factors that influence those rates. Chemists use this knowledge to determine how reactions happen at the molecular level—that is, the *mechanisms* of reactions. With this knowledge, chemists can manipulate reaction conditions to increase reaction rates and, ultimately, product yields. This fundamental branch of chemistry is the focus of this chapter.

Glossary

photochemical smog

a mixture of gases formed in the lower atmosphere when sunlight interacts with compounds produced in internal combustion engines and other pollution sources.

chemical kinetics
: the study of the rates of change of concentrations of substances involved in chemical reactions.

Endnotes

- The chorus of “Come Monday” contains the line “I spent four lonely days in a brown L.A. haze.” The song was written and recorded by Jimmy Buffett in 1974, the year that automobiles equipped with catalytic converters first went on sale. Return to reference 1

13.2 Reaction Rates

Previous chapters in this book provide a foundation on which we can build an understanding of chemical kinetics. In Chapter 5 we explored the kinetic molecular theory of gases and the relationship between temperature and the average speeds of molecules in the gas phase. Faster speeds mean more frequent and forceful collisions between molecules. As we see here in this chapter, more frequent collisions can mean more rapid reactions. Reaction rates vary over a wide range (**Figure 13.5**), from so slow that we barely perceive they are occurring to explosively fast. The following four factors influence reaction rates:

CONNECTION We discussed translational (and vibrational and rotational) motion in Section 6.3.

---

1. *Physical states of the reactants*. The more frequently that particles interact—that is, the more often they collide with one another—the faster they can react with each other. Particles in solids have the same nearest neighbors over time, whereas the particles in liquids move in relation to one another. The particles in gases are widely separated but move very rapidly. These differences in motion are one reason why reactions in the solid phase tend to be much slower than reactions in liquids and gases.
2. *Concentration of reactants*. The rates of most chemical reactions depend on the concentrations of one or more of the reactants. Greater concentrations often produce more rapid reaction rates.
3. *Temperature*. As temperature increases, the rates of chemical reactions tend to increase. The average kinetic energy (KE) of particles increases as temperature rises, and as their KE increases, the number of collisions between the particles increases, as does the probability that those collisions will lead to reactions between them.

   CONNECTION The connections between kinetic energy and temperature are discussed in Sections 5.8, 6.1, and 6.2.

4. *Catalysts*. Catalytic converters contain materials that increase the rates of reactions that consume pollutants in automobile exhaust. In general, catalysts are materials or substances that accelerate reactions without themselves being consumed in the process. Catalysts also play a key role in biochemistry, where proteins called enzymes catalyze most reactions in living systems.

With these four ideas in mind, let’s begin our investigation of reaction rates by returning to the formation of NO in internal combustion engines:

We can express the rate of this reaction in terms of the rate of change in the concentration of the product (NO) or the rate of change in the concentration of either reactant (N_2 or O_2). In equations describing concentration changes, we use square brackets around the formulas of substances to represent their concentrations expressed in moles per liter. If the concentration of NO increases from $[NO]_{initial}$ to $[NO]_{final}$ during the time between $t_{initial}$ and t_{final}, then the average rate of change in the concentration of NO during this time is

Similarly, the rates of change in the concentrations of N_2 or O_2 over the same interval are

and

Now let’s derive an equation that relates the three rate-of-change expressions in Equations 13.6, 13.7, and 13.8. The last two quantities, $\Delta[N_2]/\Delta t$ and $\Delta[O_2]/\Delta t$, are equal—that is, N_2 and O_2 are both reactants with the same stoichiometric coefficient (1) in Equation 13.1, so their concentrations decrease at the same rate as the reaction proceeds. The value of $\Delta[NO]/\Delta t$ during the same interval is different, however, because the coefficient of 2 for NO in Equation 13.1 indicates that 2 moles of NO form for every 1 mole of N_2 or O_2 that reacts. Therefore, the rate of increase in the concentration of NO is *twice* the rate of decrease in the concentrations of N_2 and O_2. We can express these relative rates of change by using an equation:

Put another way, the rate at which either N_2 or O_2 is consumed is *half* the rate at which NO is produced, as we see if we divide Equation 13.9 through by 2:

Why are there minus signs on the terms describing the rates of consumption of N_2 and O_2? The rate of change in the concentration of a reactant ($\Delta[\text{reactant}]/\Delta t$) has a negative value because reactant concentrations decrease as a reaction proceeds. In Equation 13.7, for example, $[N_2]_{initial}$ is greater than $[N_2]_{final}$, which means that the numerator of the equation has a negative value. On the other hand, the rate of change in the concentration of a product is always positive because its value increases as the reaction proceeds. The measured rate of any reaction is defined as a positive quantity, so a minus sign is used with $\Delta[\text{reactant}]/\Delta t$ values to obtain a positive value for the reaction rate.

Note that the number 2 in the denominator of the $\Delta[\text{NO}]/\Delta t$ term in Equation 13.10 matches the coefficient of NO in the balanced chemical equation. This pattern applies to all chemical reactions: the coefficient of each species in the balanced chemical equation appears in the *denominator* of its term in the relative rate expression if the numerator values are all 1.

SAMPLE EXERCISE 13.1 Predicting a Relative Reaction Rate LO1

The synthesis of ammonia:

$$N_2(g) + 3\ H_2(g) \rightarrow 2\ NH_3(g)$$

is an important reaction in the production of agricultural fertilizers. Derive an equation that relates the rates of change in the concentrations of N_2, H_2, and NH_3.

Collect and Organize We are given the balanced chemical equation describing the synthesis of NH_3 from N_2 and H_2, and we need to relate the rates of change in the concentrations of its reactants and product: $\Delta[N_2]/\Delta t$, $\Delta[H_2]/\Delta t$, and $\Delta[NH_3]/\Delta t$.

Analyze Nitrogen and hydrogen are consumed in the reaction, which means the values of $\Delta[N_2]/\Delta t$ and $\Delta[H_2]/\Delta t$ are negative. Therefore, we need to place minus signs in front of these terms in an equation that includes the positive $\Delta[NH_3]/\Delta t$ term. The coefficients of N_2, H_2, and NH_3 are 1, 3, and 2, respectively, so the coefficients in their rate of change terms are 1, 1/3, and 1/2.

Solve The relative rates are related as follows:

Think About It The solution to the problem tells us that the rate of consumption of N_2 is one-third the rate of consumption of H_2, which makes sense given that three molecules of H_2 react for every one molecule of N_2. Likewise, the rate of consumption of N_2 is one-half the rate of production of NH_3 because two molecules of NH_3 are produced for every molecule of N_2 that reacts.

Practice Exercise How is the rate of change in the concentration of CO_2 related to the rate of change in the concentration of O_2 during the oxidation of carbon monoxide? The equation is

$$2\ CO(g) + O_2(g) \rightarrow 2\ CO_2(g)$$

(Answers to Practice Exercises are in the back of the book.)

Experimentally Determined Reaction Rates

Rates of product formation or reactant consumption are ratios of changes in concentration divided by changes in time, so they have units of concentration per unit time, such as molarity per second (*M*/s). Reaction rates can only be determined experimentally. Once the rate of a reaction is known, it can be used along with the coefficients in the balanced equation describing the reaction to calculate the rate of change in the concentration of any reactant or product.

For example, suppose we find that the rate of production of ammonia in the reaction in Sample Exercise 13.1 is 0.472 *M*/s, and we want to calculate the rate of consumption of N_2 during the reaction. To do so, we insert the known value of $\Delta[NH_3]/\Delta t$ into the equation derived in Sample Exercise 13.1 and solve for $\Delta[N_2]/\Delta t$:

This result makes sense because (1) it is negative, reflecting the decreasing concentration of a reactant, and (2) its absolute value is half the rate of production of ammonia, which fits the stoichiometry of the reaction equation.

Of the two values ($\Delta[NH_3]/\Delta t = 0.472$ *M*/s or $\Delta[N_2]/\Delta t = -0.236$ *M*/s), which, if either, should we use to express the rate of the reaction? The answer is that rate of any reaction is based on the rate of change in the concentration of the reactant or product with a coefficient of 1 in the reaction equation. If none of the coefficients is 1, divide the rate of change in the concentration of any of the products by its coefficient to get the reaction rate. Furthermore, the reaction rate is always expressed as a positive value. Therefore, the rate of the ammonia reaction described above is 0.236 *M*/s.

We have just seen how a balanced chemical equation enables us to predict the *relative* rates at which reactants are consumed and products are formed in a particular reaction. It provides no information, however, on the numerical values of the rates. Although computational tools can be used to predict the rates of very simple reactions, in this chapter we limit our discussion of actual reaction rates to those based on experiments.

SAMPLE EXERCISE 13.2 Converting Reaction Rates LO1

Suppose that during the reaction between NO and O_2 to form NO_2,

$$2\ NO(g) + O_2(g) \rightarrow 2\ NO_2(g)$$

the rate of change in the concentration of O_2 is -0.033 *M*/s. What is the rate of formation of NO_2?

Collect and Organize We need to determine the rate of formation of a product in a reaction, knowing the balanced chemical equation and the rate of change in concentration of one of the reactants. The rate of formation of NO_2 is related to the rates of consumption of NO and O_2 by the balanced chemical equation. The coefficients of O_2 and NO_2 are 1 and 2, respectively.

Analyze We can write an equation that expresses the relative rates of change in $[O_2]$ and $[NO_2]$ from the coefficients in the balanced chemical equation:

The negative sign is needed because the concentration of O_2 decreases as the concentration of NO_2 increases.

Solve Solving for the rate of change of $[NO_2]$, we get

Think About It This result is twice the magnitude of $\Delta[O_2]/\Delta t$, which is consistent with the stoichiometry of the reaction: 2 moles of NO_2 are produced for every mole of O_2 that reacts.

Practice Exercise The gas NO reacts with H_2, forming N_2 and H_2O:

$$2\ NO(g) + 2\ H_2(g) \rightarrow 2\ H_2O(g) + N_2(g)$$

If $\Delta[NO]/\Delta t = -21.5\ M/s$ under a given set of conditions, what are the rates of change of $[N_2]$ and $[H_2O]$?

Average Reaction Rates

Suppose we run an experiment to determine the rate of formation of NO in an automobile engine. In the laboratory, we use a reaction vessel as hot as the combustion chambers in the engine, and we obtain the data listed in **Table 13.1** and plotted in **Figure 13.6**. We can use the data to calculate the reaction rate based on the change in the concentration of any participant in the reaction over a particular interval. Such calculations of reaction rates based on $-\Delta[\text{reactant}]/\Delta t$ or $\Delta[\text{product}]/\Delta t$ are *average* reaction rates. Suppose, for example, that we want to calculate the average rate of change in [NO] between 5.0 and 10.0 μs:

During the same interval, the average rate of change in the concentration of N_2 (or O_2) is

These results give us two $\Delta[X]/\Delta t$ values for expressing the rate of the reaction. By convention we choose the value associated with the substance having a coefficient of 1 in the balanced equation, though we have to change the value's sign if that substance is a reactant. This means we can choose the rate of change of either $[N_2]$ or $[O_2]$. Therefore, the average rate of this reaction is

The numerical value of this reaction rate applies only to the interval from $t = 5.0$ μs to $t = 10.0$ μs because the graph lines in Figure 13.6 are curved. Any other 5.0 μs interval would have a different average rate because the reaction slows as more time passes.

Instantaneous Reaction Rates

We can also determine the *instantaneous* rate of a reaction—that is, its rate at a particular instant during the reaction. To see how, let's revisit the oxidation of NO to NO_2 in the atmosphere:

Suppose that chemical analyses of a reaction mixture of these three gases yield the concentration data listed in **Table 13.2**. Among the three gases, only O_2 has a coefficient of 1 in the balanced chemical equation, so we will use the rate of change of $[O_2]$ to calculate the rate of the reaction.

What is the instantaneous rate of the reaction at $t = 2000.0$ s? We can plot the $[O_2]$ data from Table 13.2 versus time—this is the green curve in **Figure 13.7**—and then draw a tangent to the curve at $t = 2000.0$ s. Next, we select two convenient points along the tangent—for example, at $t = 1000.0$ s and $t = 3000.0$ s—to use in calculating the slope of the tangent. The slope is a measure of the instantaneous rate of change in $[O_2]$ at $t = 2000.0$ s, and the negative of the slope is the instantaneous rate of the reaction at that time.[2]

CONCEPT TEST

Which of the following statements is/are true about the instantaneous rate of the chemical reaction $A \rightarrow B$ as the reaction proceeds?

1. $-\Delta[A]/\Delta t$ increases, $\Delta[B]/\Delta t$ decreases
2. $-\Delta[A]/\Delta t$ decreases, $\Delta[B]/\Delta t$ increases
3. $-\Delta[A]/\Delta t$ and $\Delta[B]/\Delta t$ both increase
4. $-\Delta[A]/\Delta t$ and $\Delta[B]/\Delta t$ both decrease

(Answers to Concept Tests are in the back of the book.)

SAMPLE EXERCISE 13.3 Determining an Instantaneous Reaction Rate LO2

(a) What is the instantaneous rate of change of [NO] at $t = 2000.0$ s in the experiment that produced the data in Table 13.2? (b) What is the rate of the reaction based on your result in part (a)?

Collect and Organize We are asked to determine the instantaneous rate of change of [NO] and the corresponding reaction rate at $t = 2000.0$ s. The coefficient of NO is 2 in the balanced chemical equation:

$$2\ NO(g) + O_2(g) \rightarrow 2\ NO_2(g)$$

Analyze The instantaneous rate of change in [NO] at 2000.0 s can be determined from a graph of [NO] versus time and the slope of the curve at 2000.0 s. The corresponding reaction rate will be the slope value multiplied by $-1/2$.

Solve

1. First we plot [NO] versus time and draw a tangent to the curve at the point $t = 2000.0$ s (**Figure 13.8**). We then choose two points along the tangent, $t = 1000.0$ and 3000.0 s, and determine the concentrations corresponding to those times along the vertical axis. By using those values, we calculate the slope of the line:
$$\frac{\Delta[\mathrm{NO}]}{\Delta t} = \frac{(0.0046 - 0.0070)\ M}{(3000.0 - 1000.0)\ \mathrm{s}} = -1.2 \times 10^{-6}\ M/\mathrm{s}$$

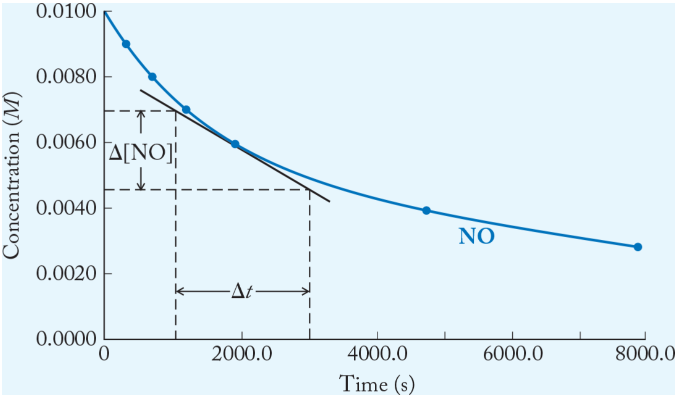

FIGURE 13.8 Plot from data in Table 13.2.

We could also have used a scientific calculator or a graphing program to calculate the slope of the tangent.

2. The corresponding reaction rate is

$$\text{Rate} = -\frac{1}{2}\frac{\Delta[\text{NO}]}{\Delta t} = -\frac{1}{2}(-1.2 \times 10^{-6}\ M/\text{s}) = 6.0 \times 10^{-7}\ M/\text{s}$$

Think About It The sign of $\Delta[\text{NO}]/\Delta t$ is negative because NO is a reactant whose concentration decreases with time. However, the rates of chemical reactions have positive values. Therefore, we needed a minus sign in front of the $\Delta[\text{NO}]/\Delta t$ term in the solution to part (b). Note that the instantaneous reaction rate calculated in this exercise is the same as the one we calculated previously based on the rate of change of $[O_2]$.

Practice Exercise What is the instantaneous rate of change in $[NO_2]$ at $t = 2000.0$ s in the experiment that produced the data in Table 13.2?

Endnotes

- If you have studied calculus, you may know that the average rate of a reaction approaches the instantaneous rate as Δt approaches zero. The slope of the tangent to a curve at a given point is the derivative of the curve at that point and can be calculated using a scientific calculator. Appendix 1 discusses how to determine the slope and intercept of a line. Return to reference 2

FIGURE 13.17 Summary of how to distinguish between zero-order, first-order, and second-order kinetics for reactions involving a

single reactant (X).

13.3 Effect of Concentration on Reaction Rate

Figure 13.9 shows a typical plot of reactant concentration as a function of time. Tangents have been drawn to the curve at three points: (a) at the instant the reaction begins ($t = 0$), (b) when the reaction is about halfway to completion, and (c) when the reaction is nearly over. The slope of the tangent at point (a) can be used to calculate the initial rate of the reaction.

As with nearly all plots of reactant or product concentration versus time, the most rapid changes in concentration take place at the beginning of the reaction. As the reaction proceeds, the slopes of tangents to the curve decrease, approaching zero. When the slope of the tangent to the curve reaches zero, there are no more changes in the concentrations of the product(s) or any remaining reactant(s).

Kinetic molecular theory explains why reaction rates change over time. If we assume that most reactions take place as a result of collisions between reactant molecules, then the more reactant molecules there are in a given volume, the more collisions per unit time there are, and there are more opportunities for reactants to turn into products. As reactants collide and change into products, fewer reactant molecules are present in the system (i.e., the concentrations of the reactants decrease), so the frequency of collisions decreases and the rate at which reactants change into products slows down.

Reaction Order and Rate Constants

Experimental observations and theoretical considerations tell us that reaction rates depend on reactant concentrations. However, they do not tell us *to what extent* rates depend on reactant concentrations. For example, if the concentration of a reactant doubles, does the reaction rate also double? The answer to this question comes from experimentally determining the reaction order, a parameter that tells us how reaction rate depends on reactant concentrations. Knowing the order of a reaction also provides insights into how the reaction takes place—that is, which molecules collide with which other molecules as bonds break, new bonds form, and reactants are converted into products.

Let's consider one way in which reaction order is determined by revisiting the reaction between nitrogen monoxide and oxygen:

To evaluate the kinetics of this reaction, multiple experiments can be conducted, each with different initial concentrations of NO and O_2 introduced into a reaction vessel at 25°C, and the initial reaction rate is determined in each case. **Table 13.3** shows the results of three such determinations.

TABLE 13.3 Effect of Reactant Concentrations on Initial Reaction Rates at 25°C for the Reaction $2\ NO(g) + O_2(g) \rightarrow 2\ NO_2(g)$

Experiment	$[NO]_0$ (M)	$[O_2]_0$ (M)	Initial Reaction Rate (M/s)
[illegible]	[illegible]	[illegible]	[illegible] $\times 10^{-6}$
[illegible]	[illegible]	[illegible]	[illegible] $\times 10^{-6}$
[illegible]	[illegible]	[illegible]	[illegible] $\times 10^{-7}$

To interpret the data in Table 13.3, we select pairs of experiments in which the concentrations of one reactant differ but the concentrations of the other are the same. For example, $[NO]_0$ is the same in experiments 1 and 2, but $[O_2]_0$ in experiment 1 is twice $[O_2]_0$ in experiment 2. (The zero subscripts indicate that these are the concentrations of NO and O_2 at the start of the experiments, when $t = 0$.) The initial reaction rate in experiment 1 is twice that in experiment 2, allowing us to state that doubling the concentration of O_2 while holding the NO concentration constant doubles the initial reaction rate. We conclude that the initial reaction rate is directly proportional to the O_2 concentration:

$$\text{Rate}\ \alpha\ [O_2]$$

In experiments 1 and 3, $[O_2]_0$ is the same, but $[NO]_0$ in experiment

1 is twice $[NO]_0$ in experiment 3. Comparing the initial reaction rates for these two experiments, we find that the rate in experiment 1 is four times the rate in experiment 3. Thus, the reaction rate is proportional to the square of the NO concentration:

$$\text{Rate} \propto [NO]^2$$

Collision Theory

We can combine these two rate expressions to get an overall rate expression for the reaction by multiplying the right sides of the rate expressions for the two reactants:

$$\text{Rate} \propto [NO]^2[O_2]$$

To understand why we multiply the concentration terms together, let's consider another reaction between oxygen and nitrogen monoxide. This one involves the reaction of ozone (O_3) with NO that produces NO_2 and O_2:

$$NO(g) + O_3(g) \rightarrow NO_2(g) + O_2(g)$$

Figure 13.10 shows how different numbers of NO and O_3 molecules in a reaction vessel might collide with each other and how the probability of collisions between NO and O_3 molecules increases in proportion to the *product* of the number of NO molecules times the number of O_3 molecules. If the reaction occurs as a result of these collisions, then increasing the number of collisions should produce a proportionate increase in the rate of the reaction. Therefore, the rate of the reaction should depend on the product of the concentrations of NO and O_3:

Similar patterns exist for other chemical reactions whose rates depend on the frequency of molecular collisions. We can convert the expression in Equation 13.11 into the rate law for this reaction, which is an equation that relates reaction rate to reactant concentrations, by inserting a proportionality constant *k*, called the reaction's rate constant:

Now let's consider a generic chemical reaction with two reactants, A and B:

$A + B \rightarrow C$

The rate law expression for this reaction may be written

where *m* is the reaction order with respect to A, and *n* is the reaction order with respect to B. There is no [C] term in the rate law for this reaction because the rates of most chemical reactions depend on the concentrations of one or more reactants, and *never* on the concentrations of products.

We can determine reaction order values by comparing differences in reaction rates with differences in reactant concentrations. Sometimes these comparisons are easy to make, as with the data for the reaction between NO and O_2 in Table 13.3. Other times the comparisons are not so easy. On those occasions we can use a different mathematical approach. For example, suppose we conduct three experiments to solve for the values of *m* and *n* in Equation 13.13. In experiments 1 and 2 the value of [A] is the same, but the values of [B] are different. In experiments 2 and 3 we keep [B] constant and vary the concentrations of [A]. The ratio of the reaction rates in experiments 1 (Rate_1) and 2 (Rate_2) is related to the ratio of the concentrations of B:

We can solve this equation for *n* by taking the logarithm of both sides:

Now rearrange the terms to solve for *n*:

An equation with this format can also be used to calculate the value of *m* from the results of experiments 2 and 3, or to calculate the order of any reaction with respect to a reactant (X) whose concentration differs in a pair of reaction rate experiments:

CONCEPT TEST

In the reaction A → B, the rate of the reaction triples when [A] is tripled.

1. What is the correct value of m in the rate law: rate $= k[\mathrm{A}]^m$?
2. What is the value of m if the rate is unchanged when [A] is tripled?

The power to which a concentration term is raised (such as the m or n in Equation 13.13) is the order of the reaction in terms of that reactant. In our example from Table 13.3, the reaction of NO and O_2 is *second order* in NO and *first order* in O_2. The overall reaction order for a reaction is the sum of the powers in the rate equation, so the reaction of NO and O_2 is *third order* overall.

An exponent in a rate law may be a whole number, a fraction, zero, or, in rare cases, negative. It is important to remember that rate laws and reaction orders must be determined experimentally. They cannot be predicted from the coefficients in a balanced chemical equation, even though they sometimes do match the coefficients. The significance of reaction order in describing how a reaction takes place is addressed in Section 13.5.

The value of the rate constant k is unique to each particular reaction at a given temperature, and right now we will consider k simply as a proportionality constant. It does not change with concentration; in other words, *reaction rate depends on the concentration of the reactants, but the rate constant does not.* The rate constant changes only with changing temperature or in the presence of a catalyst.

We can calculate k for a reaction run at some specified temperature from initial reaction rate data. Let's do so for the reaction of O_2 and NO by selecting the results of one experiment in Table 13.3. Which experiment we use does not matter; as long as the temperature is the same, the value of *k* will be the same. The proportionality we derived for this reaction's overall rate expression was

$$\text{Rate} \propto [\text{NO}]^2[\text{O}_2]$$

When we convert this to an equation, we obtain

$$\text{Rate} = k[\text{NO}]^2[\text{O}_2]$$

We can insert the data from experiment 1 into this equation and solve for *k*:

This value, like any rate constant calculated from experimental data, is valid only at the temperature at which the experiments were carried out.

The units of *k* look a bit unusual in comparison with units we have seen before. Remember that reaction rates themselves have units of concentration per unit time, such as *M*/s. In a first-order reaction, then, in which concentration is expressed in molarity and time in seconds, the units of *k* must be per second (s^{-1}):

TABLE 13.4 Units on Rate Constants for Different Reaction Orders

Overall Reaction Order	**Units on *k***
1	s^{-1}
2	$M^{-}s^{1}$
3	$M^{-2}s^{-1}$
4	$M^{-3}s^{-1}$

The units of the rate constant for a reaction that is second order overall can be derived in a similar way. If the reaction is first order in reactants X and Y, we have

The units of *k* for a reaction that is third order overall are $M^{-2}s^{-1}$, as we determined in Equation 13.15. Therefore, the units of *k* for each reaction ultimately depend on its overall reaction order as summarized in **Table 13.4**.

CONCEPT TEST

The reaction A + 2 B → C is found to be third order overall. How many possible rate laws of the form

$$\text{Rate} = k[\text{A}]^m[\text{B}]^n$$

could we write, assuming that m and n are non-negative integers?

SAMPLE EXERCISE 13.4 Deriving a Rate Law from Initial Reaction Rate Data LO3

Use the data in **Table 13.5** to write the rate law for the following reaction of N_2 with O_2:

$$N_2(g) + O_2(g) \rightarrow 2\ NO(g)$$

Determine the overall reaction order and the value of the rate constant.

TABLE 13.5 Initial Reaction Rates at Constant Temperature for the Reaction $N_2(g) + O_2\,(g) \rightarrow 2\ NO(g)$

[illegible]
[illegible]
[illegible]
[illegible]

Collect and Organize We need to determine the rate law and rate constant for a reaction, given the initial reaction rate (note the subscript zero on the concentration terms in Table 13.5) for each of three sets of initial concentrations.

Analyze The general form of the rate law for any reaction between reactants A and B is

$$\text{Rate} = k[\text{A}]^m[\text{B}]^n$$

We can use the experimental data given to find the values of k, m, and n for the reaction in which $[A] = [N_2]$ and $[B] = [O_2]$. The overall order of the reaction is the sum of the reaction orders of the individual reactants. Once we have established the rate law, we can calculate the rate constant by using concentrations of reactants from any row in Table 13.5. The rate constant must have units that express the reaction rate in $M\ s^{-1}$.

Solve To determine the order of the reaction (m) with respect to N_2, we use the data from experiments 2 and 3 because in these two experiments the $[N_2]$ values are different, but the $[O_2]$ values are the same. When the concentration of N_2 is increased by a factor of 4, the rate increases by a factor of 4. Thus, the reaction rate is proportional to $[N_2]$, which means that $m = 1$. We can confirm the value of m by applying Equation 13.14:

There are different values of $[O_2]$ in experiments 1 and 2, but $[N_2]$ is the same. Therefore, we can use these data to calculate the value of n. The ratio of the reaction rates (707/500) is not a whole number, so let's apply Equation 13.14:

Thus, the reaction is $\frac{1}{2}$ order with respect to O_2, first order with respect to N_2, and $\left(\frac{1}{2} + 1\right) = \frac{3}{2}$ order overall:

$\text{Rate} = k[N_2][O_2]^{1/2}$

We can use the data from any experiment to obtain the value of k. Let's use experiment 1:

$707\ M/s = k(0.040\ M)(0.020\ M)^{1/2}$

$k = 1.2 \times 10^5\ M^{-1/2}\ s^{-1}$

Think About It The units of the rate constant, $M^{-1/2}\ s^{-1}$, are appropriate because when we substitute the units for each term into the rate law, we end up with the correct units for reaction rate: (M

$^{-1/2}$ s^{-1})(M)($M^{1/2}$) = M s^{-1}. The reaction order of $\frac{1}{2}$ for oxygen is determined from experimental data, not from the balanced chemical equation.

Practice Exercise Nitrogen monoxide reacts rapidly with unstable nitrogen trioxide (NO_3) to form NO_2:

$NO(g) + NO_3(g) \rightarrow 2\ NO_2(g)$

Determine the rate law for the reaction and calculate the rate constant from the data in **Table 13.6**.

TABLE 13.6 Initial Reaction Rates at 25°C for the Reaction $NO(g) + NO_3(g) \rightarrow 2\ NO_2(g)$

Experiment	[NO] (M)	[NO_3] (M)	Initial Reaction Rate (M/s)
1	1.25×10^{-3}	1.25×10^{-3}	2.45×10^{-4}
2	1.25×10^{-3}	2.50×10^{-3}	4.90×10^{-4}
3	2.50×10^{-3}	2.50×10^{-3}	9.80×10^{-4}

Integrated Rate Laws: First-Order Reactions

Determining a rate law by using initial reaction rate data means that several experiments must be performed with different concentrations of reactants, and that these concentrations must be manipulated in a systematic fashion. We also must accurately determine the reaction rate at the instant the reaction begins. It would be much better if we could determine the rate law and calculate the rate constant of a reaction by using data from only a single experiment. In fact, we can do this for reactions in which the reaction rate depends on the concentration of only one substance. One such reaction is the photochemical decomposition of ozone in the stratosphere:

TABLE 13.7 Concentrations for Photochemical Decomposition of Ozone

[illegible]
[illegible] $\times 10^{-4}$
[illegible] $\times 10^{-4}$
[illegible] $\times 10^{-4}$
[illegible] $\times 10^{-4}$
[illegible] $\times 10^{-4}$
[illegible] $\times 10^{-4}$
[illegible] $\times 10^{-4}$

This decomposition reaction can be studied in the laboratory by using high-intensity ultraviolet lamps to simulate solar radiation. One such study yielded the results listed in **Table 13.7**. The data were plotted (**Figure 13.11a**) using the graphing feature of a computer spreadsheet program (Excel). Because ozone is the only reactant, the rate law for the reaction should depend only on the ozone concentration. In our interpretation of the data in Table 13.7, we start with the assumption that the reaction is first order in O_3, which means that the rate law can be written

$$\text{Rate} = k[O_3]$$

The O_3 consumption rate $-\Delta[O_3]/\Delta t$ equals the reaction rate, and we can write

This rate law can be transformed into an expression that relates the concentration of ozone $[O_3]$ at any instant during the reaction to the initial concentration $[O_3]_0$:

Note that Equation 13.16 uses ln, the *natural* logarithm function, not log, the base 10 logarithm function. This version of the rate law is called an integrated rate law because integral calculus is used to derive it, and it describes the change in reactant concentration with time. The general integrated rate law for any reaction that is first order in reactant X is

Using the identity $\ln(a/b) = \ln a - \ln b$, we can rearrange this equation to

This is the equation of a straight line of the form

$$y = mx + b$$

where $\ln[X]$ is the y variable and t is the x variable. The slope of the line (m) is $-k$, and the y intercept (b) is $\ln[X]_0$. Rearranging Equation 13.16 to fit the format of Equation 13.18 gives

$$\ln[O_3] = -kt + \ln[O_3]_0$$

A graph of the natural logarithm of $[O_3]$ versus time does indeed produce a straight line as shown in **Figure 13.11b**. This linearity means that our assumption was correct and the reaction is first order in O_3.

TABLE 13.8 Concentration of N_2O_5 and $\ln[N_2O_5]$ as a Function of Time

Time (s)	$[N_2O_5]$ (M)	$\ln[N_2O_5]$
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]

The same spreadsheet program that was used to plot the data is also used to calculate the equation of the line that best fits all the data points, which is also shown in Figure 13.11b. The program does not display the units of the slope, but we know that the slope of the line represents the ratio of $\Delta\ln[O_3]/\Delta t$. Logarithm terms are unitless and the time values in this data set are expressed in seconds, so the units on the slope value are actually 1/s or s^{-1}. Therefore, the value of m is $-0.00110\ s^{-1}$ and the value of k is $-(-0.00110\ s^{-1})$ or $1.10 \times 10^{-3}\ s^{-1}$.

SAMPLE EXERCISE 13.5 Using an Integrated Rate Law LO4

The concentration of dinitrogen pentoxide in the atmosphere is low in part because it rapidly decomposes to N_2O_4 and O_2:

$$2\ N_2O_5(g) \rightarrow 2\ N_2O_4(g) + O_2(g)$$

A kinetic study of the decomposition of N_2O_5 at a particular temperature yielded the data in the first two columns of **Table 13.8**. Assume that the decomposition of N_2O_5 is first order in N_2O_5. (a) Test the validity of your assumption, and (b) determine the value of the rate constant.

Collect and Organize We are given experimental data showing the concentration of a single reactant as a function of time and are told to assume a first-order reaction. We can verify the assumption by using the integrated rate law for a first-order reaction (Equation 13.18) and then calculate the rate constant.

Analyze Equation 13.18 has the form $y = mx + b$, which means that a plot of $\ln[N_2O_5](y)$ versus time (x) should be linear if the decomposition of N_2O_5 is first order. The slope (m) of the graph corresponds to $-k$, the negative of the rate constant.

Solve The first step is to convert the $[N_2O_5]$ values into $\ln[N_2O_5]$ values, which are listed in the third column of Table 13.8.

1. Plotting the time and $\ln[N_2O_5]$ values in Table 13.8 as x and y variables produces the graph shown in **Figure 13.12**. The same spreadsheet program that plots the data also calculates the equation of the straight line that best fits the data (Figure 13.12). All of the points lie near a straight line, confirming that the reaction is first order in N_2O_5.
2. The value of the rate constant (k) is the negative of the value of the slope of the line and has units of s^{-1}, which makes it $-(-0.00693\ s^{-1})$ or $6.93 \times 10^{-3}\ s^{-1}$.

Think About It Using a calculator or computer program to plot the data and determine the slope of the line that best fits it tends to generate the most accurate slope and rate constant values because these programs use all of the points in the data set. To check our answer, we can calculate the slope, $\Delta y/\Delta x$, using the coordinates of two of the plotted points. For example, had we estimated the slope using the coordinates for the points at $t = 100.0$ and 400.0 seconds, we would have obtained a value of k equal to $-[-5.133 - (-2.881)]/(400.0 - 100.0)\ \mathrm{s} = 7.51 \times 10^{-3}\ \mathrm{s}^{-1}$, which is 8.3% higher than the slope calculated using all of the data points. Calculating slope in this fashion is likely to be less accurate because there is inherent uncertainty in experimental results that can cause some of the plotted points to be slightly above or below the line that best fits them, as you can see in Figure 13.12.

Practice Exercise Hydrogen peroxide (H_2O_2) decomposes into water and oxygen:

Use the data in **Table 13.9** to determine whether the decomposition of H_2O_2 is first order in H_2O_2, and calculate the value of the rate constant at the temperature of the experiment that produced the data.

TABLE 13.9 Concentration of Hydrogen Peroxide as a Function of Time

Time (s) / [H_2O_2] (M)

[illegible]		

SAMPLE EXERCISE 13.6 Calculating the Concentration of a Reactant from an Integrated Rate Law LO5

In Sample Exercise 13.5 we confirmed that the decomposition of dinitrogen pentoxide

$2\ N_2O_5(g) \rightarrow 2\ N_2O_4(g) + O_2(g)$

is first order in N_2O_5 and has a rate constant $k = 0.00693\ s^{-1}$. If this reaction is run in the laboratory under the same conditions as in Sample Exercise 13.5 and the initial concentration of N_2O_5 in the reaction vessel is 0.375 *M*, what is the concentration of N_2O_5 after exactly 3 minutes?

Collect and Organize We are given the rate constant for a first-order reaction, the initial concentration of reactant, and the reaction time. We are asked to calculate the concentration of reactant remaining at that time. We also have the general rate equation for a first-order reaction (Equation 13.18).

Analyze We know all the terms in the rate equation

$\ln[X] = -kt + \ln[X]_0$

except [X], which is what we want to calculate. The rate constant *k* is given in terms of seconds, so we must convert $t = 3$ min into $t = 180$ s. In the data set for Sample Exercise 13.5, $[N_2O_5]$ dropped to about $\frac{1}{4}[N_2O_5]_0$ in 200 s, so we estimate that the concentration of N_2O_5 in this example will drop to about one-quarter of its initial value, or around 0.09 *M*.

Solve Substituting the given values into Equation 13.18:

$\ln[X] = -kt + \ln[X]0$

$\ln[N_2O_5\ ] = -(0.00693\ s^{-1})(180\ s) + \ln(0.3752)$

$\ln[N_2O_5\ ] = -1.247 + (-0.981) = -2.228$

$[N_2O_5] = e_{-22.228} = 0.108\ M$

Think About It The answer is less than the starting concentration of N_2O_5, as we would expect, and close to our estimated value.

Practice Exercise Under a different set of conditions from those in Sample Exercise 13.5, dinitrogen pentoxide decomposes into nitrogen dioxide and O_2:

$$2\ N_2O_5(g) \rightarrow 4\ NO_2(g) + O_2(g)$$

This reaction is also first order in N_2O_5 and has a rate constant $k = 9.55 \times 10^{-4}\ s^{-1}$. What is the concentration of N_2O_5 in this system after exactly 10 min if $[N_2O_5]_0 = 0.763\ M$?

Reaction Half-Lives

A parameter frequently cited in kinetic studies is the half-life ($t_{1/2}$) of a reaction, which is the interval during which the concentration of a reactant decreases by half. Half-life is inversely related to the rate constant of a reaction: the higher the reaction rate, the shorter the half-life.

Let's consider reaction half-life in the context of another nitrogen oxide found in the atmosphere: dinitrogen monoxide, also called nitrous oxide or laughing gas, an anesthetic sometimes used by dentists. Atmospheric concentrations of this potent greenhouse gas have been increasing in recent years, although the principal source is not automotive emissions but rather bacterial degradation of nitrogen compounds in soil. Dinitrogen monoxide is not produced in internal combustion engines, because at high temperatures, N_2O rapidly decomposes (**Figure 13.13**) into nitrogen and oxygen:

We can derive a mathematical relation between half-life $t_{1/2}$ and rate constant k for this or any other first-order reaction by starting with Equation 13.17:

After one half-life has passed, $t = t_{1/2}$, and the concentration of X is half its original value: $[X]_0/2$. Inserting these values for [X] and t into the equation yields

The natural log of $\frac{1}{2}$ is -0.693, so

$-0.693 = -kt_{1/2}$

or

Thus, the half-life of a first-order reaction is inversely proportional to the rate constant, as noted at the beginning of this discussion. The absence of any concentration term in Equation 13.19 means that the half-life of a first-order reaction is constant throughout the reaction and independent of concentration: no matter the initial concentration of the reactant, half of it is consumed in one half-life.

SAMPLE EXERCISE 13.7 Calculating the Half-Life of a First-Order Reaction LO5

The rate constant for the decomposition of N_2O_5 at a particular temperature is $7.8 \times 10^{-3}\ s^{-1}$. What is the half-life of N_2O_5 at that temperature?

Collect, Organize, and Analyze We are asked to determine the half-life of N_2O_5 from the rate constant of its decomposition reaction. We know from Sample Exercise 13.5 that the decomposition of N_2O_5 is a first-order process, so the values of $t_{1/2}$ and k are related by Equation 13.19.

Solve

Think About It The calculated value makes sense because the k value is small—a little less than 0.01—so dividing 0.693 by it should produce a $t_{1/2}$ value a little larger than 69 s. Remember that Equation 13.19 is valid for first-order reactions only.

Practice Exercise Environmental scientists calculating half-lives of pollutants often define a *transport rate constant* that is analogous to a reaction rate constant and describes how rapidly a pollutant washes out of an ecosystem. In a study of the gasoline additive MTBE in Donner Lake, California, scientists from the University of California, Davis, found that in the summer the half-life of MTBE in the lake was 28 days. Assuming that the transport process is first order, what was the transport rate constant of MTBE out of Donner Lake during the study? Express your answer in reciprocal days.

CONCEPT TEST

Which has a shorter half-life, a fast reaction or a slow reaction?

Integrated Rate Laws: Second-Order Reactions

In Section 13.1 we described how NO_2 exposed to UV rays from the Sun decomposes to NO and atomic oxygen (O). Nitrogen dioxide may also undergo thermal decomposition, producing NO and molecular oxygen (O_2):

The data in **Table 13.10** describe the rate of the thermal decomposition reaction. In this case, the plot of ln[NO_2] versus time (**Figure 13.14a**) is *not* linear, which means the thermal decomposition of NO_2 is *not* first order.

TABLE 13.10 Decomposition of NO_2 as a Function of Time

[illegible]			
[illegible]			
[illegible]			

[illegible] $\times 10^{-3}$			
[illegible] $\times 10^{-3}$			
[illegible] $\times 10^{-3}$			
[illegible] $\times 10^{-3}$			
[illegible] $\times 10^{-3}$			

What, then, is the order of the reaction? The answer is related to how the reaction takes place. If each NO_2 molecule simply fell apart, the reaction would be first order, much like the decomposition of N_2O_5. However, if the reaction happens as a result of collisions between pairs of NO_2 molecules, the reaction would be first order in each one of them and *second order* overall. In that case, the rate law expression would be

How can we determine whether this decomposition is really second order? One way is to assume that it is and then test that assumption. The test entails transforming the rate law in Equation 13.21 into the integrated rate law for a second-order reaction, again using calculus. The result of the transformation is

Like Equation 13.18, this has the form $y = mx + b$ and is the equation of a straight line, this time with $1/[NO_2]$ as the y variable and t as the x variable.

The graph obtained using data from columns 1 and 4 of Table 13.10 is shown in **Figure 13.14b**. The curve is linear, which means the decomposition of NO_2 is second order. The slope of the line provides a direct measure of k, which is 0.544 $M^{-1}\ s^{-1}$.

A general form of Equation 13.22 that applies to any reaction that is second order in a single reactant (X) is

SAMPLE EXERCISE 13.8 Distinguishing between First- and Second-Order Reactions LO4

Chlorine monoxide accumulates in the stratosphere above Antarctica each winter and plays a key role in the formation of the ozone hole above the South Pole each spring. Eventually, ClO decomposes according to the equation

$$2\ \mathrm{ClO}(g) \rightarrow \mathrm{Cl_2}(g) + \mathrm{O_2}(g)$$

A study of the kinetics of this reaction at 298 K yielded the data shown in the first two columns of **Table 13.11**. Determine the order of the reaction, the rate law, and the value of *k* at 298 K.

[illegible]			

Collect and Organize We are given experimental data describing the variation in concentration of ClO with time at 298 K, and we are asked to determine the order (first or second) of the decomposition reaction of ClO.

Analyze To distinguish between first and second order for a reaction in which ClO is the single reactant, we need to calculate ln[ClO] and 1/[ClO] values and plot them versus time. If the ln[ClO] plot is linear, the reaction is first order; if the 1/[ClO] plot is linear, the reaction is second order. The rate law has the form

$$\text{Rate} = k[\mathrm{ClO}]^m$$

where *m* equals 1 or 2 and, because there is only one reactant, *m* is also the overall order of the reaction. We determine the rate constant from the slope of whichever plot is linear.

Solve The last two columns of Table 13.11 contain the needed ln[ClO] and 1/[ClO] values. Plots of these values versus time, which were generated using Excel, are shown in **Figure 13.15**. The ln[ClO] plot is not linear, but the 1/[ClO] plot is, which means that the reaction is second order in ClO and second order overall. Thus, $m = 2$ and the rate law is

$$\text{Rate} = k[\text{ClO}]^2$$

Substituting [ClO] into the generic integrated rate law (Equation 13.23) gives

---

From the general equation $y = mx + b$, we know that k is the slope of the graph of 1/[ClO] versus time, which is $7.55 \times 10^6\ M^{-1}$ ms $^{-1}$ or $7.55 \times 10^9\ M^{-1}\ \text{s}^{-1}$ to three significant figures.

Think About It We can distinguish between first- and second-order reactions involving a single reactant by transforming the concentration data and examining which gives a linear fit with the integrated rate law.

Practice Exercise Experimental evidence shows that in the reaction

$NO_2(g) + CO(g) \rightarrow NO(g) + CO_2(g)$

the reaction rate depends only on the concentration of NO_2. Determine whether the reaction is first or second order in NO_2, and calculate the rate constant from the data in **Table 13.12**, which were obtained at 488 K.

TABLE 13.12 Concentration of NO_2 as a Function of Time

[illegible]	[illegible]

[illegible]		
[illegible]		
[illegible]		
[illegible]		

The concept of half-life can also be applied to second-order reactions. The relationship between rate constant and half-life for the decomposition of NO_2 can be derived from Equation 13.23 if we first rearrange the terms to solve for *kt*:

After one half-life has elapsed ($t = t_{1/2}$), [X] has decreased to half its initial concentration. Substituting this information into the preceding equation, we have

or

The value of $t_{1/2}$ for a second-order reaction, then, is inversely proportional to the initial concentration of X. This is unlike the $t_{1/2}$ values of first-order reactions, which are independent of concentration.

Zero-Order Reactions

In the practice exercise accompanying Sample Exercise 13.8, we introduced the reaction

$NO_2(g) + CO(g) \rightarrow NO(g) + CO_2(g)$

The rate law for the reaction is

Because there is no concentration term for CO in the rate law, the rate of the reaction does not depend upon the concentration of CO. That is, the rate of the reaction does not change with changing [CO], even when the concentrations of CO and NO_2 are comparable.

One interpretation of Equation 13.25 is that it contains a [CO] term to the zeroth power, making the reaction *zero order* in that reactant. Because any value raised to the zeroth power equals 1, we have

$$\text{Rate} = k[\text{NO}_2]^2[\text{CO}]^0 = k[\text{NO}_2]^2(1) = k[\text{NO}_2]^2$$

Reactions with a true zero-order rate law are rare, but let's consider a hypothetical zero-order reaction involving a single reactant X that forms product Y:

$$\text{X} \rightarrow \text{Y}$$

If the reaction is zero order in X, then the rate law is

$$\text{Rate} = -\Delta[\text{X}]/\Delta t = k[\text{X}]^0 = k$$

and the integrated rate law is

The slope of a plot of reactant concentration versus time (**Figure 13.16**) is the negative of the zero-order rate constant k.

We can calculate the half-life of a zero-order reaction by substituting $t = t_{1/2}$ and $[\text{X}] = [\text{X}]_0/2$ into the integrated rate law:

Figure 13.17 summarizes how to determine whether a reaction in which reactant X forms one or more products is zero, first, or second order. The figure also includes the rate laws and integrated rate laws for these reactions and the equations used to calculate the half-lives of X. The decision-making process shown in Figure 13.17 can also be used to determine the kinetics of reactions involving two reactants (X and Y) if the reaction is zero order in Y. In such cases, we focus on how the concentration of X changes with time. For now, we leave the discussion of zero-order reactions with this purely mathematical treatment. We return to these reactions and examine their meaning at the molecular level in Section 13.5.

Glossary

initial rate

the rate of a reaction at $t = 0$, immediately after the reactants are mixed.

reaction order

an experimentally determined number defining the dependence of the reaction rate on the concentration of a reactant.

rate law

an equation that defines the experimentally determined relation between the concentrations of reactants in a chemical reaction and the rate of that reaction.

overall reaction order

the sum of the exponents of the concentration terms in the rate law.

integrated rate law

a mathematical expression that describes the change in concentration of a reactant in a chemical reaction with time.

half-life ($t_{1/2}$)

the time in the course of a chemical reaction during which the concentration of a reactant decreases by half.

rate constant

the proportionality constant that relates the rate of a reaction to the concentrations of reactants at a particular temperature.

Learning Objectives

- Derive rate laws from initial reaction rate data **Return to Sample Exercise 13.4**
- Use integrated rate laws to identify zero-, first-, and second-order reactions and to determine rate constants for such reactions **Return to Sample Exercises 13.5, 13.8**

$$\ln\left(\frac{k_2}{6.45\times10^{-6}\,M^{-1}\,\text{s}^{-1}}\right) = -\frac{\left(\frac{67.1\,\cancel{\text{kJ}}}{\cancel{\text{mol}}}\right)\left(\frac{1000\,\cancel{\text{J}}}{1\,\cancel{\text{kJ}}}\right)}{\frac{8.314\,\cancel{\text{J}}}{\cancel{\text{mol}}\cdot\cancel{\text{K}}}}\left(\frac{1}{310\,\cancel{\text{K}}}-\frac{1}{298\,\cancel{\text{K}}}\right)$$

$$\ln\left(\frac{k_2}{6.45\times10^{-6}\,M^{-1}\,\text{s}^{-1}}\right) = 1.0484$$

$$\frac{k_2}{6.45\times10^{-6}\,M^{-1}\,\text{s}^{-1}} = e^{1.0484}$$

$$k_2 = 1.84\times10^{-5}\,M^{-1}\,\text{s}^{-1}$$

13.4 Reaction Rates, Temperature, and the Arrhenius Equation

CONNECTION Bond breaking is an endothermic process, whereas bond formation is an exothermic process (Section 6.3).

Chemical reactions take place when molecules collide with sufficient energy to break bonds in reactants and allow bonds to form in products. The minimum amount of energy that enables this to happen is called the activation energy (E_a). Every chemical reaction has a characteristic activation energy, usually expressed in kilojoules per mole. Activation energy, which is always a positive value, is an energy barrier that must be overcome if a reaction is to proceed—like the mountain passes that must be climbed when hiking the trails connecting two valleys shown in **Figure 13.18**. Just as a hiker is likely to get from Village A to Village B more rapidly following the trail over the lowest pass, reactions tend to be more rapid when their activation energies are small.

According to kinetic molecular theory, molecules have higher average kinetic energies at higher temperatures. Put another way, raising the temperature of a collection of molecules means that more of them have the minimum amount of energy needed to overcome the activation energy barrier of a reaction and react with each other. This principle is illustrated in **Figure 13.19a**, where the vertical dashed line represents activation energy, and the shaded areas to the right of the line represent the fraction of reactant molecules with enough energy to react with each other. Notice that the size of the shaded area is larger at higher temperature. This is why the rates of chemical reactions tend to increase with increasing temperature, as shown in **Figure 13.19b**.

CONCEPT TEST

Why does increasing the temperature increase the frequency of collisions between molecules in the gas phase?

CONNECTION The van ’t Hoff factor introduced in Section 11.5 is named after the same Jacobus van ’t Hoff who studied the temperature dependence of reaction rates.

In the late 19th century, experiments carried out in the laboratories of Jacobus van ’t Hoff and the Swedish chemist Svante Arrhenius (1859–1927) led to a fundamental advance in understanding how temperature affects the rates of chemical reactions. The mathematical connection between temperature, the rate constant k for a reaction, and its activation energy is given by the Arrhenius equation:

where R is the gas constant in J/(mol · K) and T is the reaction temperature in kelvin. The factor $\boldsymbol{A}$, called the frequency factor, is the product of the collision frequency and a term that accounts for the fact that not every collision results in a chemical reaction.

Some collisions do not lead to products because the colliding molecules are not oriented with respect to each other in the right way. To examine the importance of molecular orientation during collisions, consider the reaction between O_3 and NO:

$O_3(g) + NO(g) \rightarrow O_2(g) + NO_2(g)$

Two ways in which ozone and nitric oxide molecules might approach each other are shown in **Figure 13.20**. Only the orientation in Figure 13.20a, the one in which an O_3 molecule collides with the nitrogen atom of NO, leads to a chemical reaction between the two molecules.

A collision between O_3 and NO molecules with the correct orientation and enough kinetic energy may result in the formation of the activated complex shown in Figure 13.20a. In this species, one of the O□O bonds in the O_3 molecule has started to break and the new N□O bond is beginning to form. Activated complexes have extremely brief lifetimes and fall apart rapidly, either forming products or reforming reactants. Activated complexes are formed by reacting species that have acquired enough energy to react with each other. The internal energy of an activated complex represents a high-energy transition state of the reaction. In fact, the energy of an activated complex for a reaction defines the height of the activation energy barrier for the reaction. Activation energies typically vary from a few kilojoules to hundreds of kilojoules per mole.

An energy profile for a chemical reaction shows the changes in energy for the reaction as a function of the progress of the reaction from reactants to products. We have already seen one energy profile in Figure 13.18a. Now let’s consider the energy profile for the reaction between nitric oxide and ozone, shown in **Figure 13.21a**. The *x*-axis represents the progress of the reaction, whereas the *y*-axis represents energy. The activation energy is equivalent to the difference in energy between the transition state and the reactants. The size of the activation energy barrier depends on the direction from which it is approached. In the forward direction ($NO + O_3 \rightarrow NO_2 + O_2$; Figure 13.21a), E_a is smaller than in the reverse direction ($NO_2 + O_2 \rightarrow NO + O_3$; **Figure 13.21b**). A smaller activation energy barrier means that the forward reaction proceeds at a higher rate than the reverse reaction if we have equal concentrations of reactants and products.

One of the many uses of the Arrhenius equation (Equation 13.28) is to calculate the value of E_a for a chemical reaction. When we take the natural logarithm of both sides of Equation 13.28,

the result fits the general equation of a straight line ($y = mx + b$) if we make ln k the y variable and $1/T$ the x variable. We can calculate E_a by determining the rate constant k for the reaction at several temperatures. Plotting ln k versus $1/T$ should give a straight line, the slope of which is $-E_a/R$. **Table 13.13** and **Figure 13.22** show data for the reaction between NO and O_3 at six different temperatures.

The slope of the line in Figure 13.22 is equal to $-E_a/R$, so

The y intercept ($1/T = 0$) in Figure 13.22 is 27.39. From Equation 13.29, we know that this value represents ln A, which means

$$A = e^{27.39} = 7.86 \times 10^{11}$$

Now we can use the values of E_a and A to calculate k at any temperature. For example, at $T = 250$ K:

SAMPLE EXERCISE 13.9 Calculating an Activation Energy from Rate Constants LO6

The data in the first two columns of **Table 13.14** were collected in a study of the effect of temperature on the rate of the decomposition reaction

$$2\ \mathrm{ClO}(g) \rightarrow \mathrm{Cl_2}(g) + \mathrm{O_2}(g)$$

Determine the activation energy for the reaction.

TABLE 13.14 Effect of Temperature on the Value of the Rate Constant for the Decomposition of ClO

[illegible]			
[illegible]			
[illegible]			
[illegible]			
[illegible]			

Collect and Organize We can calculate activation energy by using the Arrhenius equation (Equation 13.28). We are given values of the rate constant k as a function of absolute temperature. According to Equation 13.29, the slope of a plot of ln k against $1/T$ is equal to $-E_a/R$, where E_a is the activation energy and R is the ideal gas constant with units of J/(mol · K).

Analyze First, we need to convert the T and k values in the first two columns in Table 13.14 to $1/T$ and ln k, respectively. We predict a positive value for E_a because activation energy represents a barrier that costs energy to overcome. The rate constant for the reaction is fairly large, about $10^9\ M^{-1}\ \mathrm{s}^{-1}$, so we predict that the activation energy barrier will be relatively low.

Solve The calculated values of $1/T$ and ln k (in the last two columns of Table 13.14) are used to plot ln k versus $1/T$ (**Figure 13.23**). The slope of the straight line that best fits the data is -1545 K.

We use the values of the slope and R [8.314 J/(mol · K)] to calculate the value of E_a:

Think About It The activation energy is the height of a barrier that has to be overcome before a reaction can proceed. As predicted, the activation energy for ClO decomposition has a small positive value.

Practice Exercise The rate constant for the reaction

$Br(g) + O_3(g) \rightarrow BrO(g) + O_2(g)$

was determined at the four temperatures shown in **Table 13.15**. Calculate the activation energy for this reaction.

TABLE 13.15 Rate Constant as a Function of Temperature for the Reaction of Br with O_3

T (K)	k [$cm^3/(molecule \cdot s)$]
238	5.9×10^{-13}
258	7.7×10^{-13}
278	9.6×10^{-13}
298	1.2×10^{-12}

Calculating activation energies by using the graphical method generally requires measurement of the rate constant at a minimum of three different temperatures to verify that the plot of ln k versus $1/T$ is a straight line. Once we know the value of E_a, we can use it and the value of the rate constant (k_1) of a reaction at one temperature (T_1) to calculate the value of the rate constant (k_2) at another temperature (T_2). We start by substituting k_1, k_2, T_1, and T_2 into Equation 13.29:

Subtracting these two expressions, ln k_2- ln k_1, gives

Using the mathematical properties of logarithms, we can rearrange the terms to obtain Equation 13.30:

SAMPLE EXERCISE 13.10 Determining the Effect of Temperature on Rate Constants LO6

The kinetics of decomposition of a potential drug have been tested in experiments at room temperature (25°C), where $k = 6.45 \times 10^{-6}$ M^{-1} s^{-1}. If the activation energy for this reaction is 67.1 kJ/mol, what will happen to the reaction rate when the same kinetics experiments are conducted at body temperature (37°C)?

Collect and Organize We are asked to calculate what happens to the rate of the reaction when kinetics experiments are run at a higher temperature. We are given values of the activation energy E_a, one rate constant k, and two temperatures. We can use Equation 13.30 to solve for the second rate constant, where R is the ideal gas constant with units of J/(mol · K).

Analyze First, we need to convert the temperature values from Celsius degrees to kelvin. We have one (k, T) pairing—(6.45×10^{-6} M^{-1} s^{-1}, 298 K)—and we need to find the k value for the second temperature, 310 K. We predict that as the temperature increases from room temperature to body temperature, the reaction will go faster and k will increase.

Solve Substituting the given values into Equation 13.30 gives us:

Think About It As predicted, k increases as T increases; in fact, it nearly triples. A higher temperature increases kinetic energy, which leads to more collisions of molecules with sufficient energy to exceed the threshold value of the activation energy and to a more rapid reaction rate.

Practice Exercise What temperature would be required to double the reaction rate when compared to the rate at room temperature for the potential drug tested in this sample exercise?

CONCEPT TEST

Which of the following statements is/are true about activation energies?

1. Exothermic reactions have negative activation energies.
2. Fast reactions have large rate constants *and* large activation energies.
3. The forward reaction sometimes has a lower activation energy than the reverse reaction.
4. Endothermic reactions always have large activation energies.

Glossary

activation energy (E_a)	the minimum energy molecules need to react when they collide.
Arrhenius equation	an equation relating the rate constant of a reaction to absolute temperature (T), the activation energy of the reaction (E_a), and the frequency factor (A).
activated complex	a transient species in a chemical reaction in which molecules have both the proper orientation and enough energy to react with each other.
frequency factor (A)	the product of the frequency of molecular collisions and a factor that expresses the probability that the orientation of the molecules is appropriate for a reaction to occur.
transition state	a high-energy state between reactants and products in a chemical reaction.
energy profile	a graph showing the changes in energy for a reaction as a function of the progress of the reaction from reactants to products.

$$\begin{array}{lll} \text{Step 1} & 2\,A(g) + B(g) \rightleftharpoons C(g) & \text{fast and reversible} \\ \text{Step 2} & B(g) + C(g) \rightarrow D(g) & \text{slow} \\ \text{Overall} & 2\,A(g) + 2\,B(g) \rightarrow D(g) & \end{array}$$

$$\begin{array}{lll} \text{Step 1} & N_2O_5(g) \rightleftharpoons NO_2(g) + NO_3(g) & \text{slow} \\ \text{Step 2} & NO_2(g) + NO_3(g) \rightarrow NO(g) + NO_2(g) + O_2(g) & \text{fast} \\ \text{Step 3} & NO(g) + N_2O_5(g) \rightarrow 3\,NO_2(g) & \text{fast} \end{array}$$

$$
\begin{aligned}
&N_2O_5(g) \rightleftharpoons NO_2(g) + NO_3(g)\\
+\ &NO_2(g) + NO_3(g) \rightarrow NO(g) + NO_2(g) + O_2(g)\\
+\ &NO(g) + N_2O_5(g) \rightarrow 3\ NO_2(g)\\
\hline
&N_2O_5(g) + \cancel{NO_2(g)} + \cancel{NO_3(g)} + \cancel{NO(g)} + N_2O_5(g) \rightarrow\\
&\qquad \cancel{NO_2(g)} + \cancel{NO_3(g)} + \cancel{NO(g)} + NO_2(g) + O_2(g) + 3\ NO_2(g)
\end{aligned}
$$

Elementary step 1 $H_2(g) + NO(g) \rightarrow N(g) + H_2O(g)$

Elementary step 2 $N(g) + NO(g) \rightarrow N_2(g) + O(g)$

Elementary step 3 $H_2(g) + O(g) \rightarrow H_2O(g)$

$NO_2(g) + CO(g) \rightarrow NO(g) + CO_2(g)$ Rate $= k[NO_2]^2$

(1) $2\ NO_2(g) \rightarrow NO_3(g) + NO(g)$ Rate $= k_1[NO_2]^2$

(2) $NO_3(g) + CO(g) \rightarrow NO_2(g) + CO_2(g)$ Rate $= k_2[NO_3][CO]$

13.5 Reaction Mechanisms

Up to this point we have described reactions in terms of macroscopically observable quantities such as pressure, temperature, volume, and numbers of moles of substances. In this section we explore how reactions proceed at the molecular level. Being able to suggest what goes on at the molecular level by observing macroscopic properties is a remarkable achievement. We will connect the minimum amount of energy that is needed to break bonds in the reactants and form bonds in the products to an exact determination of which bonds break and which bonds form. The evaluation of the stepwise behavior of molecules—the mechanism of a reaction—provides valuable insights into reactions, ranging from the subtlest biochemical processes taking place in cells to the chemistry of industrial processes that yield tons of product.

Let’s start by revisiting the thermal decomposition of NO_2:

$$2\ NO_2(g) \rightarrow 2\ NO(g) + O_2(g)$$

We noted in Section 13.3 that this reaction is second order in NO_2 because it takes place as a result of collisions between two NO_2 molecules at a time. How do the atoms in two colliding NO_2 molecules rearrange themselves to form two NO molecules and one O_2 molecule? The answer to this question is contained in the mechanism of the reaction. A reaction mechanism describes the stepwise manner in which the bonds in reactant molecules break and the bonds in product molecules form. Chemists use the results of reaction rate measurements to develop explanations of how reactions actually happen. Sometimes they can test for the presence of the products formed in preliminary steps, but, until recently, this was not possible for most reactions. Today, technological advances allow chemists to follow the transformation of reactants to products in the time that it takes for individual covalent bonds to break and new ones to form. These processes occur as rapidly as the bonds vibrate—that is, in femtoseconds (10^{-15} s), so the area of research based on monitoring these ultrafast processes is called *femtochemistry*.[3]

Elementary Steps

A reaction mechanism proposed for the decomposition of NO_2 is shown in **Figure 13.24**. In the first step of the mechanism, a collision between two NO_2 molecules produces a molecule of NO and a molecule of NO_3. In a second step, the NO_3 decomposes to NO and O_2. Both steps in the mechanism involve very short-lived activated complexes. In the activated complex of the first step, two molecules share an oxygen atom. The bonds in the activated complex of the second step rearrange so that two oxygen atoms bond together, forming a molecule of O_2 and leaving behind a molecule of NO. The NO_3 molecule is an intermediate in this mechanism because it is produced in one step and consumed in the next. Intermediates are not considered reactants or products and do not appear in the equation describing a reaction. In some cases, intermediates in chemical reactions are sufficiently long-lived to be isolated. In contrast, activated complexes have never been isolated, although they have been detected.

This reaction mechanism is a combination of two elementary steps. An elementary step that involves a single molecule is called unimolecular, and one that involves a collision between two molecules is bimolecular. Bimolecular elementary steps are much more common than termolecular (three-molecule) elementary steps because the chance of three molecules colliding at exactly the same time in the proper orientation is much smaller. The terms *uni-*, *bi-*, and *termolecular* are used by chemists to describe the molecularity of an elementary step, which refers to the number of atoms, ions, or molecules involved in that step.

A valid reaction mechanism must be consistent with the stoichiometry of the reaction. In other words, the sum of the elementary steps in Figure 13.24 must be consistent with the observed proportions of reactants and products as defined in the balanced chemical equation. In this case, the sum matches the overall stoichiometry:

Summing the two elementary steps and simplifying by canceling out the intermediate (NO_3) terms:

---

we get the overall reaction

$2\ NO_2(g) \rightarrow 2\ NO(g) + O_2(g)$

What does the energy profile of a two-step reaction such as this one look like? **Figure 13.25** shows that the two elementary steps produce an energy profile with two maxima, each with its own activation energy. In elementary step 1, collisions between pairs of NO_2 molecules result in the formation of an activated complex associated with the first transition state in Figure 13.25. As this activated complex transforms into NO and NO_3, the energy of the system drops to the bottom of the trough between the two maxima. In elementary step 2, NO_3 forms the activated complex associated with the second transition state. As this complex transforms into the final products NO and O_2, the energy of the system drops to its final level.

Figure 13.25 shows that the energy barrier for elementary step 1 is much greater than that for elementary step 2. This difference is consistent with the relative rates of the two steps: step 1 is slower than step 2. If the reaction were to proceed in the reverse direction (i.e., $2\ NO + O_2 \rightarrow 2\ NO_2$), the first energy barrier would be the smaller of the two, and the first elementary step would be the more rapid one. Experimental evidence supports these expectations.

CONCEPT TEST

For a reaction mechanism with *n* elementary steps, how many activation energies does the overall reaction have?

Rate Laws and Reaction Mechanisms

Any mechanism proposed for a reaction must be consistent with the rate law derived from experimental data. We saw in Section 13.3 that the thermal decomposition of NO_2 is second order in NO_2:

$$\text{Rate} = k[NO_2]^2$$

We have also seen that the coefficients in the balanced chemical equation for any chemical reaction do not necessarily match the exponents in the rate law for the reaction. For any *elementary step* in a reaction mechanism, however, *we can* use the balanced chemical equation to write a rate law for that step. For the thermal decomposition of NO_2, the rate law for the first elementary step, $2\ NO_2(g) \rightarrow NO_3(g) + NO(g)$, is

We obtain this rate law by writing the concentration for each reactant raised to a power equal to the coefficient of that reactant in the balanced equation. For the second elementary step in the NO_2 decomposition, $NO_3(g) \rightarrow NO(g) + O_2(g)$, the sole reactant, NO_3, has a coefficient of 1, so the rate law is

How do we use the rate laws in Equations 13.31 and 13.32 to determine the validity of the mechanism—that is, to show that they conform to the observed second-order rate law for the decomposition of NO_2?

The two steps in the mechanism proceed at different rates, with different activation energies. One step is slower than the other, and this slower step is the rate-determining step in the reaction. The rate-determining step is the slowest elementary step in a chemical reaction, and the rate of this step controls the overall reaction rate.

We can use the rate laws for the two steps to identify the rate-determining step. Because the rate law for step 1 matches the experimentally determined rate law, we may assume that step 1 defines how rapidly the reaction proceeds.

One way of visualizing the concept of a rate-determining step is to analyze the flow of people through a busy airport. Many travelers arrive at the airport with their boarding passes in hand or print them from convenient kiosks that allow them to avoid lines at ticket counters and move quickly toward their departure gate. The next step in the process is passing through security. Typically, the number of people in line outside security points greatly exceeds the number of screening machines, so the time required to reach a departure gate depends mostly on the time needed to pass through security. Security screening is the rate-determining step on the way through an airport.

If the first step in the mechanism in Figure 13.24 is the rate-determining step, then the value of k for the overall reaction is equal to k_1 from Equation 13.31. In addition, the value of k_1 must be smaller than the value of k_2 from Equation 13.32. NO_3 is sufficiently stable that we can make small amounts of it and test whether $k_1 < k_2$. Experiments run at 300 K starting with NO_2 or NO_3 yield these values: $k_1 \approx 1 \times 10^{-10}\ M^{-1}\ s^{-1}$ and $k_2 \approx 6.3 \times 10^4\ s^{-1}$. Therefore, as soon as any NO_3 forms in step 1, it rapidly falls apart to NO and O_2 in step 2.

Now let’s consider the reverse reaction of NO_2 decomposition—namely, the formation of NO_2 from NO and O_2:

We determined in Section 13.3 that this reaction is second order in NO and first order in O_2:

One proposed mechanism, shown in **Figure 13.26**, has two elementary steps:

We obtained the rate laws in Equations 13.34 and 13.35 by writing the concentration for each reactant raised to a power equal to the reactant's coefficient in the balanced elementary step. If step 1 were the rate-determining step, the reaction would be first order in NO and O_2, but that does not match the experimentally determined rate law. If step 2 were the rate-determining step, the reaction would be first order in NO and NO_3, but that does not match the rate law either. How, then, can we account for the experimental rate law?

If step 2 is slow while step 1 is fast *and reversible*, then NO_3 forms rapidly from NO and O_2 but decomposes just as rapidly back into NO and O_2. Expressing these rates in equation form:

Rate of forward reaction $= k_f[NO][O_2] =$ fast

Rate of reverse reaction $= k_r[NO_3] =$ equally fast

The subscripts "f" and "r" refer to the forward and reverse reactions, respectively.

Setting these two expressions equal to each other, we have

Now, if we replace the $[NO_3]$ term in the rate law of Equation 13.35 (which we select because step 2 is the rate-determining step) with the right side of Equation 13.36, we get

The three rate constants can be combined,

and the rate law for the overall reaction becomes

Rate $= k_{overall}[NO]^2[O_2]$

This expression matches the overall rate law in Equation 13.33, so the proposed mechanism—a fast and reversible step 1 followed by a slow step 2—may be valid.

Even though the proposed reaction mechanism is consistent with the overall stoichiometry of the reaction and with the experimentally derived rate law, these consistencies do not *prove* that the proposed mechanism is correct. Other mechanisms could be consistent with the rate law, too. On the other hand, *not* finding a reactive (and transient) intermediate would not necessarily disprove a reaction mechanism because we could be limited by our ability to detect such a short-lived species.

CONCEPT TEST

Could the products of an elementary step in a chemical reaction include activated complexes?

SAMPLE EXERCISE 13.11 Linking Reaction Mechanisms to Experimental Rate Laws LO7

The experimentally determined rate law for the reaction

$$2\ NO(g) + 2\ H_2(g) \rightarrow N_2(g) + 2\ H_2O(g)$$

is

$$\text{Rate} = k[NO]^2[H_2]$$

A proposed mechanism for the reaction is

Is this reaction mechanism consistent with the stoichiometry of the reaction and with the rate law? If so, which is the rate-determining step?

Collect and Organize We need to determine whether the proposed two-step reaction mechanism is consistent with the overall reaction stoichiometry and the rate law of the overall reaction. We know that a rate law derived from the stoichiometry of the rate-determining step in a reaction mechanism should match the rate law of the overall reaction.

Analyze To answer the questions posed in this exercise, we need to

1. Determine whether the chemical equations of the elementary steps add up to the overall reaction equation.
2. Write rate laws for each elementary step.

3. Compare the rate laws of the elementary steps to the experimental rate law of the overall reaction to assess the validity of the mechanism.
4. Decide which step is rate determining by matching its rate law to the observed rate law.

Solve Adding up the elementary steps:

This is indeed the equation of the overall reaction. The elementary steps are consistent with the stoichiometry of the overall reaction.

Next we need to focus on the reaction mechanism. Elementary step 1 involves two molecules of NO colliding with one molecule of H_2 in a termolecular reaction. Elementary step 2 is a bimolecular reaction between the N_2O produced in step 1 and another molecule of H_2. The rate law for any elementary step can be written directly from the balanced equations, using the equation coefficients as exponents in the rate law:

The rate law of step 1 matches the observed rate law of the overall reaction. Therefore, the proposed two-step mechanism is consistent with the experimental rate law, and step 1 is the rate-determining step.

Think About It Since the rate law we derived for our mechanism matches the observed rate law and data, the mechanism is reasonable, although we lack definitive proof that the proposed mechanism is the correct one.

Practice Exercise The following mechanism is proposed for a reaction between compounds A and B:

What is the rate law for the overall reaction based on the proposed mechanism?

SAMPLE EXERCISE 13.12 Testing a Proposed Reaction Mechanism LO7

A proposed mechanism for the decomposition of N_2O_5 to NO_2 and O_2 involves three elementary steps:

Is the mechanism consistent with the stoichiometry of the overall reaction? What is the rate law of the overall reaction based on the proposed mechanism?

Collect and Organize We are given three elementary steps and their relative rates and are asked whether they constitute a reaction mechanism that is consistent with the overall stoichiometry of a chemical reaction, and we are asked to predict the rate law of the overall reaction based on the proposed mechanism. The rate law for the overall reaction is linked to the rate law for the rate-determining step.

Analyze The first step in the proposed mechanism is the slowest of the three and should be the rate-determining step. The rate law for an elementary step is linked directly to its molecularity. The reactant in step 1 is a single molecule of N_2O_5. To determine if the proposed mechanism is consistent with the overall reaction, we need to add the reactants consumed and the products formed in the three steps to see if they give a balanced chemical equation describing the overall reaction.

Solve Summing the reactants and products of the three elementary steps:

Combining the remaining terms:

$$2\ N_2O_5(g) \rightarrow 4\ NO_2(g) + O_2(g)$$

This balanced equation consists of just the reactant and products, and is consistent with the overall reaction.

The rate law for step 1 is

$$\text{Rate} = k[N_2O_5]$$

Step 1 is the rate-determining step, so its rate law is the rate law of the overall reaction.

Think About It The rate law we derived for our mechanism is consistent with a slow initial step that represents first-order, unimolecular decomposition of N_2O_5 followed by two fast steps to account for the observed stoichiometry of the reaction.

Practice Exercise The following is another proposed mechanism for the reaction of NO with H_2 in Sample Exercise 13.11:

Is this a valid mechanism? Explain why or why not.

Mechanisms and Zero-Order Reactions

Before we complete our discussion of reaction mechanisms, let’s revisit the reaction between NO_2 and CO, which has an experimentally determined rate law that is zero order in CO, second order in NO_2, and second order overall:

What does this overall rate law tell us about how the reaction happens at the molecular level? Remember that the overall rate depends on the concentrations of the reactants in the rate-determining step, which means that CO is not a reactant in the rate-determining step. Carbon monoxide is involved in the reaction—it is converted into CO_2—but whatever step involves CO must occur *after* the rate-determining step. As a result, the reaction must have at least two elementary steps, one rate-determining and one not.

The proposed reaction mechanism is

The experimentally determined overall rate law matches the rate law for the first step, which must be the slower, rate-determining step. The overall reaction is zero order in CO because CO is not a reactant in that step.

CONCEPT TEST

The rate law for the reaction $XO_2(g) + M(g) \rightarrow XO(g) + MO(g)$, where X and M represent nonmetallic elements, is second order in $[XO_2]$ and zero order in [M] for a wide variety of compounds XO_2 and M. Why can we conclude that these reactions probably proceed by the same mechanism?

Glossary

reaction mechanism

a set of steps describing how a reaction occurs at the molecular level; the mechanism must be consistent with the experimentally determined rate law for the reaction.

intermediate

a species produced in one step of a reaction and consumed in a subsequent step.

elementary step

a molecular view of a collision taking place in a chemical reaction.

unimolecular step

a step in a reaction mechanism involving only one molecule on the reactant side.

bimolecular step

a step in a reaction mechanism involving a collision between two molecules.

termolecular step

a step in a reaction mechanism involving a collision among three molecules.

molecularity

the number of ions, atoms, or molecules involved in an elementary step in a reaction.

rate-determining step

the slowest step in a multistep reaction mechanism.

13.6 Catalysts

Slow reactions often have high activation energies (Section 13.4). How could we increase the rate of such a reaction? One way is to increase the temperature of the reaction mixture. In some chemical reactions, however, elevated temperatures can lead to undesired products or to lower yields. Another way is to add a catalyst, a substance that increases the rate of a reaction but is not consumed in the process.

Catalysts and the Ozone Layer

As we discussed in Chapter 8, the way we think about ozone depends on where the ozone is located. Ozone in the stratosphere between 10 and 40 km above Earth’s surface is necessary to protect us from UV radiation, but ozone at ground level is hazardous to our health. In this section we discuss the role of catalysis in the loss of stratospheric ozone that has led to the annual formation of ozone holes over Antarctica.

The natural photodecomposition of ozone in the stratosphere occurs through the reaction

$$2\ O_3(g) \rightarrow 3\ O_2(g)$$

It begins with the absorption of UV radiation from the Sun and the generation of atomic oxygen:

$$O_3(g) \rightarrow O_2(g)\ +\ O(g)$$

The oxygen atom may react with another ozone molecule to form two more molecules of oxygen:

$O_3(g) + O(g) \rightarrow 2\ O_2(g)$

The second elementary step is slow because its activation energy is relatively high: 17.7 kJ/mol.

In 1974 two American scientists, F. Sherwood Rowland (1927–2012) and Mario J. Molina (1943–), predicted significant depletion of stratospheric ozone because of the release of a class of volatile compounds called chlorofluorocarbons (CFCs) into the atmosphere at ground level, which ultimately enter the stratosphere. This prediction was later supported by experimental evidence of a thinning of the ozone layer and the formation of annual ozone holes over Antarctica. By 2000 stratospheric ozone concentrations over Antarctica were less than half of what they were in 1980, and the ozone hole covered nearly all of Antarctica and the tip of South America (**Figure 13.27**). Less severe thinning of stratospheric ozone was observed in the Northern Hemisphere.

In 1989 an international agreement known as the Montreal Protocol, which called for an end to the production of ozone-depleting CFCs, went into effect. It has had a dramatic effect on CFC production and emission into the atmosphere, and as the trend line in Figure 13.27 indicates, the ozone layer over Antarctica appears to be slowly recovering. However, these compounds last for many years in the atmosphere, and full recovery of the ozone layer may take most of the 21st century.

How do CFCs contribute to the destruction of ozone? Three of the more widely used CFCs were CCl_2F_2, CCl_3F, and $CClF_3$. In the stratosphere, these molecules encounter UV radiation with enough energy to break C–Cl bonds, releasing chlorine atoms. For example,

Free chlorine atoms react with ozone, forming chlorine monoxide:

Chlorine monoxide then reacts with more ozone, producing oxygen and regenerating atomic chlorine:

If we add Equations 13.38 and 13.39 and cancel species as needed, we get

$2\ O_3(g) \rightarrow 3\ O_2(g)$

The overall reaction is exactly the same as the natural photodecomposition of ozone. The difference is the presence of chlorine atoms in Equations 13.38 and 13.39. Chlorine atoms act as a catalyst for the destruction of ozone because they speed up the reaction but are not consumed by it. Chlorine is a catalyst, not an intermediate, because it is consumed in an early elementary step of the mechanism and then regenerated in a later one, whereas an intermediate is produced and then consumed. A single chlorine atom can catalyze the destruction of hundreds to thousands of stratospheric O_3 molecules before it combines with other atoms and forms a less reactive molecule.

The activation energy for the O_3 decomposition following the Cl-catalyzed reaction is only 2.2 kJ/mol, whereas the activation energy for the uncatalyzed reaction pathway described in Equations 13.38 and 13.39 is 17.7 kJ/mol (**Figure 13.28**). Its smaller E_a value means that the catalyzed destruction of ozone is faster than the natural photodecomposition process. In the reaction describing the destruction of ozone, the catalyst, Cl(*g*), and reactant, $O_3(g)$, exist in the same physical phase. When a catalyst and the reacting species are in the same phase, we call the catalyst a homogeneous catalyst.

CONCEPT TEST

Which of the following statements is/are true about the elementary step shown in Equation 13.38?

1. Its rate law is first order in [Cl].
2. Its rate law does not include [Cl] because Cl is a catalyst.
3. Its rate is zero order (i.e., independent of) [Cl].

The rates of the above reactions increase in the presence of drops of liquid, such as those in the clouds that cover much of Antarctica each spring. These clouds form from crystals of ice and tiny drops of nitric acid in the winter, when temperatures in the lower stratosphere dip to -80°C. The clouds become collection sites for HCl, ClO, and other compounds containing chlorine. In August (the end of the Antarctic winter), the ice in the clouds melts and ClO is free to react on the surface of the drops of liquid water. These drops catalyze reactions by *adsorbing* (binding to the surface of) the reactants. The drops are not reactants, but they provide a surface on which the reactants collect. The resulting proximity of the reactants increases the likelihood of reaction and, coupled with a decrease in activation energy, increases the reaction rate. When the catalyst is a liquid drop on which gas molecules adsorb, the drop is in a different phase than the reacting species and is called a heterogeneous catalyst. Both homogeneous and heterogeneous catalysts play a role in the reactions that diminish the amount of ozone in the stratosphere.

CONCEPT TEST

Is the ClO produced in Equation 13.38 a catalyst or an intermediate?

SAMPLE EXERCISE 13.13 Identifying Catalysts in Reaction Mechanisms LO8

A reaction mechanism proposed for the decomposition of ozone in the presence of NO at high temperatures consists of three elementary steps:

If the rate of the overall reaction is higher than the rate of the uncatalyzed decomposition of ozone to oxygen, $2\ O_3(g) \rightarrow 3\ O_2(g)$, is NO a catalyst in the reaction?

Collect and Organize We are asked to determine whether NO is a catalyst in a reaction. A catalyst increases the rate of a reaction and is not consumed by the overall reaction. We are given the elementary steps of the reaction and are told that the reaction is more rapid in the presence of NO.

Analyze We can sum the reactions to determine the overall reaction. If NO is consumed in an early step before it is regenerated in a later one, and it is not consumed in the overall process, then it is a catalyst.

Solve Summing the three elementary steps,

gives the overall reaction,

$2\ O_3(g) \rightarrow 3\ O_2(g)$

This equation does not include NO, and the rate of the reaction is higher when NO is present. Thus, NO fulfills both requirements for being a catalyst.

Think About It NO behaves much like the Cl atoms in Equations 13.38 and 13.39. NO is *not* an intermediate because it is used in the reaction and then regenerated in a subsequent step. If it were an intermediate, it would have been produced and then consumed.

Practice Exercise The combustion of fossil fuels results in the release of SO_2 into the atmosphere, where it reacts with oxygen to form SO_3:

$2\ SO_2(g) + O_2(g) \rightarrow 2\ SO_3(g)$

In the atmosphere, SO_2 may react with NO_2, forming SO_3 and NO:

$NO_2(g) + SO_2(g) \rightarrow NO(g) + SO_3(g)$

The rate of reaction of SO_2 with NO_2 is faster than the rate of reaction of SO_2 with oxygen. If the NO produced in the reaction of NO_2 and SO_2 is then oxidized to NO_2,

$2\ NO(g) + O_2(g) \rightarrow 2\ NO_2(g)$

is NO_2 a catalyst in the reaction of SO_2 with O_2?

Catalysts and Catalytic Converters

We started this chapter discussing air pollution caused by vehicles and the technology that has been developed to clean the air. **Figure 13.29** shows a catalytic converter in a car's exhaust system and the reactions that take place in the converter to remove one representative pollutant, NO, from the engine exhaust. Hot exhaust gases flowing through the converter pass through a fine honeycomb mesh coated with one or more of the transition metals palladium, platinum, and rhodium. These metals are the catalysts, and they have two roles: (1) to speed up oxidation of carbon monoxide to CO_2 and of unburned hydrocarbons to CO_2 and water vapor; and (2) to convert NO and NO_2 into N_2 and O_2.

The metals used in making catalytic converters are dissolved as metal salts and dispersed on the mesh, and they are then reduced to clusters that are 2 to 10 nm in diameter. The large surface area of the metal clusters provides sites where the oxidation and reduction of the gases take place.

Catalysts not only speed up reactions but also allow them to take place at lower temperatures. For example, CO reacts rapidly with O_2 above 700°C, but the presence of a Pd or Pt/Rh catalyst enables this reaction to take place rapidly at the much lower temperature of automobile exhaust, about 250°C. The catalysts have similar effects on the reduction reactions taking place in the converters.

The catalysts are selective in terms of the molecules they interact with and specific in the reactions they promote. What makes the catalysts selective is that several reactions are possible for each pollutant, but one reaction proceeds more rapidly than the others. For example, the preferred reduction of the nitrogen in NO is to N_2, as shown in Figure 13.29, rather than to N_2O or to NH_3. However, carbon monoxide and hydrocarbons are also potential reducing agents for this reaction. Oxidizing CO and hydrocarbons is one of the two primary goals of a catalytic converter. If these compounds are oxidized, no additional NO reduction can take place via this process. Fortunately, the reduction of NO by CO and hydrocarbons is much faster than the reactions of CO and hydrocarbons with O_2. As a result, additional NO reduction by CO and hydrocarbons is essentially complete before any of the necessary reducing agents are consumed by reaction with oxygen.

Enzymes: Biological Catalysts

Large biomolecules called enzymes are highly selective catalysts; they mediate very specific reactions in biological systems. For example, the chemical reactions involved in metabolism, which includes both the breaking down of molecules and the synthesis of complex substances from simpler precursors, are catalyzed in large part by enzymes. Sequences of reactions called *metabolic pathways* consist of steps, each of which is catalyzed by a specific enzyme. For example, carbonic anhydrase is an enzyme that speeds up the hydrolysis of CO_2:

In the presence of carbonic anhydrase, this reaction proceeds about 10 million times faster than in its absence. Without carbonic anhydrase, we would not be able to expel carbon dioxide fast enough to survive (as the reaction in Equation 13.40 runs in reverse). One molecule of carbonic anhydrase can hydrolyze from 10^4 to 10^6 molecules of CO_2 in 1 s. This value is called the *turnover number* for the enzyme; in general, the higher the turnover number, the faster the enzyme-catalyzed reaction proceeds. Turnover numbers for enzymes typically range from 10^3 to 10^7. The higher the turnover number, the lower the activation energy of the catalyzed reaction. As we learned earlier in this chapter, for reactions to proceed, molecules must collide with the proper orientation. Carbonic anhydrase is essentially a perfect enzyme because it catalyzes the hydrolysis reaction nearly every time it collides with CO_2.

Enzymes are specific because the idea of an effective collision has a different connotation in biochemistry from what we have depicted for other reactions and catalysts. A simplified approach to understanding and quantifying how enzymes work involves consideration of the interaction between the enzyme (E) and its *substrate* (S), the reactant molecule (**Figure 13.30**). We refine these ideas in Chapter 20 when we discuss specific enzymes, but for now it is sufficient to envision the substrate fitting into an *active site* in the enzyme, very much like a hand fits into a glove. Once in the active site, the substrate is converted into product (P) via a pathway that has a lower-energy transition state (the *enzyme–substrate complex* ES), which is absent without the enzyme.

Even in the simplest organism, hundreds of enzyme-catalyzed chemical reactions are constantly taking place. Most of these enzymes are effective only under limited reaction conditions: in aqueous media and at temperatures between 4°C and 37°C. These hundreds of catalyzed reactions require hundreds of different enzymes, many operating with exquisite efficiency and producing one pure product.

In the pharmaceutical industry, research is focused on using enzymes outside living systems to produce high yields of specific products. This research area, called biocatalysis, uses enzymes to catalyze chemical reactions run in industrial-sized reactors. Because it deals with both isolated enzymes and microorganisms, it is considered a special type of heterogeneous catalysis.

The mathematical treatment of enzyme kinetics can be quite complex, but determining the rate of enzyme-catalyzed reactions is an important part of biochemical and medical research. We can think of the following elementary steps in the process:

Biochemists commonly assume that the formation of ES and its decomposition are both rapid and that step 2 is rate determining. A typical reaction profile for a system that meets these criteria is shown in **Figure 13.31**, and the rate of such a reaction is given by

Initially, the rate of reaction increases rapidly as the concentration of S increases (**Figure 13.32**). The rate of reaction is proportional to

[S], so the reaction is first order and rate $= k[S]$. At some specific concentration of S, all of the active sites in available enzymes are occupied, and the rate of the reaction becomes constant. At this stage, the rate is zero order in S (rate $= k$); thus, adding more S has no effect because all the active sites are full.

In this chapter we have seen how studying the rates of chemical reactions can lead to an understanding of how reactions happen. Determinations of the rates of chemical reactions are crucial for us to understand processes on a molecular level. The mechanisms of the reactions of volatile oxides produced during combustion and by other natural events had to be thoroughly understood so that these substances in the environment could be effectively managed. The continued development of catalytic converters for vehicles to diminish the problems caused by burning fossil fuels and to clean our air requires a thorough knowledge of the kinetics and mechanisms of many of the reactions discussed in this chapter. Many biological catalysts are responsible for a myriad of reactions in living systems, and their behavior may be understood by applying the same methods of study we used for inorganic catalysts in reactions of small molecules.

SAMPLE EXERCISE 13.14 Integrating Concepts: Simulations of Smog

As we have seen throughout this chapter, reactions in the atmosphere are complex. **Figure 13.33** shows three graphs of data from programs that simulated atmospheric conditions arising from known reactions when the hydrocarbon propylene was introduced into air. Propylene enters the atmosphere from the evaporation of unburned petroleum fuels. The three graphs show simulated concentration versus time profiles on (a) a sunny day, (b) a cloudy day, and (c) a sunny day when the concentration of propylene is twice the amount in (a) .

1. Both alkanes and alkenes are present as dissolved gases in unburned fuels. In studies of both propylene ($CH_2{=}CHCH_3$) and butane ($CH_3CH_2CH_2CH_3$), the alkene was shown to react more rapidly than the alkane. Suggest a reason for this observation.

2. In Figure 13.33a, which substances are reactants and which are products? Are there any intermediates?
3. Compare Figures 13.33a and 13.33c. How does doubling the concentration of propylene affect the level of air pollutants such as ozone and peroxyacetyl nitrate (PAN)?
4. What are the major differences between the reactions on a sunny day (Figure 13.33a) and a cloudy day (Figure 13.33b)?

Collect and Organize We have three graphs for different conditions, and we can use them to get relative quantitative information.

Analyze The graphs show differences in the appearance and disappearance of reactants, intermediates, and products of reactions involving an alkene, NO_x, ozone, and PAN.

Solve

1. Alkenes react more rapidly than alkanes because of the presence of C□C π bonds. The electrons in these π bonds are more accessible to reactants than are those in σ bonds, and these π bonds are weaker than σ bonds.
2. Propylene and NO are reactants. Their concentrations start out high and drop continuously throughout the time of observation. PAN and O_3 are products. Their concentrations start out at zero and gradually build. NO_2 is an intermediate. Its concentration begins to increase at $t = 0$, reaches a peak around 75 min, and then decreases as PAN and O_3 form and accumulate. The decrease in propylene concentration begins immediately and accelerates as O_3 concentration builds. Some organic substances other than PAN must be forming to account for the drop; their concentrations are not shown on the graph.
3. Doubling the initial concentration of propylene caused it to be consumed at a faster rate and to accelerate the formation and consumption of other smog components. NO concentrations decreased more rapidly in (c); NO_2 concentrations reached a maximum in a shorter time and then decreased more rapidly than in (a). Ozone and PAN were detected earlier, reached much higher concentrations, and achieved concentration maxima in (c) that were not

observed in (a).

4. PAN and O_3 are not evident at all in (b) on the cloudy day, and propylene and NO disappear more slowly than on a sunny day.

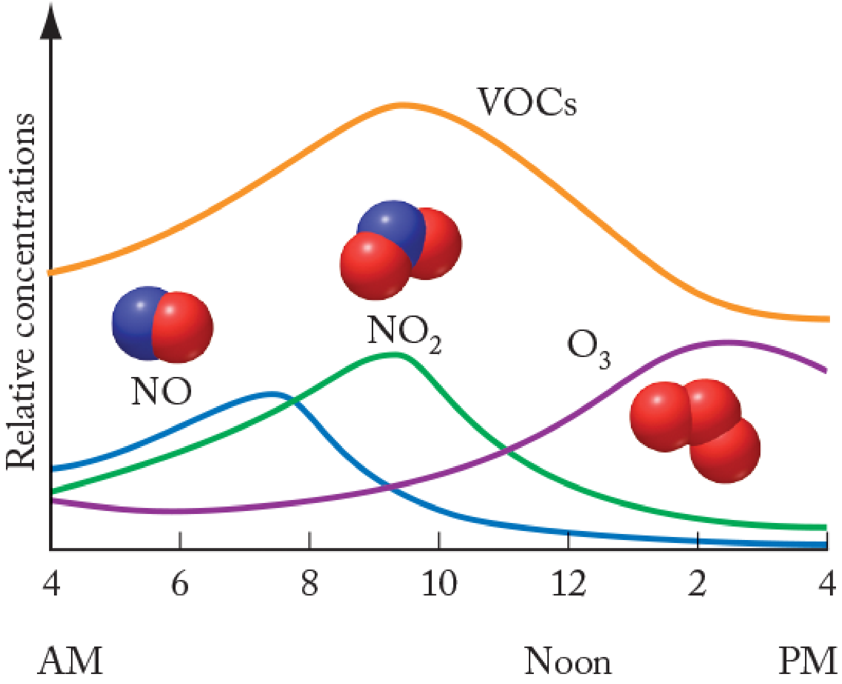
Think About It Our analysis of data presented in the three graphs is consistent with a key concept in this chapter: reaction rates depend on concentrations of reactants. Our answers are also consistent with recognized differences in reactivity between molecules such as butane and propylene as reflected in the kinetics of their reactions with ozone.

Glossary

catalyst	a substance added to a reaction that increases the rate of the reaction but is not consumed in the process.
homogeneous catalyst	a catalyst in the same phase as the reactants.
heterogeneous catalyst	a catalyst in a different phase from the reactants.
enzyme	a protein that catalyzes a reaction.
biocatalysis	the use of enzymes to catalyze reactions on a large scale; it is becoming especially important in processes that involve chiral materials.

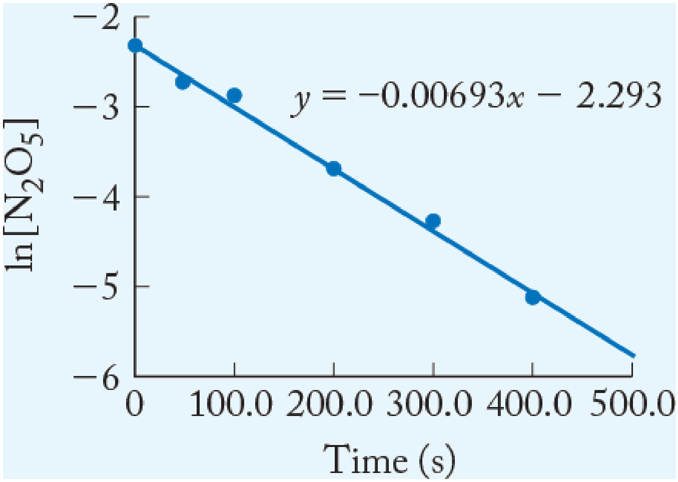
Learning Objectives

- Describe catalysts and explain how they alter reaction mechanisms in ways that increase reaction rates **Return to Sample Exercise 13.13**



SUMMARY

- LO1 The relative rates of the disappearance of reactants and the appearance of products are related by the stoichiometry of the reaction. Chemical kinetics is the study of these changing rates. (Sections 13.1 and 13.2)
- LO2 The rate of a reaction may be expressed as an average rate over a specified time interval based on the change in concentration of a reactant or product from the beginning to the end of that interval, or as an instantaneous rate at a particular time during the course of a reaction, based on the instantaneous rate of change in the concentration of a reactant or product. (Section 13.2)
- LO3 The dependence of the rate of a reaction $A + B \rightarrow C$ on reactant concentrations is expressed in the rate law for the reaction:



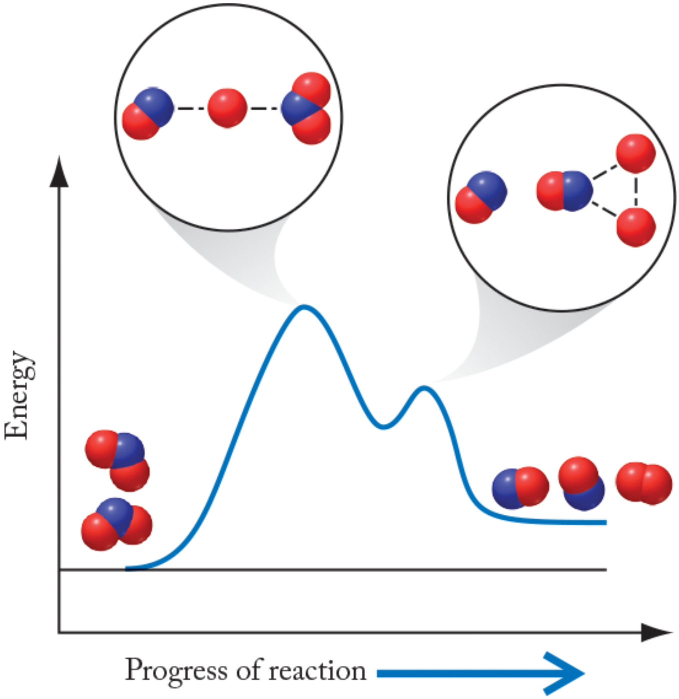
$$\text{Rate } = k[\mathrm{A}]^m[\mathrm{B}]^n$$

where m and n are the reaction order with respect to reactants A and B, respectively, and k is the rate constant. The order of a reaction and the rate law for the reaction can be determined from differences in the initial rates of reaction. (Section 13.3)

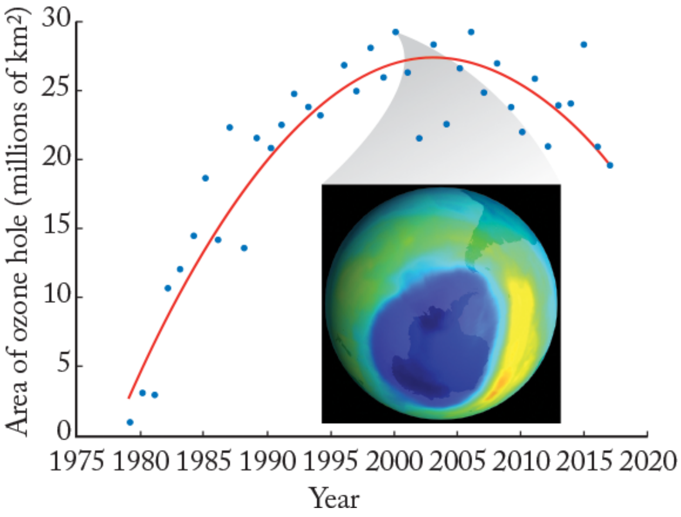
- LO4 Determinations of changing reactant concentration over time can be used to find the order of a single-reactant reaction. The rates of most reactions, except those that are zero order, decrease over time as the reactant is consumed. Plots of reactant concentration versus time are linear in zero-order reactions, but are curved in most others because rates decrease as reactant is consumed. Natural log plots of reactant concentration versus time are linear in first-order reactions, and plots of the reciprocal of reactant concentration are linear in second-order reactions. (Section 13.3)
- LO5 A first-order reaction has a characteristic half-life that is inversely proportional to the rate constant of the reaction. The half-life of a second-order reaction is inversely proportional to the rate constant and to the initial concentration of the reactant. The half-life of a zero order reaction is inversely proportional to the rate constant and

directly proportional to the initial concentration. (Section 13.3)

- LO6 Increasing the temperature of a chemical reaction increases its rate and rate constant because reactant particles collide more frequently and with enough energy to overcome the activation energy of the reaction, which is the minimum energy required for molecules to react when they collide. (Section 13.4)



- LO7 Rate studies give insight into reaction mechanisms, which describe what is happening at the molecular level. A reaction mechanism consists of one or more elementary steps that describe how the reaction takes place on the molecular level. The proposed mechanism for any reaction must be consistent with the observed rate law and with the stoichiometry of the overall reaction. (Section 13.5)



- LO8 A catalyst increases the rate of a reaction by changing the mechanism of the reaction and decreasing its activation energy; a catalyst is not consumed in the overall reaction. Enzymes are catalysts in living systems. (Section 13.6)

PARTICULATE PREVIEW WRAP-UP

The NO_2 molecules collide most frequently in sample (a) owing to the highest concentration of the three samples, so the reaction proceeds most rapidly for sample (a). The number of collisions in sample (b) is four times the number of collisions in sample (c) because the reaction is second order in NO_2.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts and Equations	Sample Exercises
Relating rates of change in reactant and product concentrations	For the generic reaction $x\text{X} \rightarrow y\text{Y}$, the rates of change of [X] and [Y] are related as follows: $$-\frac{1}{x}\frac{\Delta[\text{X}]}{\Delta t}=\frac{1}{y}\frac{\Delta[\text{Y}]}{\Delta t}$$	13.1, 13.2
Determining an instantaneous rate	Determine the slope of a tangent line to a point on the plot of concentration versus time.	13.3
Deriving a rate law from initial reaction rate data	[illegible] of one	13.4

		reactant is changed (while the concentrations of other reactants are kept constant) to determine the reaction order (usually whole numbers) with respect to that reactant: $$n = \frac{\log\left(\frac{\text{Rate}_1}{\text{Rate}_2}\right)}{\log\left(\frac{[\text{X}]_1}{[\text{X}]_2}\right)} \quad (13.14)$$
13.5, 13.8	**Using integrated rate laws to distinguish among zero-, first-, and second-order reactions, and to calculate the value of *k***	A linear plot of concentration versus time indicates a zero-order reaction with a slope of $-k$, whereas a linear plot of the natural logarithm of concentration versus time indicates a first-order reaction with a slope of $-k$, and a linear plot of the reciprocal of reactant concentration $1/[\text{X}]$ versus time indicates a second-order reaction.
13.6	**Calculating the remaining concentration of a reactant in a zero-, first-, or second-order reaction**	Use the integrated rate law: Zero order: $[\text{X}] = -kt + [\text{X}]_0$ (13.26) First order: $\ln[\text{X}] = -kt + \ln[\text{X}]_0$ (13.18) Second order: $\frac{1}{[\text{X}]} = kt + \frac{1}{[\text{X}]_0}$ (13.23) to calculate concentrations of reactant X at any given time t.
13.7	**Calculating the half-life of a zero-, first-, or second-order reaction**	Use the rate constant to calculate half-life: Zero order: $t_{1/2} = \frac{[\text{X}]_0}{2k}$ (13.27) First order: $t_{1/2} = \frac{0.693}{k}$ (13.19) Second order: $t_{1/2} = \frac{1}{k[\text{X}]_0}$ (13.24)
13.10	**Calculating an activation energy from rate constants**	Using the logarithmic form of the Arrhenius equation, $\ln k = -\frac{E_a}{R}\left(\frac{1}{T}\right) + \ln A$ (13.29) plot $\ln k$ versus $1/T$. The slope is $-E_a/R$. The rates of a reaction at two temperatures can be found using $\ln\frac{k_2}{k_1} = -\frac{E_a}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$ (13.30)
13.11, 13.12	**Linking reaction mechanisms to experimental rate laws and testing a proposed reaction mechanism**	The order of each reactant in an elementary step equals its coefficient in that step. The rate law for the mechanism must be the same as the observed rate law and must not include intermediates.
13.13	**Identifying catalysts in reaction mechanisms**	Determine whether a catalyst is present by summing the elementary-step reactions to get the overall reaction. If that procedure reveals a potential catalyst, determine whether it increases the rate of reaction and whether it is initially consumed and then regenerated in the process.

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

Nitrous oxide decomposes to nitrogen and oxygen in the following reaction:

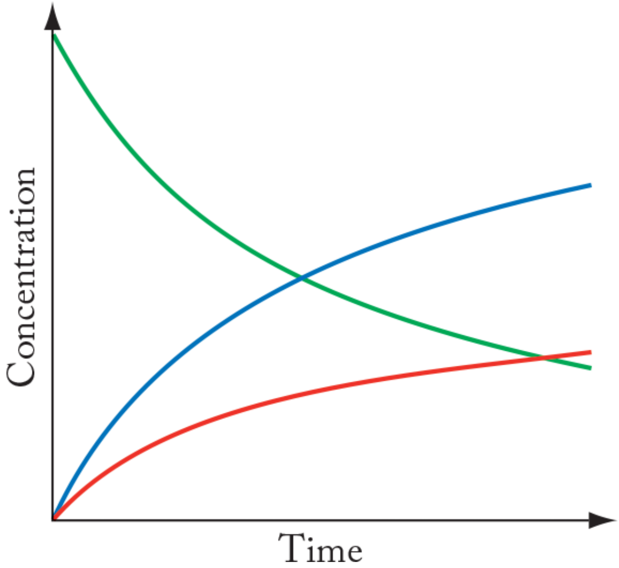


FIGURE P13.1

$2\ N_2O(g) \rightarrow 2\ N_2(g)\ +\ O_2(g)$

In Figure P13.1, which curve represents $[N_2O]$ and which curve represents $[O_2]$?

Sulfur trioxide is formed in the reaction

$$SO_2(g) + \frac{1}{2}O_2(g) \rightarrow SO_3(g)$$

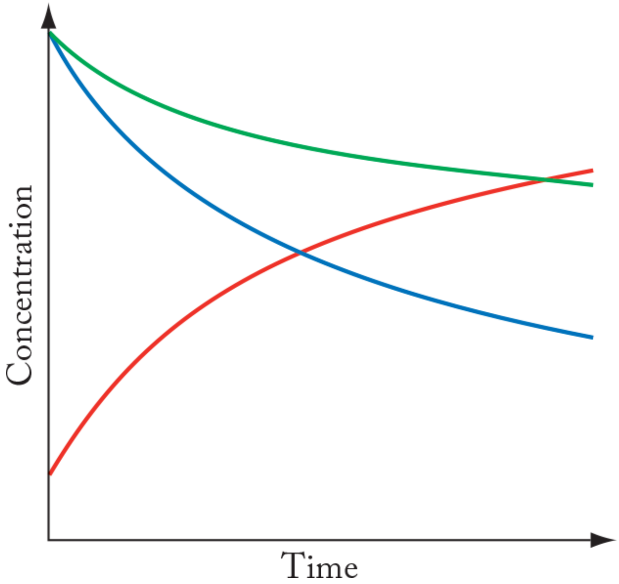

FIGURE P13.2

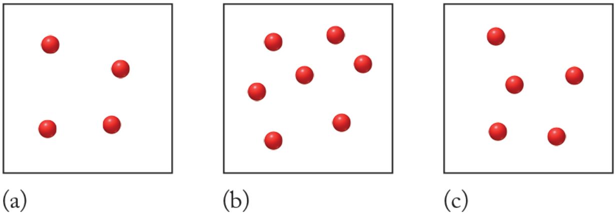
In Figure P13.2, which curve represents [SO_2] and which curve represents [O_2]? All three gases are present initially.

The rate law for the reaction 2 A → B is second order in A. Figure P13.3 represents samples with different concentrations of A (the red spheres). In which sample will the reaction A → B proceed most rapidly?



(a) (b) (c)

FIGURE P13.3

The rate law for the reaction A + B → C is first order in both A and B. Figure P13.4 represents samples with different concentrations of A (red spheres) and B (blue spheres). In which sample will the reaction A + B → C proceed most rapidly?

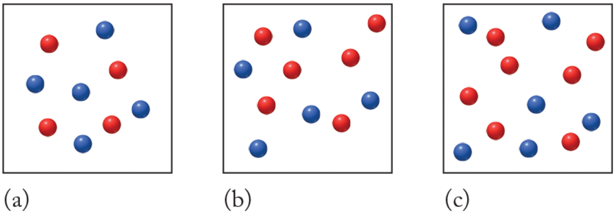


FIGURE P13.4

Figure P13.5 shows plots of reactant concentrations versus time for four reactions. Which one has the greatest initial rate?

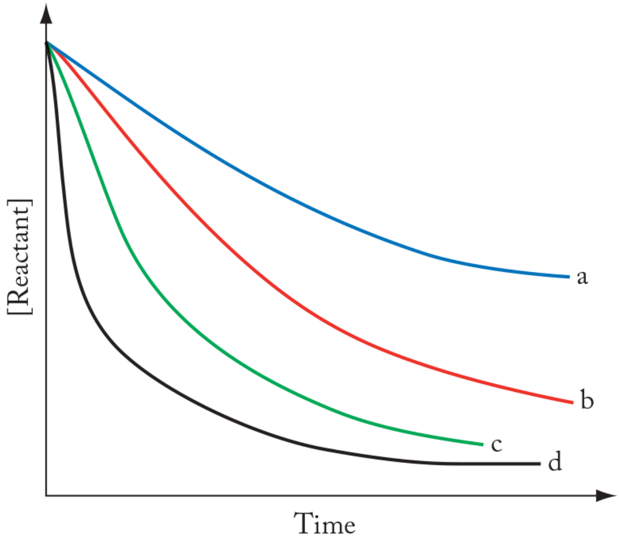

FIGURE P13.5

For a given temperature, which of the reaction profiles in Figure P13.6 represents (a) the slowest reaction? (b) the fastest reaction?

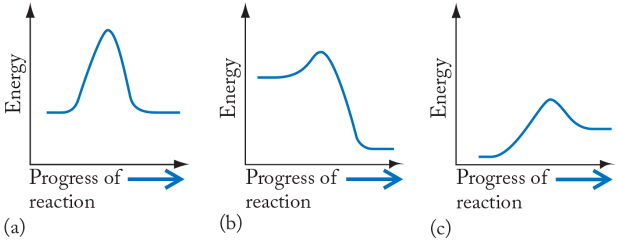

FIGURE P13.6

Which of the following mechanisms is consistent with the reaction profile shown in Figure P13.7?

$$2\,A \xrightarrow{\text{slow}} B$$
$$B \xrightarrow{\text{fast}} C$$

$$2\,A \overset{\text{fast}}{\rightleftharpoons} B$$
$$B \xrightarrow{\text{slow}} C$$

$$2\,A \overset{\text{fast}}{\rightleftharpoons} B$$
$$B \xrightarrow{\text{slow}} C$$

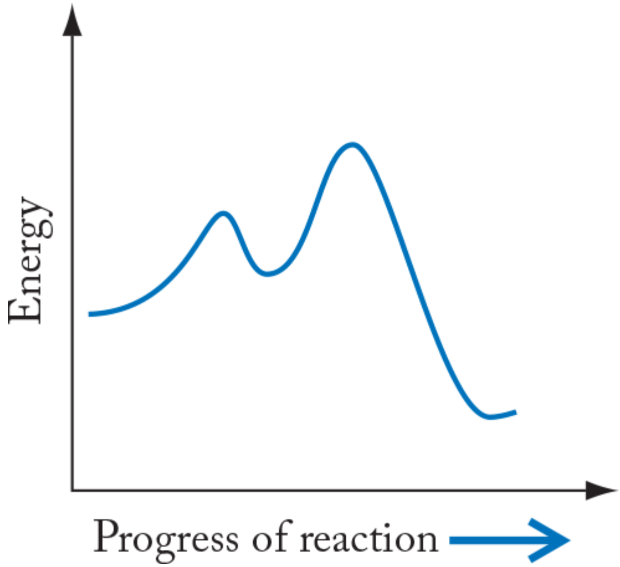

FIGURE **P13.7**

Which of the following mechanisms is consistent with the reaction profile shown in Figure P13.8?

$$A + B \xrightarrow{\text{slow}} C$$

$$C \xrightarrow{\text{fast}} D$$

$$A + B \rightarrow C$$

$$2\,A \xrightarrow{\text{fast}} B$$

$$B + C \xrightarrow{\text{slow}} D$$

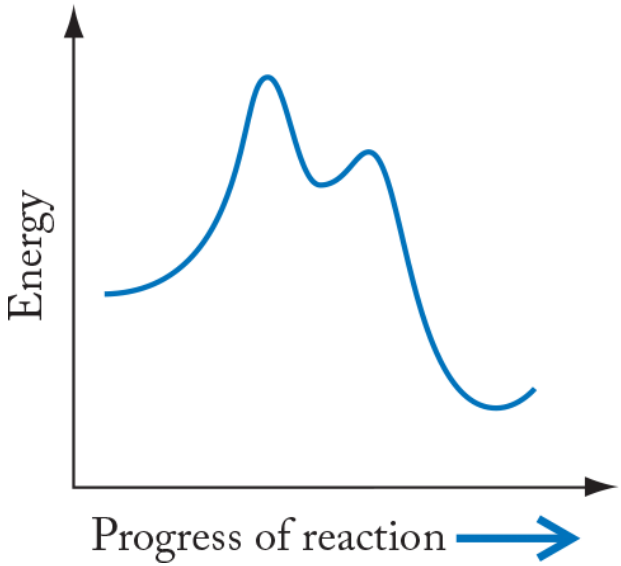

FIGURE P13.8

Use Figure P13.9 to answer the following questions:

1. Which asterisk identifies a transition state?
2. Which arrow identifies the activation energy of the reaction in the forward direction?
3. Which arrow identifies the activation energy of the reaction in the reverse direction?
4. Which arrow identifies the change in energy that accompanies the reaction—that is, the energy of the products less the energy of the reactants?

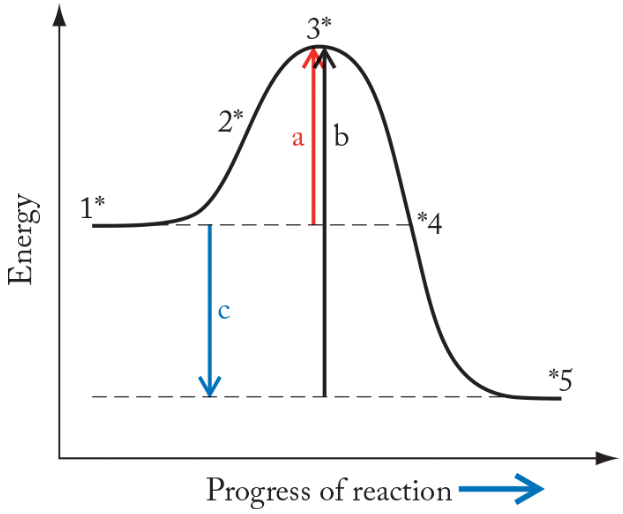

FIGURE P13.9

In the mechanism for decomposition of NO_2 to NO and O_2, through an NO_3 intermediate, why are the activated complexes in Figure P13.10 *unlikely* to lead to products?

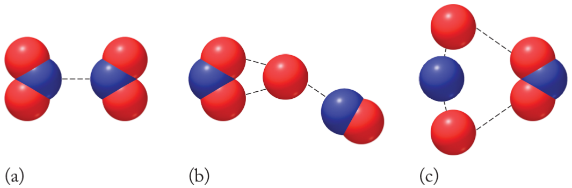

FIGURE P13.10

Figure P13.11 shows a plot of ln *k* versus $1/T$ for two reactions with different activation energies. Which reaction has a higher activation energy? The rate of which reaction is more sensitive to temperature changes?

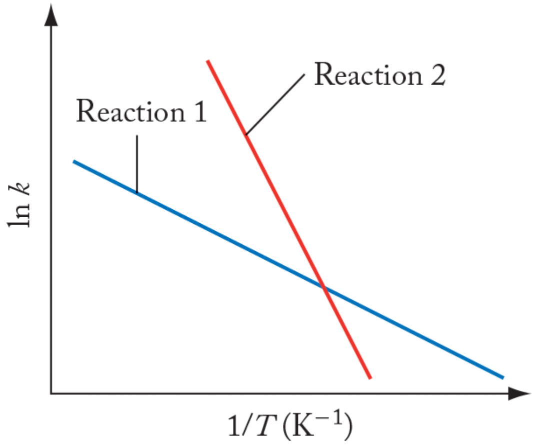

FIGURE P13.11

Use representations [A] through [I] in Figure P13.12 to answer questions (a)–(f).

1. Which two images describe elementary steps that, when combined, depict the chlorine-catalyzed destruction of ozone?
2. Which representation is the overall reaction for the chlorine-catalyzed destruction of ozone?
3. Which two images describe elementary steps that combine in an overall reaction in which NO_3 is an intermediate?
4. Write the chemical equation for the overall reaction described in question (c).
5. Which image shows the photodecomposition of a chlorofluorocarbon?
6. Rank images [C], [F], and [I] in decreasing order of number of collisions between Cl atoms and O_3 molecules in the stratosphere.

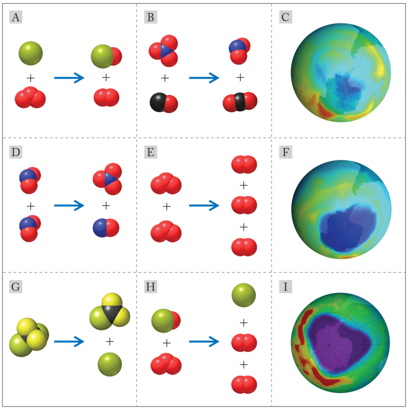

FIGURE P13.12

QUESTIONS AND PROBLEMS

Cars, Trucks, and Air Quality

Concept Review

Why does the maximum concentration of NO_2 on a smoggy day, as graphed in Figure 13.4, occur several hours after the maximum concentration of NO?

Why does the maximum concentration of ozone graphed in Figure 13.4 occur much later in the day than the maximum concentrations of NO and NO_2?

Which are more reactive: O atoms or O_2 molecules? Why?

Why is gaseous OH so much more reactive than H_2O vapor?

Which of the highlighted elements in Figure P13.17 forms volatile oxides associated with the formation of photochemical smog?

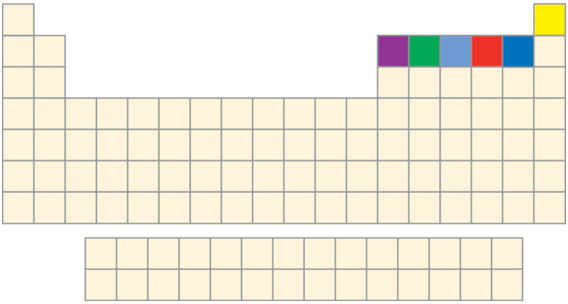

FIGURE P13.17

Which of the highlighted elements in Figure P13.17 has an allotrope associated with the formation of photochemical smog?

Reaction Rates

Concept Review

Explain the difference between the rate of a reaction at 25°C and its rate constant at 25°C.

Explain the difference between the average rate and the instantaneous rate of a chemical reaction.

Suggest three possible ways of monitoring the rate of the following reaction:

$CH_3CHO(g) \rightarrow CH_4(g) + CO(g)$

Would the rate data (changing concentration with time) be the same for all the alternatives?

Suggest two ways to monitor the rate of the following reaction:

$2\ H_2O_2(aq) \rightarrow 2\ H_2O(\ell) + O_2(g)$

Would the rate data (changing concentration with time) be the same for either method?

If baking soda ($NaHCO_3$) and sidewalk deicer ($CaCl_2$) are mixed, there is no sign of a chemical reaction. If these two solids are dissolved in water and mixed, however, they rapidly react. Explain the difference in reaction rate.

Any gas-phase reaction occurs more rapidly as the temperature of the gas increases. Why?

In the decomposition reaction, $A \rightarrow B + C$, how is the rate at which A is consumed related to the rate at which B is produced?

During the Haber process for synthesizing ammonia, $N_2(g) + 3 H_2(g) \rightarrow 2 NH_3(g)$, the rate of formation of ammonia is twice the rate at which nitrogen is consumed. Does this mean that the mass of the reaction mixture increases as the reaction proceeds—seemingly defying the law of conservation of mass? Explain why or why not.

If the rate of change in the concentration of a reactant increases (becomes less negative) with time, does the rate of change in the concentration of a product of the same reaction increase or decrease?

During a reaction, can there be a time when the instantaneous rate of the reaction does not change? If you think so, describe such a time.

Problems

Catalytic Converters in Automobiles (I) Catalytic converters combat air pollution by converting NO into N_2 and O_2.

1. How is the rate of formation of O_2 related to the rate of formation of N_2?
2. How is the rate of change in $[N_2]$ related to the rate of change in [NO]?

Catalytic Converters in Automobiles (II) Catalytic converters also combat air pollution by promoting the reaction between

CO and O_2 that produces CO_2.

1. How is the rate of change in $[CO_2]$ related to the rate of change in $[O_2]$?
2. How is the rate of change in $[CO_2]$ related to the rate of change in [CO]?

A study was initiated to determine the rate of the following reaction:

$2\ NO(g) + O_2(g) \rightarrow 2\ NO_2(g)$

If the concentration of NO was 0.0300 *M* at $t = 5.0$ s and 0.0225 *M* at $t = 650.0$ s, then what was the average rate of the reaction during this period?

In a study of the thermal decomposition of ammonia into nitrogen and hydrogen:

$2\ NH_3(g) \rightarrow N_2(g) + 3\ H_2(g)$

the average rate of change in the concentration of ammonia is -0.38 *M*/s.

1. What is the average rate of change in $[H_2]$?
2. What is the average rate of change in $[N_2]$?
3. What is the average rate of the reaction?

Power Plant Emissions Sulfur dioxide emissions in stack gases at power plants may react with carbon monoxide as follows:

$SO_2(g) + 3\ CO(g) \rightarrow 2\ CO_2(g) + COS(g)$

Write an equation relating the rates for each of the following:

1. The rate of formation of CO_2 to the rate of consumption of CO
2. The rate of formation of COS to the rate of consumption of

SO_2

3. The rate of consumption of CO to the rate of consumption of SO_2

Reducing Power Plant Emissions Nitrogen monoxide can be removed from gas-fired power plant emissions by reaction with methane as follows:

$CH_4(g) + 4\ NO(g) \rightarrow 2\ N_2(g) + CO_2(g) + 2\ H_2O(g)$

Write an equation relating the rates for each of the following:

1. The rate of formation of N_2 to the rate of formation of CO_2
2. The rate of formation of CO_2 to the rate of consumption of NO
3. The rate of consumption of CH_4 to the rate of formation of H_2O

Stratospheric Ozone Depletion Chlorine monoxide (ClO) plays a major role in the creation of the ozone holes in the stratosphere over Earth's polar regions.

1. If $\Delta[\mathrm{ClO}]/\Delta t$ at 298 K is $-2.3 \times 10^7 M/\mathrm{s}$, what is the rate of change in $[Cl_2]$ and $[O_2]$ in the following reaction?

$2\ ClO(g) \rightarrow Cl_2(g) + O_2(g)$

2. If $\Delta[\mathrm{ClO}]/\Delta t$ is $-2.9 \times 10^4 M/\mathrm{s}$, what is the rate of formation of oxygen and ClO_2 in the following reaction?

$ClO(g) + O_3(g) \rightarrow O_2(g) + ClO_2(g)$

The chemistry of smog formation includes NO_3 as an intermediate in several reactions.

1. If $\Delta[\mathrm{NO_3}]/\Delta t$ is -2.2×10^5 mM/min in the following reaction, what is the rate of formation of NO_2?

$NO_3(g) + NO(g) \rightarrow 2\ NO_2(g)$

2. What is the rate of change of $[NO_2]$ in the following reaction if $\Delta[NO_3]/\Delta t$ is $-$ 2.3 mM/min?

$2\ NO_3(g) \rightarrow 2\ NO_2(g) + O_2(g)$

Nitrite ion reacts with ozone in aqueous solution, producing nitrate ion and oxygen:

$NO_2{}^-(aq) + O_3(g) \rightarrow NO_3{}^-(aq) + O_2(g)$

Time (μs)	$[O_3]$ (M)
0.0	1.13×10^{-2}
100.0	9.93×10^{-3}
200.0	8.70×10^{-3}
300.0	8.15×10^{-3}

The following data were collected for this reaction at 298 K. Calculate the average reaction rate between 0.0 and 100.0 μs (microseconds) and between 200.0 and 300.0 μs.

Biomolecular Signaling Hydrogen sulfide and nitrogen monoxide can act as signaling agents in living cells. NO is often bound in a molecule named 5-nitrosoglutathione (GSNO) and is released in a reaction with H_2S, producing glutathione (GSH) and thionitrous acid (HSNO):

$GSNO(aq) + H_2S(aq) \rightarrow GSH(aq) + HSNO(aq)$

The rate of the reaction at 25°C was determined by following the rate of consumption of H_2S:

1. Calculate the average rate of the reaction between $t = 0.0$ s and $t = 50.0$ s.
2. Estimate the instantaneous rate for the reaction at $t = 25.0$ s.

Time (s)	$[H_2S]$ (μM)
0.0	250

25.0	158
50.0	98.0
75.0	71.0

Biological Role of Nickel Nickel-containing compounds in living cells react with dissolved oxygen, forming a nickel peroxide (abbreviated as Ni_2O_2). An experiment to determine the rate decomposition of Ni_2O_2 at 298 K produced the following data:

Time (min)	$[Ni_2O_2]$ (m*M*)
5.0	0.69
10.0	0.40
15.0	0.33
20.0	0.21
25.0	0.15
30.0	0.10

Plot the data from this experiment and determine the instantaneous rates of change in the concentration of Ni_2O_2 at 10.0, 15.0, and 25.0 min.

Tropospheric Ozone Tropospheric (lower atmosphere) ozone is rapidly consumed in many reactions, including

Time (s)	[NO] (*M*)
0.000	2.00×10^{-8}
0.011	1.81×10^{-8}
0.027	1.62×10^{-8}
0.052	1.45×10^{-8}
0.102	1.20×10^{-8}

$O_3(g) + NO(g) \rightarrow NO_2(g) + O_2(g)$

Use the following data to calculate the instantaneous rate of the preceding reaction at $t = 0.000$ s and $t = 0.052$ s.

Effect of Concentration on Reaction Rate

Concept Review

Why do the rates of nearly all reactions decrease as reactants form products?

Why are the units of the rate constants different for reactions of different order?

A colleague has determined that the rate constant of the reaction you are studying is $2.5 \times 10^2 M/s$ at 25.0°C. What is the order of the reaction?

The rate of a reaction does *not* decrease with time for a reaction with which order: zero, first, or second?

The reaction between A and B that produces C is first order in both A and B with a rate law of rate $= k[A][B]$. When the $[B]_0$ is 50 times the $[A]_0$, why does the rate law appear to be rate $= k[A]$?

When measuring the kinetics of gas-phase reactions, scientists often monitor changes in the partial pressures of reactants. How is this equivalent to measuring changes in concentration?

Problems

For each of the following rate laws, determine the order with respect to each reactant and the overall reaction order.

1. Rate $= k[A][B]$
2. Rate $= k[A]^2[B]$
3. Rate $= k[A][B]^2$
4. Rate $= k[A]/[B]$

Determine the overall order of the following rate laws and the order with respect to each reactant.

1. Rate $= k[A]^2[B]^{1/2}$
2. Rate $= k[A]^2[B][C]$
3. Rate $= k[A][B]^2[C]^{0.5}$
4. Rate $= k[A][B]/[C][D]^2$

Write rate laws and determine the units of the rate constant (using the units *M* for concentration and s for time) for the following reactions:

1. The reaction of oxygen atoms with NO_2 is first order in both reactants.
2. The reaction between NO and Cl_2 is second order in NO and first order in Cl_2.
3. The reaction between Cl_2 and chloroform ($CHCl_3$) is first order in $CHCl_3$ and one-half order in Cl_2.
4. The decomposition of ozone (O_3) to O_2 is second order in O_3 and an order of -1 in O atoms.

Compounds A and B react to give a single product, C. Write the rate law for each of the following cases and determine the units of the rate constant by using the units *M* for concentration and s for time:

1. The reaction is first order in A and second order in B.
2. The reaction is first order in A and second order overall.
3. The reaction is zero order in A and second order overall.
4. The reaction is second order in both A and B.

Predict the rate law for the reaction $2\ BrO(g) \rightarrow Br_2(g) + O_2(g)$ if:

1. The rate doubles when [BrO] doubles.
2. The rate quadruples when [BrO] doubles.
3. The rate is halved when [BrO] is halved.
4. The rate is unchanged when [BrO] is doubled.

Predict the rate law for the reaction $NO(g) + Br_2(g) \rightarrow NOBr_2(g)$ if:

1. The rate doubles when [NO] is doubled and $[Br_2]$ remains constant.
2. The rate doubles when $[Br_2]$ is doubled and [NO] remains constant.
3. The rate increases by 1.56 times when [NO] is increased 1.25 times and $[Br_2]$ remains constant.

4. The rate is halved when [NO] is doubled and [Br_2] remains constant.

The rate of the reaction:

$NO(g) + O_3(g) \rightarrow NO_2(g) + O_2(g)$

quadruples when the concentrations of NO and O_3 are doubled. Does this prove that the reaction is first order in both reactants? Why or why not?

Chlorine monoxide reacts with nitrogen dioxide to form chlorine nitrate ($ClONO_2$):

$ClO(g) + NO_2(g) + M(g) \rightarrow ClONO_2(g) + M(g)$

A third molecule (M) takes part in the reaction but is unchanged by it. The reaction is first order in both NO_2 and ClO, and it is second order overall.

1. Write the rate law for this reaction.
2. What is the reaction order with respect to M?

Rate Laws for Destruction of Tropospheric Ozone NO_2 reacts with ozone to produce NO_3 in a reaction that is second order overall:

$NO_2(g) + O_3(g) \rightarrow NO_3(g) + O_2(g)$

1. Write the rate law for the reaction if the reaction is first order in each reactant.
2. The rate constant for the reaction is $1.93 \times 10^4 M^{-1}\ s^{-1}$ at 298 K. What is the rate of the reaction when [NO_2] $= 1.8 \times 10^{-8} M$ and [O_3] $= 1.4 \times 10^{-7} M$?
3. What is the rate of formation of NO_3 under these conditions?
4. What happens to the rate of the reaction if the concentration of $O_3(g)$ is doubled?

Sources of Nitric Acid in the Atmosphere The reaction between N_2O_5 and water,

$N_2O_5(g) + H_2O(g) \rightarrow 2\ HNO_3(g)$

is a source of nitric acid in the atmosphere.

1. The reaction is first order in each reactant. Write the rate law for the reaction.
2. When $[N_2O_5]$ is 0.132 m*M* and $[H_2O]$ is 230 m*M*, the rate of the reaction is 4.55×10^{-4} m*M* min^{-1}. What is the rate constant for the reaction?

Each of the following reactions is first order in the reactants and second order overall. Which reaction is fastest if the initial concentrations of the reactants are the same? All reactions are run at 298 K.

1. $ClO_2(g) + O_3(g) \rightarrow ClO_3(g) + O_2(g)$

   $k = 3.0 \times 10^{-19}\ \text{cm}^3/(\text{molecule} \cdot \text{s})$

2. $ClO_2(g) + NO(g) \rightarrow NO_2(g) + ClO(g)$

   $k = 3.4 \times 10^{-13}\ \text{cm}^3/(\text{molecule} \cdot \text{s})$

3. $ClO(g) + NO(g) \rightarrow Cl(g) + NO_2(g)$

   $k = 1.7 \times 10^{-11}\ \text{cm}^3/(\text{molecule} \cdot \text{s})$

4. $ClO(g) + O_3(g) \rightarrow ClO_2(g) + O_2(g)$

   $k = 1.5 \times 10^{-17}\ \text{cm}^3/(\text{molecule} \cdot \text{s})$

Two reactions in which there is a single reactant have nearly the same magnitude of rate constant. One is first order, whereas the other is second order.

1. If the initial concentrations of the reactants are both 1.0 m*M*, which reaction will proceed at the higher rate?

If the initial concentrations of the reactants are both 2.0 *M*, which reaction will proceed at the higher rate?

The rate constant for the decomposition of N_2O_5 to NO_2 and O_2,

$2\ N_2O_5(g) \rightarrow 4\ NO_2(g) + O_2(g)$

is $3.4 \times 10^{-5}\ s^{-1}$ at 298 K. What is the rate law expression for the reaction at 298 K?

Hydroperoxyl Radicals in the Atmosphere During a smog event, trace amounts of many highly reactive substances are present in the atmosphere. One of these is the hydroperoxyl radical (HO_2), which reacts with sulfur trioxide (SO_3). The rate constant for the reaction

$2\ HO_2(g) + SO_3(g) \rightarrow H_2SO_3(g) + 2\ O_2(g)$

is $2.6 \times 10^{11} M^{-1}\ s^{-1}$ at 298 K. The initial rate of the reaction doubles when the concentration of SO_3 or HO_2 is doubled. What is the rate law for the reaction?

Disinfecting Municipal Water Supplies Chlorine dioxide (ClO_2) is a disinfectant used in municipal water treatment plants (Figure P13.61). It dissolves in basic solution, producing ClO_3^- and ClO_2^-:

$2\ ClO_2(g) + 2\ OH^-(aq) \rightarrow ClO_3^-(aq) + ClO_2^-(aq) + H_2O\ (\ell)$

FIGURE P13.61

The following kinetic data were obtained at 298 K for the reaction:

[illegible]	[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]	[illegible]

Determine the rate law and the rate constant for this reaction at 298 K.

Oxygen Atom Transfer A nickel compound containing peroxide (abbreviated as Ni_2O_2) can donate O atoms to other molecules. A model for such a reaction is the conversion of cyclooctene to 1,2-cyclooctene oxide shown in Figure P13.62.

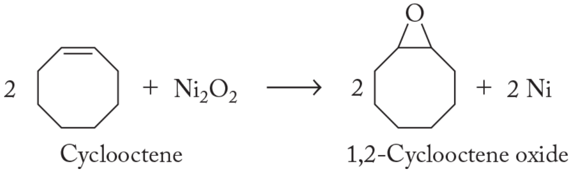

FIGURE P13.62

The following rate data were collected for the reaction at 243 K:

Experiment	[Cyclooctene] (M)	[Ni_2O_2] (M)	Initial Rate (M/s)
1	[illegible]	[illegible]	[illegible]
2	[illegible]	[illegible]	[illegible]
3	[illegible]	[illegible]	[illegible]

Determine the rate law and the rate constant for this reaction at 243 K.

Hydrogen gas reduces NO to N_2 in the following reaction:

$2\ H_2(g)\ +\ 2\ NO(g) \rightarrow 2\ H_2O(g)\ +\ N_2(g)$

The initial reaction rates of four mixtures of H_2 and NO were measured at 900°C with the following results:

Experiment	[H_2] (M)	[NO] (M)	Initial Rate (M/s)
1	[illegible]	[illegible]	[illegible]
2	[illegible]	[illegible]	[illegible]
3	[illegible]	[illegible]	[illegible]
4	[illegible]	[illegible]	[illegible]

Determine the rate law and the rate constant for the reaction at 900°C.

The rate of the reaction

$NO_2(g) + CO(g) \rightarrow NO(g) + CO_2(g)$

was determined in three experiments at 225°C. The results are listed in the following table:

1. Determine the rate law for the reaction.
2. Calculate the value of the rate constant at 225°C.
3. Calculate the rate of formation of CO_2 when $[NO_2] = [CO] = 0.500\ M$.

Experiment	$[NO_2]_0$ (*M*)	$[CO]_0$ (*M*)	Initial Rate $-\Delta[NO2]/\Delta t$ (*M*/*s*)
1	0.263	0.826	1.44×10^{-5}
2	0.263	0.413	1.44×10^{-5}
3	0.526	0.413	5.76×10^{-5}

Use the data for the decomposition of the nickel peroxide in Problem 13.39 at 298 K to answer the following questions:

1. What is the rate law for the reaction?
2. What is the rate constant for the reaction at 298 K?
3. What is the half-life of the reaction?

Two structural isomers of ClO_2 are shown in Figure P13.66.

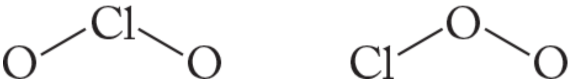

FIGURE P13.66

The isomer with the Cl□O□O skeletal arrangement is unstable and rapidly decomposes according to the reaction $2\ ClOO(g) \rightarrow Cl_2(g) + 2\ O_2(g)$. The following data were collected for the decomposition of ClOO at 298 K:

Time (μs)	[ClOO] (*M*)
0.0	1.76×10^{-6}
0.7	2.36×10^{-7}
1.3	3.56×10^{-8}

3.13×10^{-9}

2.96×10^{-10}

Determine the rate law for the reaction and the value of the rate constant at 298 K.

Carbon Monoxide in Cancer Therapy Scientists are investigating a class of potential anticancer drugs that selectively releases low doses of carbon monoxide. One such compound reacts with myoglobin, forming a myoglobin–CO complex when the mixture is irradiated with UV light at 379 nm. The half-life for the first-order reaction at 293 K is 9.37 minutes.

1. What is the rate constant for the reaction?
2. What fraction of the drug remains after 30 minutes of irradiation?

Yogurt Expiration Date Labels of many food products have expiration dates, at which point they are typically removed from supermarket shelves. A particular natural yogurt degrades with a half-life of 45 days. The manufacturer of the yogurt wants unsold product pulled from the shelves when it degrades to no more than 80% of its original quality. Assume the degradation process is first order. What should be the “best if used before” date on the container with respect to the date the yogurt was packaged?

Acetoacetic acid (CH_3COCH_2COOH) decomposes in aqueous acidic solution to form acetone and carbon dioxide:

$$CH_3COCH_2COOH(aq) \rightarrow CH_3COCH_3(aq) + CO_2(g)$$

The reaction is first order. At room temperature, the half-life of the reactant is 139 min.

1. What is the rate constant of the decomposition reaction?
2. If the initial concentration of acetoacetic acid is 2.75 *M*, what

is its concentration after 5 hours?

p-Toluenesulfinic acid undergoes a second-order redox reaction at room temperature (Figure P13.70).

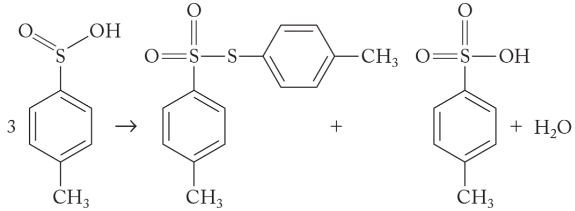

FIGURE P13.70

1. The value of the rate constant *k* for the reaction is 0.141 L mol^{-1} min^{-1}. What is the half-life of *p*-toluenesulfinic acid?
2. If the initial concentration of *p*-toluenesulfinic acid is 0.355 *M*, at what time will its concentration be 0.0355 *M*?

Laughing Gas Nitrous oxide (N_2O) is used as an anesthetic (laughing gas) and in aerosol cans to produce whipped cream. It is a potent greenhouse gas and decomposes slowly to N_2 and O_2:

$$2\ N_2O(g) \rightarrow 2\ N_2(g) + O_2(g)$$

1. If the plot of ln[N_2O] as a function of time is linear, what is the rate law for the reaction?
2. How many half-lives will it take for the concentration of the N_2O to reach 6.25% of its original concentration?

[*Hint*: The amount of reactant remaining after time *t* (A_t) is related to the amount initially present (A_0) by the equation $A_t/A_0 = (0.5)^n$, where *n* is the number of half-lives in time *t*.]

The unsaturated hydrocarbon butadiene (C_4H_6) dimerizes to 4-vinylcyclohexene (C_8H_{12}). When data collected in studies of the kinetics of this reaction were plotted against reaction time, plots of [C_4H_6] or ln[C_4H_6] produced curved lines, but the plot of 1/[C_4H_6] was linear.

1. What is the rate law for the reaction?
2. How many half-lives will it take for the [C_4H_6] to decrease to 3.1% of its original concentration?

Tracing Phosphorus in Organisms Radioactive isotopes such as ^{32}P are used to follow biological processes. The following radioactivity data (in relative radioactivity values) were collected for a sample containing ^{32}P:

Time (days)	Radioactivity (relative radioactivity values)
0	10.0
1	9.53
2	9.08
5	7.85
10	6.16
20	3.79

1. Write the rate law for the decay of ^{32}P and determine the value of the first-order rate constant.
2. What is the half-life of ^{32}P?

Nitrous acid slowly decomposes to NO, NO_2, and water in the following second-order reaction:

$$2\ HNO_2(aq) \rightarrow NO(g) + NO_2(g) + H_2O(\ell)$$

1. Use the data in the table to determine the rate constant for this reaction at 298 K.

Time (min)	[HNO_2] (μM)
0	0.0560
1000	0.0466
1500	0.0424
2000	0.0380

[illegible]	[illegible]
[illegible]	[illegible]

Determine the half-life for the decomposition of HNO_2.

The dimerization of ClO,

$2\ ClO(g) \rightarrow Cl_2O_2(g)$

is second order in ClO. Use the following data to determine the value of *k* at 298 K:

Time (s)	[ClO] (molecules/cm3)
0	2.60×10^{11}
1	1.08×10^{11}
2	6.83×10^{10}
3	4.99×10^{10}
4	3.93×10^{10}

Determine the half-life for the dimerization of ClO.

Kinetic data for the reaction $Cl_2O_2(g) \rightarrow 2\ ClO(g)$ are summarized in the following table:

Time (μs)	[Cl2O2] (*M*)
0	6.60×10^{-8}
172	5.68×10^{-8}
345	4.89×10^{-8}
517	4.21×10^{-8}
690	3.62×10^{-8}
862	3.12×10^{-8}

Determine the value of the first-order rate constant, then determine the half-life for the decomposition of Cl_2O_2.

Reaction Rates, Temperature, and the Arrhenius Equation

Concept Review

Suppose the high-energy reactants in a reaction form lower-energy products. Is the activation energy barrier higher in the forward or the reverse direction?

Explain why gas-phase reactions go faster at a higher temperature, yet rate laws such as rate $= k[\mathrm{A}]$ do not include T.

The order of a reaction is independent of temperature, but the value of the rate constant varies with temperature. Why?

Are exothermic reactions faster than endothermic reactions? Explain why or why not.

Two first-order reactions have activation energies of 15 and 150 kJ/mol. Which reaction will show the larger increase in rate as temperature is increased?

The activation energy for a particular reaction is nearly zero. Is its rate constant very sensitive to temperature changes? Explain why.

Wine Chemistry Some New Zealand wines have distinctive aromas that suggest guava and passion fruit. These aromas tend to disappear when the wines are stored because the esters that produce the aromas hydrolyze. Why does storing the wine at low temperature reduce the loss of the desired aromas?

Ripening Bananas Bananas ripen in the presence of ethylene (C_2H_4) gas. The source of the ethylene is the banana itself, although shippers will typically treat green bananas with ethylene to speed up the process. The same effect can be achieved by storing green bananas in a plastic bag. Why does storing them in plastic bags cause bananas to ripen faster?

Problems

The rate constant for the reaction of ozone with oxygen atoms was determined at four temperatures. Calculate the activation energy and frequency factor *A* for the reaction

$O(g) + O_3(g) \rightarrow 2\ O_2(g)$

given the following data:

T (K)	k ($M^{-1}\ s^{-1}$)
250	1.72×10^6
275	2.69×10^6
300	5.02×10^6
325	8.51×10^6

The rate constant for the reaction

$NO_2(g) + O_3(g) \rightarrow NO_3(g) + O_2(g)$

was determined over a temperature range of 40 K, with the following results:

T (K)	k ($M^{-1}\ s^{-1}$)
203	4.14×10^5
213	7.30×10^5
223	1.22×10^6
233	1.96×10^6
243	3.02×10^6

1. Determine the activation energy for the reaction.
2. Calculate the rate constant of the reaction at 300 K.

Activation Energy of a Smog-Forming Reaction The initial step in the formation of smog is the reaction between nitrogen and oxygen. The activation energy of the reaction can be determined from the temperature dependence of the rate constants. At the temperatures indicated, values of the rate constant of the reaction

$N_2(g) + O_2(g) \rightarrow 2\ NO(g)$

are as follows:

T (K)	k ($M^{-1/2}\ s^{-1}$)
2000	3180
2100	7820
2200	1270
2300	3733
2400	7396

1. Calculate the activation energy of the reaction.
2. Calculate the frequency factor for the reaction.
3. Calculate the value of the rate constant at ambient temperature, $T = 300$ K.

Nitrogen Fixation Nitrogen fixation is the biological process by which the N{N bonds in molecules of atmospheric N_2 are broken and nitrogen compounds such an NH_3 are produced. For decades chemists have studied reactions that mimic biological nitrogen fixation. In one such investigation the rate constant for an N_2 dissociation reaction was measured at five different temperatures. The following results were obtained:

T (K)	k (s^{-1})
263	5.20×10^{-4}
268	9.91×10^{-4}
274	2.07×10^{-3}
278	3.29×10^{-3}
284	6.56×10^{-3}

1. Calculate the activation energy for the reaction.
2. What is the value of k at 298 K?

Activation Energy of Stratospheric Ozone Destruction The value of the rate constant for the reaction between chlorine dioxide and ozone was measured at four temperatures between 193 and 208 K. The following results were obtained:

T (K)	k ($M^{-1}\ s^{-1}$)
193	340

698	128
203	102.8
296	108.7

Calculate the values of the activation energy and the frequency factor for the reaction.

Chlorine atoms react with methane, forming HCl and CH_3. The rate constant for the reaction is $6.0 \times 10^7 M^{-1}\ s^{-1}$ at 298 K. When the experiment was repeated at three other temperatures, the following data were collected:

T (K)	k ($M^{-1}\ s^{-1}$)
303	6.5×10^7
308	7.0×10^7
313	7.5×10^7

Calculate the values of the activation energy and the frequency factor for the reaction.

Reaction Mechanisms

Concept Review

The reaction between NO and Cl_2 is first order in each reactant. Does this mean that the reaction could occur in just one step? Explain your answer.

The reaction between NO and H_2 is second order in NO. Does this mean that the reaction could occur in just one step?

If a reaction is zero order in a reactant, does that mean the reactant is never involved in collisions with other reactants? Explain your answer.

In question 13.45, is reactant B ever involved in collisions with the other reactant A?

Problems

Substance A decomposes slowly into substance B, which then rapidly decomposes into substances C and D. Sketch a reaction profile for the reaction A → C + D, adding labels in the appropriate locations for the four substances involved.

How would the reaction profile in Problem 13.95 change if the first step were fast and the second step were slow?

Write the rate laws for the following elementary steps and identify them as uni-, bi-, or termolecular steps:

1. $SO_2Cl_2(g) \rightarrow SO_2(g) + Cl_2(g)$
2. $NO_2(g) + CO(g) \rightarrow NO(g) + CO_2(g)$
3. $2\ NO_2(g) \rightarrow NO_3(g) + NO(g)$

Write the rate laws for the following elementary steps and identify them as uni-, bi-, or termolecular steps:

1. $Cl(g) + O_3(g) \rightarrow ClO(g) + O_2(g)$
2. $2\ NO_2(g) \rightarrow N_2O_4(g)$

*c. $^{14}_{6}C \rightarrow ^{14}_{7}N + ^{0}_{-1}\beta$

Write the overall reaction that consists of the following elementary steps:

(1) $N_2O_5(g) \rightarrow NO_3(g) + NO_2(g)$
(2) $NO_3(g) \rightarrow NO_2(g) + O(g)$
(3) $2\ O(g) \rightarrow O_2(g)$

What overall reaction consists of the following elementary steps?

(1) $ClO^-(aq) + H_2O(l) \rightarrow HClO(aq) + OH^-(aq)$
(2) $I^-(aq) + HClO(aq) \rightarrow HIO(aq) + Cl^-(aq)$
(3) $OH^-(aq) + HIO(aq) \rightarrow H_2O(l) + IO^-(aq)$

In the following mechanism for NO formation, oxygen atoms are produced by breaking O□O bonds at high temperature in a fast, reversible reaction. If $\Delta[\mathrm{NO}]/\Delta t = k[\mathrm{N_2}][\mathrm{O_2}]^{1/2}$, which step in the mechanism is the rate-determining step?

(1) $O_2(g) \rightleftharpoons 2O(g)$
(2) $O(g) + N_2(g) \rightarrow NO(g) + N(g)$
(3) $N(g) + O(g) \rightarrow NO(g)$
Overall $N_2(g) + O_2(g) \rightarrow 2\,NO(g)$

A proposed mechanism for the decomposition of hydrogen peroxide consists of three elementary steps:

(1) $H_2O_2(g) \rightarrow 2\,OH(g)$
(2) $H_2O_2(g) + OH(g) \rightarrow H_2O(g) + HO_2(g)$
(3) $HO_2(g) + OH(g) \rightarrow H_2O(g) + O_2(g)$

If the rate law for the reaction is first order in H_2O_2, which step in the mechanism is the rate-determining step?

A complex silver ion whose formula is abbreviated $\mathrm{Ag(EBG)^+}$ reacts with two moles of dithionate ion ($S_2O_8{}^{2-}$) in a two-step reaction to produce a compound with silver in the +3 oxidation state:

$\mathrm{Ag(EBG)^+} + S_2O_8{}^{2-} \rightarrow \mathrm{Ag(EBG)^{2+}} + S_2O_8{}^{3-}$

$\mathrm{Ag(EBG)^{2+}} + S_2O_8{}^{2-} \rightarrow \mathrm{Ag(EBG)^{3+}} + S_2O_8{}^{3-}$

1. The activation energies for the two steps are 55 kJ/mol and 60 kJ/mol, respectively. Which step is the rate-determining step?
2. Sketch a graph of energy as a function of the reaction progress consistent with the two activation energies. Label the transition states and any intermediates in the reaction.

Mechanism of Ozone Destruction Ozone decomposes thermally to oxygen in the following reaction:

$2\ O_3(g) \rightarrow 3\ O_2(g)$

The following mechanism has been proposed:

$O_3(g) \rightarrow O(g) + O_2(g)$

$O(g) + O_3(g) \rightarrow 2\ O_2(g)$

The reaction is second order in ozone. What properties of the two elementary steps (specifically, relative rate and reversibility) are consistent with this mechanism?

Mechanism of NO2Destruction Which of the following mechanisms are possible for the thermal decomposition of NO2, given that the rate $= k[NO_2]^2$?

a.
$$NO_2(g) \xrightarrow{\text{slow}} NO(g) + O(g)$$
$$O(g) + NO_2(g) \xrightarrow{\text{fast}} NO(g) + O_2(g)$$

b.
$$NO_2(g) + NO_2(g) \xrightarrow{\text{fast}} N_2O_4(g)$$
$$N_2O_4(g) \xrightarrow{\text{slow}} NO(g) + NO_3(g)$$
$$NO_3(g) \xrightarrow{\text{fast}} NO(g) + O_2(g)$$

c.
$$NO_2(g) + NO_2(g) \xrightarrow{\text{slow}} NO(g) + NO_3(g)$$
$$NO_3(g) \xrightarrow{\text{fast}} NO(g) + O_2(g)$$

The rate laws for the thermal and photochemical decomposition of NO2 are different. Which of the following mechanisms are possible for the photochemical decomposition of NO2 given that the rate $= k[NO_2]$?

a. $NO_2(g) + NO_2(g) \xrightarrow{\text{slow}} N_2O_4(g)$
$N_2O_4(g) \xrightarrow{\text{fast}} N_2O_3(g) + O(g)$
$N_2O_3(g) + O(g) \xrightarrow{\text{fast}} N_2O_2(g) + O_2(g)$
$N_2O_2(g) \xrightarrow{\text{fast}} 2\ NO(g)$

b. $NO_2(g) + NO_2(g) \xrightarrow{\text{slow}} NO(g) + NO_3(g)$
$NO_3(g) \xrightarrow{\text{fast}} NO(g) + O_2(g)$

c. $NO_2(g) \xrightarrow{\text{slow}} N(g) + O_2(g)$
$N(g) + NO_2(g) \xrightarrow{\text{fast}} N_2O_2(g)$
$N_2O_2(g) \xrightarrow{\text{slow}} 2\ NO(g)$

Catalysts

Concept Review

Does a catalyst affect both the rate and the rate constant of a reaction? Explain your answer.

Is the rate law for a catalyzed reaction the same as that for the uncatalyzed reaction?

Does a substance that increases the rate of a reaction also increase the rate of the reverse reaction?

The rate of the reaction between NO_2 and CO is zero order in [CO]. Does this mean that CO is a catalyst in the reaction?

Does the concentration of a homogeneous catalyst appear in the rate law for the reaction it catalyzes?

The rate of a chemical reaction is too slow to measure at room temperature. We could either raise the temperature or add a catalyst. Which would be a better solution for making an accurate determination of the rate constant?

Problems

Is NO a catalyst for the decomposition of N_2O in the following two-step reaction mechanism, or is N_2O a catalyst for the conversion of NO to NO_2?

(1) $NO(g) + N_2O(g) \rightarrow N_2(g) + NO_2(g)$

(2) $2\ NO_2(g) \rightarrow 2\ NO(g) + O_2(g)$

NO as a Catalyst for Ozone Destruction Explain why NO is a catalyst in the following two-step process that results in the depletion of ozone in the stratosphere:

(1) $NO(g) + O_3(g) \rightarrow NO_2(g) + O_2(g)$

(2) $O(g) + NO_2(g) \rightarrow NO(g) + O_2(g)$

Overall $O(g) + O_3(g) \rightarrow 2\ O_2(g)$

On the basis of the frequency factors and activation energy values of the following two reactions, determine which one will have the larger rate constant at room temperature (298 K).

$O_3(g) + O(g) \rightarrow O_2(g) + O_2(g)$

$A = 8.0 \times 10^{-12}\ \text{cm}^3/(\text{molecules} \cdot \text{s})$ $E_a = 17.1\ \text{kJ/mol}$

$O_3(g) + Cl(g) \rightarrow ClO(g) + O_2(g)$

$A = 2.9 \times 10^{-11}\ \text{cm}^3/(\text{molecules} \cdot \text{s})$ $E_a = 2.16\ \text{kJ/mol}$

On the basis of the frequency factors and activation energy values of the following two reactions, determine which one will have the larger rate constant at room temperature (298 K).

$O_3(g) + Cl(g) \rightarrow ClO(g) + O_2(g)$

$A = 2.9 \times 10^{-11}\ \text{cm}^3/(\text{molecules} \cdot \text{s})$ $E_a = 2.16\ \text{kJ/mol}$

$O_3(g) + NO(g) \rightarrow NO_2(g) + O_2(g)$

$A = 2.0 \times 10^{-12}\ \text{cm}^3/(\text{molecules} \cdot \text{s})$ $E_a = 11.6\ \text{kJ/mol}$

Additional Problems

A student inserts a glowing wood splint into a test tube filled with O_2. The splint quickly catches fire (Figure P13.117). Why does the splint burn so much faster in pure O_2 than in air?

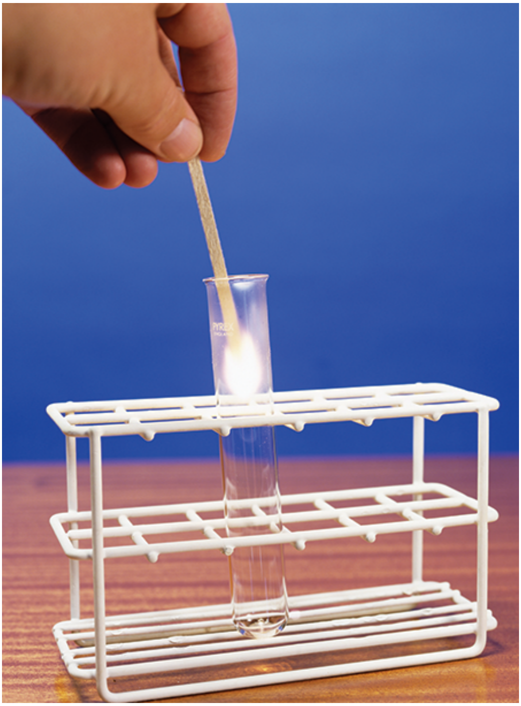

FIGURE P13.117

A backyard chef turns on the propane gas to a barbecue grill. Even though the reaction between propane and oxygen is spontaneous, the gas does not begin to burn until the chef pushes an igniter button to produce a spark. Why is the spark needed?

On average, someone who falls through the ice covering a frozen lake is less likely to experience anoxia (lack of oxygen) than someone who falls into a warm pool and is underwater for the same length of time. Why?

Ethanol Metabolism The half-life of ethanol in the human body is $t_{1/2} = [\text{ethanol}]_0/2k$, where $[\text{ethanol}]_0$ is the initial concentration of ethanol and k is the zero-order rate constant. Write the rate law for the metabolism of ethanol and sketch the concentration–time curve.

If the rate of the reverse reaction is much slower than the rate of the forward reaction, does the method used to determine a rate law from initial concentrations and initial rates also work at some other time *t*? What concentrations would we use in the case where we use the rate when *t*Z 0?

What is wrong with the following statement: The reaction rate and the rate constant for a reaction both depend on the number of collisions and on the concentrations of the reactants.

Why can't an elementary step in a mechanism have a rate law that is zero order in a reactant?

Testing for a Banned Herbicide Sodium chlorate was used in weed-control preparations, but its sale has been banned in EU countries since 2009. A simple colorimetric test for the presence of the chlorate ion in a solution of herbicide relies on the following reaction:

$2\ MnO_4^-(aq) + 5\ ClO_3^-(aq) + 6\ H^+(aq) \rightarrow 2\ Mn^{2+}(aq) + 5\ ClO_4^-(aq) + 3\ H_2O(\ell)$

The following table contains rate data for this reaction.

[illegible]	[illegible] (*M*/s)
[illegible]	[illegible] × 10^{-3}
[illegible]	[illegible] × 10^{-2}
[illegible]	[illegible] × 10^{-2}
[illegible]	[illegible] × 10^{-3}

Determine the rate law and the rate constant for this reaction.

Predict the initial rate of reaction in experiment 4.

An important reaction in the formation of photochemical smog is the reaction between ozone and NO:

$NO(g) + O_3(g) \rightarrow NO_2(g) + O_2(g)$

The reaction is first order in NO and O_3. The rate constant of the reaction is 80 $M^{-1}s^{-1}$ at 25°C and 3000 $M^{-1}s^{-1}$ at 75°C.

1. If this reaction were to occur in a single step, would the rate law be consistent with the observed order of the reaction for NO and O_3?
2. What is the value of the activation energy of the reaction?
3. What is the rate of the reaction at 25°C when $[NO] = 3 \times 10^{-6}M$ and $[O_3] = 5 \times 10^{-9}M$?
4. Predict the values of the rate constant at 10°C and 35°C.

Ammonia reacts with nitrous acid to form an intermediate, ammonium nitrite (NH_4NO_2), which decomposes to N_2 and H_2O:

$NH_3(g) + HNO_2(aq) \rightarrow NH_4NO_2(aq) \rightarrow N_2(g) + 2\ H_2O(\ell)$

1. The reaction is first order in ammonia and second order in nitrous acid. What is the rate law for the reaction? What are the units of the rate constant if concentrations are expressed in molarity and time in seconds?
2. The rate law for the reaction has also been written as

$\text{Rate} = k[NH_4^+][NO_2^-][HNO_2]$

Why might this expression of the rate law be considered equivalent to the one you wrote in part (a)?

3. Use the data in Appendix 4 to calculate the value of $\Delta H^\circ_{\text{rxn}}$ for the overall reaction ($\Delta H^\circ_{\text{f}}$ for $HNO_2 = -43.1$ kJ/mol).
4. Draw an energy profile for the process with the assumption that E_a of the first step is lower than E_a of the second step.

Lachrymators in Smog The combination of ozone, volatile hydrocarbons, nitrogen oxide, and sunlight in urban environments produces peroxyacetyl nitrate (PAN), a potent lachrymator (eye irritant). PAN decomposes to peroxyacetyl radicals and nitrogen dioxide in a process that is second order in PAN, as shown in Figure P13.128:

1. The half-life of the reaction, at 23°C and $P_{CH_3CO_3NO_2} = 10.5$ torr, is 100 h. Calculate the rate constant for the reaction.
2. Determine the rate of the reaction at 23°C and $P_{CH_3CO_3NO_2} = 10.5$ torr.
3. Draw a graph showing P_{PAN} as a function of time from 0 to 200 h, starting with $P_{CH_3CO_3NO_2} = 10.5$ torr.

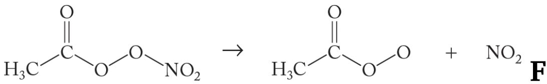

FIGURE P13.128

Nitrogen Oxide in the Human Body Nitrogen oxide is a free radical that plays many biological roles, including regulating neurotransmission and the human immune system. One of its many reactions involves the peroxynitrite ion ($ONOO^-$):

$NO(aq) + ONOO^-(aq) \rightarrow NO_2(aq) + NO_2^-(aq)$

1. Use the following data to determine the rate law and rate constant of the reaction at the experimental temperature at which these data were generated.

[illegible] (M)					
[illegible] × 10[illegible]					
[illegible] × 10[illegible]					
[illegible] × 10[illegible]					
[illegible] × 10[illegible]					

2. Draw the Lewis structure of peroxynitrite ion (including all resonance forms) and assign formal charges. Note which form is preferred.
3. Use the average bond energies in Table A4.1 to estimate the value of ΔH°_{rxn} by using the preferred structure from part (b).

Reducing NO Emissions Adding NH_3 to the stack gases at an electric-power-generating plant can reduce NO_x emissions. This selective noncatalytic reduction process depends on the reaction between NH_2 (an odd-electron molecule) and NO:

$NH_2(g) + NO(g) \rightarrow N_2(g) + H_2O(g)$

The following kinetic data were collected at 1200 K.

[illegible] × 10^{-5}					
[illegible] × 10^{-5}					
[illegible] × 10^{-5}					
[illegible] × 10^{-5}					

1. What is the rate law for the reaction?
2. What is the value of the rate constant at 1200 K?

Glossary

chemical kinetics

the study of the rates of change of concentrations of substances involved in chemical reactions.

rate law

an equation that defines the experimentally determined relation between the concentrations of reactants in a chemical reaction and the rate of that reaction.

reaction order

an experimentally determined number defining the dependence of the reaction rate on the concentration of a reactant.

rate constant

the proportionality constant that relates the rate of a reaction to the concentrations of reactants at a particular temperature.

initial rate

the rate of a reaction at $t = 0$, immediately after the reactants are mixed.

reaction mechanism

a set of steps describing how a reaction occurs at the molecular level; the mechanism must be consistent with the experimentally determined rate law for the reaction.

elementary step

a molecular view of a collision taking place in a chemical reaction.

catalyst

a substance added to a reaction that increases the rate of the reaction but is not consumed in the process.

enzyme

a protein that catalyzes a reaction.

half-life ($t_{1/2}$)

the time in the course of a chemical reaction during which the concentration of a reactant decreases by half.

activation energy (E_a)

the minimum energy molecules need to react when they collide.

AMMONIA, FERTILIZERS, AND FOOD Nearly half of the world’s food production relies on the use of fertilizers such as ammonia, which can be injected directly into the ground (as shown here) or used to make solid fertilizers such as urea and ammonium nitrate.

Chemical Equilibrium How Much Product Does a Reaction Really Make?

PARTICULATE REVIEW

Simultaneous Reactions

In Chapter 14 we explore reversible reactions, in which the reactants not only form products, but the products can also reform the reactants. Two such reactions take place simultaneously among the NO, O_2, and NO_2 molecules shown here.

- Which of these molecules could combine, forming NO_2? Which of these molecules could be produced when molecules of NO_2 collide at high temperatures?
- Write one chemical equation showing that these two reactions could take place simultaneously.
- The first reaction proceeds slowly at room temperature. Describe how you would increase its rate and explain why your approach should work.

(Review Section 4.5 and Sections 13.2–13.4 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Equal versus Equilibrium

The images show two different mixtures of steam and carbon monoxide reacting reversibly to produce carbon dioxide and hydrogen gas. Each sample is shown both in its initial state ($t = 0$) and after 5 seconds of reaction time. As you read Chapter 14, look for ideas that will help you answer these questions:

- Write one balanced chemical equation for the two simultaneous reactions taking place in each mixture.
- How does the concentration of each reactant change in sample A? In sample B? How does the concentration of each product change in sample A? In sample B?
- Which sample is more likely to be at equilibrium?

Learning Outcomes

- LO1 Describe the dynamic nature of a chemical equilibrium and write mass action or equilibrium constant expressions for reversible reactions, including those involving heterogeneous equilibria

  Sample Exercises 14.1, 14.9

- LO2 Determine the value of an equilibrium constant from equilibrium concentrations or partial pressures of reactants and products

  Sample Exercises 14.2, 14.3

- LO3 Interconvert the K_c and K_p values of gas-phase reactions

  Sample Exercise 14.4

- LO4 Relate the values of K for a reaction, for the reverse reaction, for a reaction with different coefficients, and for combined reactions

  Sample Exercises 14.5, 14.6, 14.7

- LO5 Determine the value of a reaction quotient and use it to predict the direction of a reversible chemical reaction

  Sample Exercise 14.8

- LO6 Predict how a reaction at equilibrium responds to changes in reaction conditions, including adding or removing quantities of reactants and products or changing temperature

  Sample Exercises 14.10, 14.11, 14.12

- LO7 Relate the concentrations or partial pressures of reactants and products in a reaction mixture at equilibrium to their initial values and the value of K

  Sample Exercises 14.13, 14.14, 14.15

$$\mathrm{CH_4}(g) + \mathrm{H_2O}(g) \rightleftharpoons \mathrm{CO}(g) + 3\,\mathrm{H_2}(g) \qquad \Delta H^\circ = 206\ \mathrm{kJ/mol} \qquad (14.1)$$

$$\mathrm{CO}(g) + \mathrm{H_2O}(g) \rightleftharpoons \mathrm{CO_2}(g) + \mathrm{H_2}(g) \qquad \Delta H^\circ = -41\ \mathrm{kJ/mol} \qquad (14.2)$$

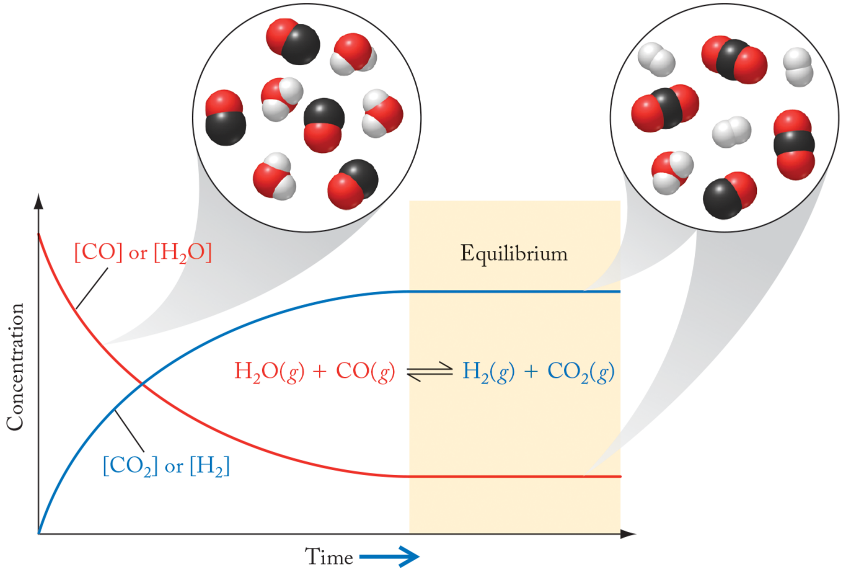

FIGURE 14.1 Concentrations of reactants (red curve) and products (blue curve) in the water–gas shift reaction change over time until equilibrium is reached (the yellow zone).

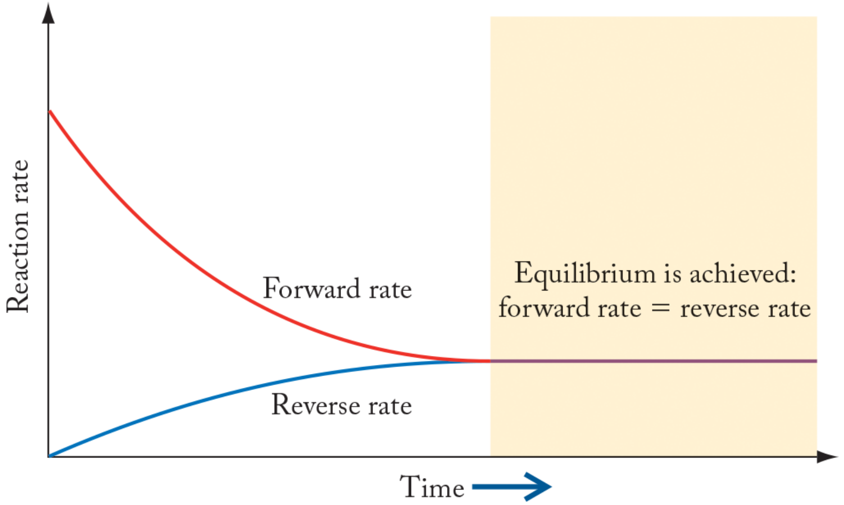

FIGURE 14.2 Equilibrium is achieved when the rates of a reversible reaction in the forward direction (red curve) and reverse direction (blue curve) become equal.

14.1 The Dynamics of Chemical Equilibrium

CONNECTIONEnthalpy and enthalpy changes were introduced in Section 6.4.

Chemical fertilizers have become key components of modern agriculture and the global effort to feed the world's expanding population. Gaseous ammonia, NH_3, is used to produce solid nitrogen-based fertilizers such as urea and ammonium nitrate, and it is injected directly into soil as shown in the opening photo of this chapter. Over 150 million metric tons of ammonia are produced worldwide each year and over 80% of it is used in food production. Ammonia is produced in a reaction between N_2 from the atmosphere and H_2 gas. In most countries H_2 gas comes from high-temperature chemical reactions between methane (CH_4), which is the principal component in natural gas, and water vapor. We begin Chapter 14 by exploring these chemical reactions and return to the production of ammonia in Section 14.7.

Most of the hydrogen gas needed to make ammonia is generated in a two-step process that begins with a reaction that is so widely used it has its own name—*steam–methane reforming*:

The value of ΔH° indicates that the reaction is highly endothermic, which is why it is typically run at temperatures between 700°C and 1000°C. To increase the rate of the reaction, nickel or nickel-containing alloys are used as catalysts, and the reaction is run at pressures as high as 25 atm.

CONCEPT TEST

Why does raising the temperature or increasing the pressure of a gas-phase reaction help increase the rate of the reaction?

(Answers to Concept Tests are in the back of the book.)

In the second step, carbon monoxide produced in the first step reacts with more steam to produce more hydrogen gas:

This reaction, called the water–gas shift reaction, also requires a catalyst and reaction temperatures greater than 350°C to achieve respectable reaction rates.

CONNECTIONWe introduced the double arrow in Section 4.4 when discussing the dissociation of weak electrolytes.

What is the purpose of the double arrow that connects the reactants and products in Equations 14.1 and 14.2? These arrows are meant to convey that steam–methane reforming and the water–gas shift reaction are reversible. Reversible reactions proceed in both the forward and the reverse directions at the same time.

To better understand how reactants become products and products become reactants, consider what happens if we run the water–gas shift reaction in a sealed vessel that initially contains equal numbers of moles of steam and carbon monoxide, but no products. As the reaction proceeds in the forward direction, the concentrations of H_2O and CO decrease, as shown by the red curve in **Figure 14.1**. The concentrations of H_2 and CO_2 start at zero and increase over time, as shown by the blue curve. Because H_2O and CO react in a 1:1 stoichiometric ratio, their concentrations decrease at the same rate. Similarly, H_2 and CO_2 are formed in a 1:1 ratio, so their concentrations increase at the same rate.

Eventually, both the red and blue curves level off (in the yellow equilibrium region of Figure 14.1), which means there is no net change in the concentrations of either the reactants or the products with time. Note that the unchanging (equilibrium) concentrations of H_2O and CO are significantly above zero. This means that the reaction mixture will contain some reactants no matter how long we let the reaction run.

To obtain another perspective on why the concentration curves in Figure 14.1 level off before all the reactants are consumed, recall from Chapter 13 that the rates of most chemical reactions depend on the concentrations of their reactant(s). Therefore, we expect the rate of the forward reaction to decrease as the concentrations of the reactants, H_2O and CO, decrease, which is shown by the downward trend of the red curve in **Figure 14.2**. As the reaction proceeds, the concentrations of H_2 and CO increase, which results in an increase in the rate of the reverse reaction as shown by the rising blue curve. Eventually, the increasing rate of the reverse reaction matches the slowing rate of the forward reaction, and the reaction has reached the yellow equilibrium zone in Figure 14.2, just as it did in Figure 14.1. Once there, the two rates remain equal unless some external intervention alters the conditions of the reaction. Equal reaction rates mean that H_2O and CO are consumed in the forward reaction at the same rate at which they are produced by the reverse reaction. Similarly, H_2 and CO_2 are produced and consumed at the same rate. The reaction has achieved chemical equilibrium.

Later in this chapter we learn how to manipulate the extent to which a reaction proceeds before it reaches equilibrium. We also determine the composition of reaction mixtures at equilibrium, and we learn how to determine whether a reaction has in fact achieved equilibrium. As we make these determinations, keep in mind that the results we obtain tell us the quantities of products that reversible reactions could produce; they do *not* tell us how long it will take to produce those quantities. To determine the time involved also requires knowing the rate of the reaction, which is why this chapter on chemical equilibrium immediately follows the one on chemical kinetics.

CONNECTIONIn Chapter 13 (Chemical Kinetics) we discussed how reactions occur when molecules collide; the higher the concentrations of reactants, the more frequently molecules collide, and the faster a reaction proceeds.

A final key point about chemical equilibria: they are *dynamic*. Just because the concentrations of reactants and products are not changing does not mean that a reaction has stopped. The reaction still proceeds, but it does so equally rapidly in both the forward and reverse directions simultaneously.

Glossary

chemical equilibrium

a dynamic process in which the concentrations of reactants and products remain constant over time and the rate of the reaction in the forward direction matches its rate in the reverse direction.

$$\text{Experiments 1 and 2: } \frac{[H_2][CO_2]}{[H_2O][CO]} = \frac{(0.0164)(0.0164)}{(0.0036)(0.0036)} = 21$$

$$\text{Experiment 3: } \frac{[H_2][CO_2]}{[H_2O][CO]} = \frac{(0.0280)(0.0180)}{(0.0120)(0.0020)} = 21$$

$$\text{Experiment 4: } \frac{[H_2][CO_2]}{[H_2O][CO]} = \frac{(0.0350)(0.0450)}{(0.0050)(0.0150)} = 21$$

$$K = \frac{[H_2][CO_2]}{[H_2O][CO]} = 21$$

$$K_c = \frac{[C]^c[D]^d}{[A]^a[B]^b} \tag{14.3}$$

$$K_p = \frac{(P_C)^c(P_D)^d}{(P_A)^a(P_B)^b} \tag{14.4}$$

$$K_c = \frac{[NO_2]^2}{[NO]^2[O_2]}$$

$$K_p = \frac{(P_{NO_2})^2}{(P_{NO})^2(P_{O_2})}$$

$$K_c = \frac{[N_2O_4]}{[NO_2]^2}$$

$$\text{Experiment 1: } K_c = \frac{[N_2O_4]}{[NO_2]^2} = \frac{0.00139}{(0.0172)^2} = 4.70$$

$$\text{Experiment 2: } K_c = \frac{0.00280}{(0.0244)^2} = 4.70$$

$$\text{Experiment 3: } K_c = \frac{0.00452}{(0.0310)^2} = 4.70$$

$$\text{Experiment 4: } K_c = \frac{0.00452}{(0.0310)^2} = 4.70$$

$$K_p = \frac{P_{N_2O_4}}{(P_{NO_2})^2} = \frac{0.80}{(0.34)^2} = 6.9$$

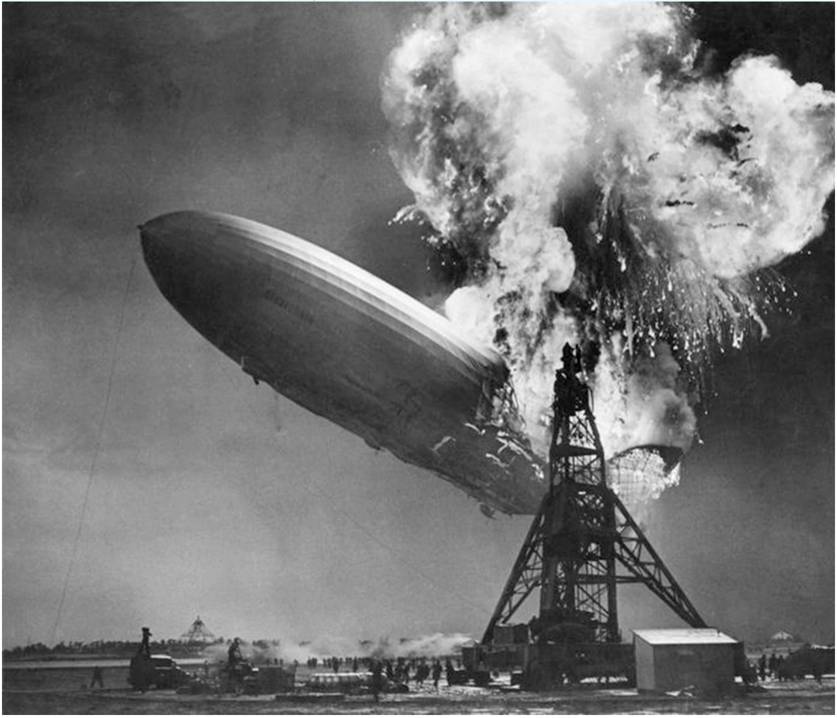

FIGURE 14.3 The German passenger airship *Hindenburg* was filled with hydrogen gas to make it less dense than air. The flammable

gas ignited as the airship docked in Lakehurst, New Jersey, on May 6, 1937. Of the 97 people aboard, 35 were killed.

14.2 The Equilibrium Constant

In this section we take a quantitative look at the concentrations of products and reactants that are present when chemical reactions come to equilibrium. Let's return to the water–gas shift reaction:

$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$

The data in **Table 14.1** describe the results of four experiments in which different quantities of H_2O gas, CO, H_2, and CO_2 are injected into a sealed reaction vessel heated to 350°C. The four gases are allowed to react and the final concentrations of all four are determined when the reaction has reached equilibrium.

TABLE 14.1 Initial and Equilibrium Concentrations of the Reactants and Products in the Water–Gas Shift Reaction at 350°C

[illegible]
[illegible]
[illegible]
[illegible]
[illegible]
[illegible]

In experiment 1 the reaction vessel initially contains equimolar concentrations of H_2O and CO but no H_2 or CO_2. In experiment 2 the vessel initially contains equimolar concentrations of H_2 and CO_2 but no H_2O or CO. Notice in Table 14.1 that when the reaction mixtures in experiments 1 and 2 achieve chemical equilibrium, the concentrations of H_2O and CO are the same (0.0036 *M*) in both experiments and so, too, are the concentrations of H_2 and CO_2 (0.0164 *M*). The identical equilibrium concentrations of the reactants and products in experiments 1 and 2 confirm that the composition of a reaction mixture at equilibrium is independent of the direction in which a reaction proceeds to achieve equilibrium.

The data from experiment 3 show that the concentrations of products increase and the concentrations of reactants decrease when the total concentrations of products and reactants are initially the same. The data from experiment 4 show that the concentrations of products increase and the concentrations of reactants decrease even when the concentrations of the products are initially *greater than* the concentrations of the reactants.

The significance of the data from the four experiments in Table 14.1 can be appreciated if we multiply the equilibrium concentrations of the products (H_2 and CO_2) together and divide that product by the product of the equilibrium concentrations of the reactants (H_2O and CO):

The ratio of the concentrations of products to reactants at equilibrium is the same in every experiment. It turns out that we would get the same ratio from *any* combination of initial concentrations of these four gases at 350°C. This concept, which applies to other reversible reactions, has been known since the mid-19th century when Norwegian chemists Cato Guldberg (1836–1902) and Peter Waage (1833–1900) discovered that any reversible reaction eventually reaches a state in which the ratio of the concentrations of products to reactants, with each value raised to a power corresponding to the coefficient for that substance in the balanced chemical equation for the reaction, has a characteristic value at a given temperature.

They called this phenomenon the law of mass action and the ratio of concentration terms the mass action expression for the reaction. This ratio is more commonly called the equilibrium constant expression, and its numerical value—which depends on temperature—is the equilibrium constant (K) of the reaction. Because K is a ratio of positive values, it is always positive. K values *much greater* than 1 are associated with reaction mixtures that consist of mostly products at equilibrium. K values *much less* than 1 are associated with reaction mixtures that contain few products at equilibrium.

For the water–gas shift reaction, the equilibrium constant expression and the value of K at 350°C are

None of the concentration terms in this expression has an exponent because all their coefficients are “1” in the balanced chemical equation, and a substance’s coefficient *always* becomes its exponent in the equilibrium constant expression for a reaction. This contrasts with the rate law expressions we discussed in Chapter 13, where the exponents are frequently not the same as the coefficients in the balanced equation because the exponents reflect the stoichiometry of the rate-determining step, not necessarily the overall reaction.

CONCEPT TEST

Suppose equal numbers of moles of water vapor, carbon dioxide, carbon monoxide, and hydrogen gas are injected into a rigid, sealed reaction vessel and heated to 350°C. Which expression about the composition of the reaction mixture at equilibrium is true?

1. $[CO] = [H_2] = [CO_2] = [H_2O]$
2. $[CO_2] = [H_2] > [CO] = [H_2O]$
3. $[CO_2] = [H_2] < [CO] = [H_2O]$
4. $[H_2O] = [H_2] > [CO_2] = [CO]$
5. $[H_2O] = [H_2] < [CO_2] = [CO]$

For a generic reaction in which *a* moles of reactant A react with *b* moles of B to form *c* moles of substance C and *d* moles of D:

$$a\mathrm{A} + b\mathrm{B} \rightleftharpoons c\mathrm{C} + d\mathrm{D}$$

the equilibrium constant expression is

The subscript “c” on the equilibrium constant indicates that it is based on a ratio of concentration values. If substances A, B, C, and D are all gases, then the equilibrium constant (designated K_p in this case) may also be expressed in terms of their partial pressures:

We distinguish between K_c and K_p because their values for a given gas-phase reaction at a given temperature may or may not be the same (see Section 14.3). It depends on whether the number of moles of gaseous reactants is the same as the number of moles of gaseous products.

K values do not have units even when there are different numbers of moles of reactants and products. This may seem odd, but there is a reason why: the concentrations and partial pressures in K_c or K_p expressions are actually ratios of the ingredient concentrations or partial pressures in a reaction mixture to an ideal standard concentration (1.000 *M*) or partial pressure (1.000 bar). These ratios take into account the nonideal behavior of substances. Because the terms in equilibrium constant expressions are, strictly speaking, ratios of values having the same units, their units cancel out, producing unitless equilibrium constants. In practice, we use concentration and partial pressure values directly in equilibrium calculations. When we do, we are assuming that all the reactants and products are behaving ideally.

SAMPLE EXERCISE 14.1 Writing Equilibrium Constant Expressions LO1

A key reaction in the formation of photochemical smog involves the reversible combination of NO and O_2 in the atmosphere, producing NO_2:

$$2\,NO(g) + O_2(g) \rightleftharpoons 2\,NO_2(g)$$

Write the K_c and K_p expressions for this reaction.

Collect, Organize, and Analyze We are given the balanced chemical equation for a reaction and asked to write K_c and K_p expressions for it. Equilibrium constant expressions are ratios of the concentrations (K_c) or partial pressures (K_p) of products to reactants, with each term raised to the power equal to its coefficient in the balanced chemical equation of the reaction. Review Equations 14.3 and 14.4, if necessary.

Solve The coefficients of NO and NO_2 in the chemical equation are both 2, so the NO and NO_2 terms in the K_c and K_p expressions must be squared:

Think About It The numerators and denominators of the K_c and K_p expressions contain terms for the same products and reactants, each raised to the same power. The difference between them is the nature of the terms: molar concentrations in the K_c expression and partial pressures in the K_p expression.

Practice Exercise Write K_c and K_p equilibrium constant expressions for the steam–methane reforming reaction:

$CH_4(g) + H_2O(g) \rightleftharpoons CO(g) + 3\ H_2(g)$

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 14.2 Calculating the Value of K_c from Equilibrium Concentrations LO2

Table 14.2 lists initial and equilibrium concentration data from four experiments on the dimerization of NO_2:

$2\ NO_2(g) \rightleftharpoons N_2O_4(g)$

The experiments were run at 100°C in a rigid, closed container. Use the data from each experiment to calculate a value of the equilibrium constant K_c for the reaction.

Collect and Organize We are given four sets of data that contain initial and equilibrium concentrations of a reactant and product. We are asked to determine the value of the equilibrium constant K_c in each experiment. The K_c expression for this reaction should have the same form as Equation 14.3—that is, the ratio of the equilibrium concentration of the product over that of the reactant, with each term raised to a power equal to its coefficient in the balanced chemical equation.

Analyze To calculate the value of K_c, we insert the pairs of equilibrium concentrations from each experiment into the K_c expression and calculate the ratio. The $[NO_2]$ values are greater than the [N_2O_4] values in every experiment, so the equilibrium reaction mixtures contain more reactant than product. Therefore, we might expect the value of K_c to be less than 1. However, all the gas concentrations are much less than 0.1 *M*, and the [NO_2] values in the denominator are squared, which makes the value of the denominator even smaller. Therefore, the value of K_c is probably greater than 1.

Solve The K_c expression is

Inserting the data from the four experiments into this expression and doing the math:

Think About It The values calculated for K_c are the same, as they should be for the same reaction at the same temperature. Moreover, they are greater than 1, as we predicted.

Practice Exercise A mixture of gaseous CO and H_2, called *synthesis gas*, is used commercially to prepare methanol (CH_3OH), a compound considered an alternative fuel to gasoline. Under equilibrium conditions at 700 K, [H_2] = 0.074 *M*, [CO] = 0.025 *M*, and [CH_3OH] = 0.040 *M*. What is the value of K_c for this reaction at 700 K?

TABLE 14.2 Data for the Dimerization of NO_2 at 100°C

SAMPLE EXERCISE 14.3 Calculating the Value of K_p from

Equilibrium Partial Pressures LO2

A sealed chamber contains an equilibrium mixture of NO_2 and N_2O_4 at 15°C. The partial pressures of NO_2 and N_2O_4 are 0.34 atm and 0.80 atm, respectively. What is the value of K_p at 15°C for the dimerization of NO_2: $2\ NO_2(g) \rightleftharpoons N_2O_4(g)$?

Collect, Organize, and Analyze We are asked to use the partial pressures of NO_2 and N_2O_4 at equilibrium to determine the value of K_p for the dimerization of NO_2. The K_p expression (shown for a general reaction in Equation 14.4) should have the same format as the K_c expression for this reaction that was used in Sample Exercise 14.2.

Solve

Think About It The value of K_p is not the same as the K_c value for this reaction that was calculated in Sample Exercise 14.2. This difference should not be surprising because the experiments in the two exercises were conducted at different temperatures, and K values change with changing temperature. Moreover, the K_p and K_c values of gas-phase reactions may differ, as noted previously in this section, depending on the number of moles of gaseous reactants and products.

Practice Exercise A reaction vessel contains an equilibrium mixture of SO_2, O_2, and SO_3. The partial pressures of the three gases are 0.0018 atm, 0.0032 atm, and 0.0166 atm, respectively. What is the value of K_p for the following reaction at the temperature inside the vessel?

$$2\ SO_2(g) + O_2(g) \rightleftharpoons 2\ SO_3(g)$$

As we end this section, let's more closely examine the connection between K values of reactions and the composition of their reaction mixtures at equilibrium. The values we have seen thus far—$K_c = 21$ for the water–gas shift reaction at 350°C, and $K_p = 6.9$ and $K_c = 4.70$ for the dimerization of NO_2 at 25°C and 100°C, respectively—are considered intermediate values. Because the range of K values is so large ($0 < K < \infty$), all three of these values are considered *close* to 1, which means that comparable concentrations of reactants and products are likely to be present at equilibrium.

On the other hand, many reactions reach equilibrium only after essentially all the reactants have formed products. We say that these equilibria *lie far to the right* (the direction of the forward reaction arrow). For example, the combustion of H_2 gas proceeds very rapidly (**Figure 14.3**) until H_2 is, for all practical purposes, completely consumed. This observation is consistent with an enormous value of K for the combustion reaction at 25°C:

$$2\ H_2(g) + O_2(g) \rightleftharpoons 2\ H_2O(g) \qquad K_c = 3 \times 10^{81}$$

In other reactions, little product is formed before equilibrium is reached. These equilibria are said to favor reactants and to *lie far to the left* (the direction of the reverse reaction arrow). For example, the decomposition of CO_2 to CO and O_2 at 25°C essentially doesn't happen, as predicted by our understanding of the stability of CO_2 and the minuscule K value for the decomposition reaction:

$$2\ CO_2(g) \rightleftharpoons 2\ CO(g) + O_2(g) \qquad K_c = 3 \times 10^{-92}$$

In the rest of this chapter, and in Chapters 15 and 16, we focus mainly on equilibria that do not lie far to the left or right but are more likely to be a little to the left or right. These reaction systems tend to have relatively small concentrations of either reactants or products at equilibrium, but not so small that they can be ignored.

Glossary

law of mass action

the principle relating the balanced chemical equation of a reversible reaction to its mass action expression (or equilibrium constant expression).

mass action expression

an expression equivalent in form to the equilibrium constant expression but applied to reaction mixtures that may or may not be at equilibrium.

equilibrium constant expression

the ratio of the concentrations or partial pressures of products to reactants at equilibrium, with each term raised to a power equal to the coefficient of that substance in the balanced chemical equation for the reaction.

equilibrium constant

the ratio of the concentrations or partial pressures of products to reactants at equilibrium, with each term raised to a power equal to the coefficient of that substance in the balanced chemical equation for the reaction.

Learning Objectives

- Describe the dynamic nature of a chemical equilibrium and write mass action or equilibrium constant expressions for reversible reactions, including those involving heterogeneous equilibria **Return to Sample Exercises 14.1, 14.9**
- Determine the value of an equilibrium constant from equilibrium concentrations or partial pressures of reactants and products **Return to Sample Exercises 14.2, 14.3**
- Determine the value of an equilibrium constant from equilibrium concentrations or partial pressures of reactants and products **Return to Sample Exercises 14.2, 14.3**

$$P = \frac{n}{V} RT$$

$$P = M \cdot RT \tag{14.5}$$

$$P_{NO_2} = \frac{n_{NO_2}}{V} RT = [NO_2]RT$$

$$P_{N_2O_4} = \frac{n_{N_2O_4}}{V} RT = [N_2O_4]RT$$

$$K_p = \frac{(P_{N_2O_4})}{(P_{NO_2})^2} = \frac{[N_2O_4]RT}{([NO_2]RT)^2} = \frac{[N_2O_4]RT}{[NO_2]^2(RT)^2}$$

$$K_p = K_c \frac{1}{RT}$$

$$K_p = \frac{(P_C)^c(P_D)^d}{(P_A)^a(P_B)^b} \tag{14.4}$$

$$K_p = \frac{([C]RT)^c([D]RT)^d}{([A]RT)^a([B]RT)^b} \tag{14.6}$$

$$K_p = \frac{[C]^c[D]^d}{[A]^a[B]^b} \times (RT)^{[(c+d)-(a+b)]}$$

$$K_p = K_c(RT)^{\Delta n} \tag{14.7}$$

$$K_p = K_c(RT)^{\Delta n}$$

$$6.9 = K_c(0.08206 \times 288)^{-1} = \frac{K_c}{0.08206 \times 288}$$

$N_2(g) + 3\ H_2(g) \rightleftharpoons 2\ NH_3(g)$ $K_p = 6.1 \times 10^5$ at 25°C

14.3 Relationships between K_c and K_p Values

As we noted in Section 14.2, the values of K_c and K_p for a given reaction and temperature may or may not be the same, depending on the numbers of moles of gaseous reactants and products. To better understand this relationship, we begin with the ideal gas law:

$$PV = nRT$$

If we solve for P and express volume in liters, then n/V has units of moles per liter, which is the same as molarity (M):

Let's apply Equation 14.5 to the gases in the NO_2–N_2O_4 equilibrium from Sample Exercise 14.3:

Substituting these values into the expression for K_p from Sample Exercise 14.3, we get

The ratio of concentration terms in the expression on the right, $[N_2O_4]/[NO_2]^2$, is the same as the K_c expression for this reaction. Substituting K_c for those terms and simplifying the RT terms gives:

This last equation defines the relationship between K_c and K_p for this specific reaction. A more general expression can be derived for the generic reaction in which a moles of gas A reacts with b moles of gas B, producing c moles of gas C and d moles of gas D:

$$aA + bB \rightleftharpoons cC + dD$$

The K_p expression for this reaction is

Replacing each partial pressure term in Equation 14.4 with the corresponding $[X]RT$ term from Equation 14.5 gives us the general expression

Combining the RT terms, we get

To simplify the right side of this equation we (1) replace the ratio of concentration terms with K_c (see Equation 14.3) and (2) replace the four values in the exponent of RT with Δn, which equals the difference between the number of moles of product gases ($c + d$) and the number of moles of reactant gases ($a + b$). With these substitutions, Equation 14.6 becomes

The message in Equation 14.7 is that the K_p and K_c values of a reaction are related by RT raised to the appropriate power. This relationship makes sense because K_p values are based on ratios of partial pressures, and K_c values are based on ratios of molar concentrations. Equation 14.5 reminds us that the partial pressure and molar concentration of an ideal gas are related by RT: $P = M \cdot RT$.

In reactions in which the number of moles of gas on both sides of the reaction arrow is the same, such as the water–gas shift reaction:

$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$

$\Delta n = 0$ and $K_p = K_c$. However, in the steam–methane reforming reaction:

$CH_4(g) + H_2O(g) \rightleftharpoons CO(g) + 3\ H_2(g)$

Two moles of gaseous reactants form 4 moles of gaseous products. Therefore,

$\Delta n = 4\ \text{mol} - 2\ \text{mol} = 2\ \text{mol}$

Inserting this value for Δn in Equation 14.7 gives us the relationship between K_p and K_c for this reaction:

$K_p = K_c(RT)^2$

CONNECTION We determined the molar volume occupied by an ideal gas at standard temperature and pressure in Chapter 5.

SAMPLE EXERCISE 14.4 Calculating K_c from K_pLO3

In Sample Exercise 14.3 we determined that $K_p = 6.9$ at 15°C for the reaction

$$2\ NO_2(g) \rightleftharpoons N_2O_4(g)$$

What is the value of K_c for this reaction at 15°C?

Collect, Organize, and Analyze We are given a K_p value and asked to calculate the corresponding K_c value for the same reaction at the same temperature: 15°C or $(15 + 273) = 288$ K. Equation 14.7 relates the values of K_p and K_c:

$$K_p = K_c(RT)^{Dn}$$

where Δn represents the change in the number of moles of gas as the reaction proceeds.

Solve Two moles of gaseous reactants yield 1 mole of gaseous product. Therefore:

$$\Delta n = 1 \text{ mol gaseous product} - 2 \text{ mol gaseous reactants} = -1 \text{ mol}$$

Inserting this value of Δn, the given value of K_p, and the values of R and absolute temperature (T) into Equation 14.7:

Cross multiplying and solving for K_c:

$$K_c = (6.9)(0.08206)(288) = 1.6 \times 10^2$$

Think About It The value of K_c is 170/6.9 or nearly 25 times larger than that of K_p, which makes sense because a Δn value of -1 means $K_c = K_p(RT)$ and the value of (RT) at 288 K is $(0.08206 \times 288) = 23.6$.

Practice Exercise An important industrial process for synthesizing the ammonia used in agricultural fertilizers involves the combination of N_2 and H_2:

What is the value of K_c of this reaction at 25°C?

Learning Objectives

- Interconvert the K_c and K_p values of gas-phase reactions **Return to Sample Exercise 14.4**

$$2\ NO_2(g) \rightleftharpoons N_2O_4(g) \qquad K_c = \frac{[N_2O_4]}{[NO_2]^2}$$

$$N_2O_4(g) \rightleftharpoons 2\ NO_2(g) \qquad K_c = \frac{[NO_2]^2}{[N_2O_4]}$$

$$K_{\text{forward}} = \frac{1}{K_{\text{reverse}}} \tag{14.8}$$

$$A \rightleftharpoons B \qquad K > 1$$

$$B \rightleftharpoons A \qquad K < 1$$

$$K_{\text{formation}} = \frac{[NO_2]^2}{[NO]^2[O_2]}$$

$$K_{\text{decomposition}} = \frac{[NO]^2[O_2]}{[NO_2]^2}$$

$$2\ NO(g) + O_2(g) \rightleftharpoons 2\ NO_2(g) \qquad K_c = \frac{[NO_2]^2}{[NO]^2[O_2]}$$

$$NO(g) + \tfrac{1}{2}\ O_2(g) \rightleftharpoons NO_2(g)$$

$$K_c = \frac{[NO_2]}{[NO][O_2]^{1/2}}$$

$$SO_2(g) + \tfrac{1}{2}\ O_2(g) \rightleftharpoons SO_3(g)$$

$$\tfrac{1}{3}\,\mathrm{N_2}(g) + \mathrm{H_2}(g) \rightleftharpoons \tfrac{2}{3}\,\mathrm{NH_3}(g)$$

$$\begin{array}{lr}
(1) & \mathrm{N_2}(g) + \mathrm{O_2}(g) \rightleftharpoons \cancel{2\,\mathrm{NO}(g)} \\
(2) & \cancel{2\,\mathrm{NO}(g)} + \mathrm{O_2}(g) \rightleftharpoons 2\,\mathrm{NO_2}(g) \\
\hline
\text{Overall:} & \mathrm{N_2}(g) + 2\,\mathrm{O_2}(g) \rightleftharpoons 2\,\mathrm{NO_2}(g)
\end{array}$$

$$K_1 = \frac{[\mathrm{NO}]^2}{[\mathrm{N_2}][\mathrm{O_2}]} \quad \text{and} \quad K_2 = \frac{[\mathrm{NO_2}]^2}{[\mathrm{NO}]^2[\mathrm{O_2}]}$$

$$K_1 \times K_2 = \frac{\cancel{[\mathrm{NO}]^2}}{[\mathrm{N_2}][\mathrm{O_2}]} \times \frac{[\mathrm{NO_2}]^2}{\cancel{[\mathrm{NO}]^2}[\mathrm{O_2}]} = \frac{[\mathrm{NO_2}]^2}{[\mathrm{N_2}][\mathrm{O_2}]^2} = K_{\text{overall}}$$

$$K_{\text{overall}} = K_1 \times K_2 \times K_3 \times K_4 \times \ldots \times K_n \qquad (14.9)$$

$$K_1 = \frac{[\mathrm{NO}]^2}{[\mathrm{N_2}][\mathrm{O_2}]} = 7.2 \times 10^{-9}$$

$$K_2 = \frac{[\mathrm{NO_2}]^2}{[\mathrm{NO}]^2[\mathrm{O_2}]} = 0.020$$

$$\begin{array}{lr}
(1) & \mathrm{N_2O_4}(g) \rightleftharpoons 2\,\mathrm{NO_2}(g) \\
(2) & \mathrm{N_2}(g) + 2\,\mathrm{O_2}(g) \rightleftharpoons 2\,\mathrm{NO_2}(g)
\end{array}$$

$$\begin{array}{ll}
\text{Reaction (1) reversed} & \cancel{2\,\mathrm{NO_2}(g)} \rightleftharpoons \mathrm{N_2O_4}(g) \\
+\ \text{Reaction (2)} & \mathrm{N_2}(g) + 2\,\mathrm{O_2}(g) \rightleftharpoons \cancel{2\,\mathrm{NO_2}(g)} \\
\hline
\text{Summing:} & \mathrm{N_2}(g) + 2\,\mathrm{O_2}(g) + \cancel{2\,\mathrm{NO_2}(g)} \rightleftharpoons \mathrm{N_2O_4}(g) + \cancel{2\,\mathrm{NO_2}(g)} \\
\text{Simplifying:} & \mathrm{N_2}(g) + 2\,\mathrm{O_2}(g) \rightleftharpoons \mathrm{N_2O_4}(g)
\end{array}$$

$$K_{\text{overall}} = \frac{1}{K_1} \times K_2 = \frac{1}{1.5 \times 10^{6}} \times 1.4 \times 10^{-10} = 9.3 \times 10^{-17}$$

$$2\,\mathrm{M}(g) \rightleftharpoons \mathrm{Z}(g) \qquad K_c = 6.2 \times 10^{-4}$$

$$\mathrm{Z}(g) \rightleftharpoons 2\,\mathrm{W}(g) + 2\,\mathrm{X}(g) \qquad K_c = 5.6 \times 10^{-2}$$

14.4 Manipulating Equilibrium

Constant Expressions

In this section we learn how to write equilibrium constant expressions for the reverse direction of reversible reactions, for chemical equations that have been multiplied or divided by a value so that a key component has a coefficient of 1, and for overall reactions that are combinations of other reactions.

K for Reverse Reactions

The *K* values for the forward and reverse directions of a reversible reaction are related, just as the reactions are. In Sample Exercise 14.2, for example, we wrote the K_c expression for the dimerization of NO_2:

Now let's write the K_c expression for the reverse reaction—that is, for the decomposition of N_2O_4:

Note how reversing the reaction turns the K_c expression upside down as reactants and products switch roles. Equation 14.8 generalizes this reciprocal relation between the forward ($K_{forward}$) and reverse ($K_{reverse}$) equilibrium constants to any reversible reaction:

Equation 14.8 makes sense if we consider a generic reversible reaction in which the equilibrium favors the formation of product B over reactant A, which is reflected in its large *K* value:

If we write the reaction in reverse, B is still favored over A, but now B is the reactant and A is the product. Therefore, the value of *K* for the reverse reaction should be small because the reciprocal of a large (*K*) value is a small one:

SAMPLE EXERCISE 14.5 Calculating the Value of *K* for a Reverse

Reaction LO4

Atmospheric NO combines with O_2 to form NO_2. The reverse reaction is the decomposition of NO_2 to NO and O_2. At 184°C, the value of K_c for the forward reaction is 1.48×10^4. Write the equilibrium constant expressions for both reactions and calculate the value of K_c for the decomposition of NO_2 at 184°C.

Collect and Organize We are asked to write equilibrium constant expressions for the formation and decomposition of NO_2 and to calculate the value of K_c of the decomposition reaction from the K_c value of the formation reaction. Each of these reactions is the reverse of the other, so their equilibrium constant expressions and K_c values are reciprocals of each other.

Analyze To write the K_c expressions for the two reactions, we first need to write a chemical equation describing one of them. That equation will provide the stoichiometric coefficients we need to use as exponents for the concentration terms in the K_c expressions for both reactions, with each expression being the reciprocal of the other.

Solve Writing a chemical equation for the formation of NO_2 from NO and O_2:

$$2\ NO(g) + O_2(g) \rightleftharpoons 2\ NO_2(g)$$

The K_c expression for this formation reaction is the same as K_c in Sample Exercise 14.1:

The K_c expression for the decomposition (reverse) reaction is

and its value is

$$K_{\text{decomposition}} = 1/K_{\text{formation}} = 1/1.48 \times 10^4 = 6.76 \times 10^{-5}$$

Think About It The value of $K_{\text{formation}}$ is large, so it makes sense that its reciprocal, $K_{\text{decomposition}}$, is small.

Practice Exercise At 300°C, the value of K_p for the combination reaction of N_2 and H_2 that produces NH_3 gas is 4.3×10^{-3}. What is the value of K_p at the same temperature for the decomposition reaction of NH_3 to produce N_2 and H_2?

K for an Equation Multiplied or Divided by a Number

As we saw in Chapter 6, sometimes we must represent a reaction by an equation containing fractional coefficients so that, for example, there is exactly 1 mole of a particular product. Suppose we want to rewrite the formation of NO_2 from NO and O_2:

to describe the formation of only 1 mole of NO_2. We do this by dividing all the coefficients by 2:

The corresponding K_c expression is

Comparing the original K_c expression with this one, we see that the concentration terms in the original expression correspond to those in the second expression *squared*. (The square root of a value is the same as raising the value to a power of $\frac{1}{2}$.) Put another way, dividing all the coefficients in the original reaction equation by 2 produces a K_c expression (and a K value) that is the *square root* of the original. We can extend this pattern to all chemical equilibria with the following general rule: if the balanced chemical equation of a reaction is multiplied by some factor n, then the value of K for the new reaction is the original K value raised to the nth power. Similarly, dividing all coefficients by n raises the value of K to the $1/n$ power.

SAMPLE EXERCISE 14.6 Calculating *K* for Different Coefficients LO4

An important reaction in the industrial production of sulfuric acid is the oxidation of SO_2 to SO_3. One way to write a chemical equation for the oxidation reaction is

If the value of K_c for this reaction at 298 K is 2.8×10^{12}, what is the value of K_c at 298 K for

$$2\ SO_2(g) + O_2(g) \rightleftharpoons 2\ SO_3(g)$$

Collect, Organize, and Analyze We are given the value of K_c for a reaction that describes the production of 1 mole of SO_3. We are asked to recalculate this K_c value for the same reaction but based on the production of 2 moles of SO_3. Multiplying the coefficients of a chemical equation by n raises the value of its equilibrium constant to the nth power.

Solve Multiplying the original chemical equation by 2 raises its K_c to the second power:

$$K_c = (2.8 \times 10^{12})^2 = 7.8 \times 10^{24}$$

Think About It Doubling the coefficients made the large original K_c value very large. However, if the original K_c value had been small (< 1), doubling the coefficients and squaring the K_c would have made its value even smaller.

Practice Exercise The industrial production of ammonia for fertilizers involves the reaction of nitrogen and hydrogen. If $K_c = 2.4 \times 10^{-3}$ at 1000 K for the reaction

$$N_2(g) + 3\ H_2(g) \rightleftharpoons 2\ NH_3(g)$$

what is K_c at 1000 K for this reaction?

In Sample Exercise 14.6 we saw that two equivalent ways to balance a chemical equation for the same reaction produced two different K_c expressions and two different K_c values. Surely the same ingredients should be present in the same proportions at equilibrium, no matter how we choose to write a balanced equation describing their reaction. In fact, they are. The difference between the K values is not chemical; it is only mathematical. It does not affect the composition of a reaction mixture at equilibrium—only the arithmetic we use to predict it.

Combining *K* Values

In Section 6.7 we introduced Hess's law to calculate the enthalpies of combined reactions. We can also combine K values to obtain an overall K for a reaction that is the sum of two or more other reactions.

Consider two reactions, labeled (1) and (2) below, that were introduced in Chapter 13 and are involved in the formation of photochemical smog. As they proceed, NO produced in a car's engine at high temperature is oxidized to NO_2 in the atmosphere:

The K_c expressions for the reactions (1) and (2) are

How are these two individual equilibrium expressions related to the K_c expression for the overall reaction? We can derive the overall expression by multiplying K_1 and K_2 together:

This approach works for all series of reactions, and as a rule

The overall equilibrium constant for a sum of two or more reactions is the product of the equilibrium constants of the individual reactions. Thus, the value of K_c for the overall reaction for the formation of NO_2 from N_2 and O_2 at 1000 K is the product of the equilibrium constants for reaction 1:

and reaction 2:

Using Equation 14.9:

$$K_{\text{overall}} = K_1 \times K_2 = 7.2 \times 10^{-9} \times 0.020 = 1.4 \times 10^{-10}$$

The equilibrium constant expression for the overall reaction must contain the appropriate terms for the products and reactants of that reaction. Just as with Hess's law in thermochemical calculations, we may need to reverse an equation or multiply an equation by a factor when we combine it with another to create the right overall equation. If we reverse a reaction, we must take the reciprocal of its K, and if we multiply or divide a reaction by n, we must raise its K to the n or $1/n$ power.

SAMPLE EXERCISE 14.7 Calculating an Overall *K* Value LO4

At 1000 K, the K_c value of the following reaction is 1.5×10^6:

The K_c value at 1000 K of the following reaction is 1.4×10^{-10}:

What is the K_c value at 1000 K of the following reaction?

$$N_2(g) + 2\ O_2(g) \rightleftharpoons N_2O_4(g)$$

Collect and Organize We are given chemical equations describing two reactions and their K_c values, and we need to combine the equations in such a way that they describe a third reaction. When two equations are added, their K_c values are multiplied together to obtain K_{overall}.

Analyze The product of the overall reaction, N_2O_4, is a reactant in reaction (1), so we need to reverse it. N_2 and O_2 are reactants in reaction (2) and they are reactants with the same coefficients in the overall reaction, so we can combine reaction (2) as written with the reverse of reaction (1).

The K_c value of any reaction running in reverse is the reciprocal of the K_c value of the forward reaction. The K_c value of reaction (1) is large ($> 10^6$), which means its reciprocal is small ($< 10^{-6}$). The product of this small value and the smaller one for reaction (2), ~10^{-10}, should be even smaller still—about 10^{-16}.

Solve

Combining the two chemical equations:

Calculating the value of K_{overall}:

Think About It The calculated K_{overall} value is close to our estimate and indeed very small. As a result, the overall equilibrium lies far to the left, meaning very little N_2O_4 forms from N_2 and O_2 at 1000 K.

Practice Exercise Calculate the value of K_c for the hypothetical reaction

$W(g) + X(g) \rightleftharpoons M(g)$

from the following information:

To summarize the key points for manipulating equilibrium constants:

- The *K* value of a reaction running in reverse is the reciprocal of the *K* of the forward reaction.
- If the original chemical equation describing a reversible reaction is multiplied by *n*, the value of *K* is the value of the original *K* raised to the *n*th power.
- If the original chemical equation describing a reversible reaction is divided by *n*, the value of *K* is the value of the original *K* raised to the (1/*n*) power.
- If an overall chemical reaction is the sum of two or more

other reactions, the overall value of K is the product of the K values of the other reactions.

$$Q_c = \frac{[NO]^2}{[N_2][O_2]}$$

$$Q_c = \frac{(0.0042)^2}{(0.50)(0.25)} = 1.4 \times 10^{-4}$$

14.5 Equilibrium Constants and Reaction Quotients

In Section 14.2 we introduced two key terms: *equilibrium constant expression* and *mass action expression*. Until now we have used the first term almost exclusively because we have been dealing with chemical reactions that have achieved equilibrium. Now we reintroduce the concept of a mass action expression because we can apply it not only to concentrations (or partial pressures) of products and reactants in reaction mixtures that have reached equilibrium, but also to reaction mixtures that are on their way to equilibrium but are not yet there.

Even if a reversible chemical reaction has not reached equilibrium, we can still insert reactant and product concentrations (or partial pressures) into its mass action expression. The mathematical result is not a K value because the reaction is not yet at equilibrium. Instead it is a Q value, where $\boldsymbol{Q}$ stands for reaction quotient. The value of Q provides us with a status report on the progress of a pair of reversible reactions.

To see how this works, let's once again consider the water–gas shift reaction and the concentration data from experiment 4 in Table 14.1:

Inserting the initial concentration values into the mass action expression for the reaction yields a value for Q based on concentration; that is, Q_c:

In this case, $Q_c = 6.00$ and $K_c = 21$. These Q_c and K_c values mean there are lower concentrations of products and higher concentrations of reactants in the initial reaction mixture than there will be at equilibrium. To achieve equilibrium, some of the reactants must form products. Mathematically, that will increase the numerator and decrease the denominator in Q_c, thereby increasing the value of Q_c until it matches the value of K_c and equilibrium has been achieved.

To put the results from the data in Table 14.1 in context, let's consider the curves in **Figure 14.4**. Starting at the left side of the graph in zone (a), we have the initial conditions of experiment 1 from Table 14.1: equal concentrations of reactants are present, but no products. Over time, reactant concentrations (the red curve) decrease as product concentrations (the blue curve) increase. At the right side of the graph in zone (c), we have the initial conditions of experiment 2: products are present, but no reactants. Over time, reactant concentrations increase as product concentrations decrease. In zone (b) in the middle of the graph, no net change occurs in the composition because the reaction is at equilibrium.

We can also characterize the three zones in Figure 14.4 based on the value of Q compared with K. In zone (a), $Q < K$ and there is a net conversion of reactants into products as the forward reaction dominates. In zone (c), $Q > K$ and a net conversion of products into reactants takes place as the reverse reaction dominates. In the middle zone (b), $Q = K$ and no net change in the composition of the reaction mixture occurs over time. The relative values of Q and K and their consequences are summarized in **Table 14.3**.

TABLE 14.3 Comparison of Q and K Values

Value of Q	What It Means
$Q < K$	Reaction as written proceeds in forward direction (→)
$Q = K$	Reaction is at equilibrium (⇌)
$Q > K$	Reaction as written proceeds in reverse direction (d)

CONCEPT TEST

In which of the three zones in Figure 14.4 do the initial reaction conditions of experiments 3 and 4 from Table 14.1 fall?

SAMPLE EXERCISE 14.8 Using Q and K Values to Predict the Direction of a Reaction LO5

At 2300 K, $K_c = 1.5 \times 10^{-3}$ for the following reaction:

$N_2(g) + O_2(g) \rightleftharpoons 2\ NO(g)$

At the instant when a reaction vessel at 2300 K contains 0.50 M N_2, 0.25 M O_2, and 0.0042 M NO, is the reaction mixture at equilibrium? If not, in which direction will the reaction proceed to reach equilibrium?

Collect and Organize We are asked whether a reaction mixture is at equilibrium. We are given the value of K and the concentrations of reactants and product.

Analyze The mass action expression for this reaction based on concentrations is

---

Inserting the given concentration values into this expression and calculating the value of Q_c will allow us to determine whether the reaction is at equilibrium ($Q_c = K_c$), will proceed in the forward direction ($Q_c < K_c$), or will proceed in the reverse direction ($Q_c > K_c$). To estimate our answer, we note that the given value of [NO] is about 10^{-2} times the concentrations of the reactants, and the [NO] term is squared in the mass action expression. These two factors together make the value of the numerator about 10^{-4} times that of the denominator. Therefore, the value of Q_c should be *less* than the value of K_c.

Solve

Because $Q_c < K_c$, the reaction mixture is *not* at equilibrium. It will proceed in the forward direction (to the right) to reach equilibrium.

Think About It Our estimate that Q_c would be less than K_c was correct. The value of K_c is small, but the value of Q_c is even smaller.

Practice Exercise $K_c = 4.7$ for the following reaction at 373 K:

$2\ NO_2(g) \rightleftharpoons N_2O_4(g)$

Is a mixture of the two gases in which $[NO_2] = 0.025\ M$ and $[N_2O_4] = 0.0014\ M$ in chemical equilibrium? If not, in which direction does the reaction proceed to achieve equilibrium?

Glossary

reaction quotient (Q)
: the numerical value of the mass action expression based on the concentrations or partial pressures of the reactants and products present at any time during a reaction; at equilibrium, $Q = K$.

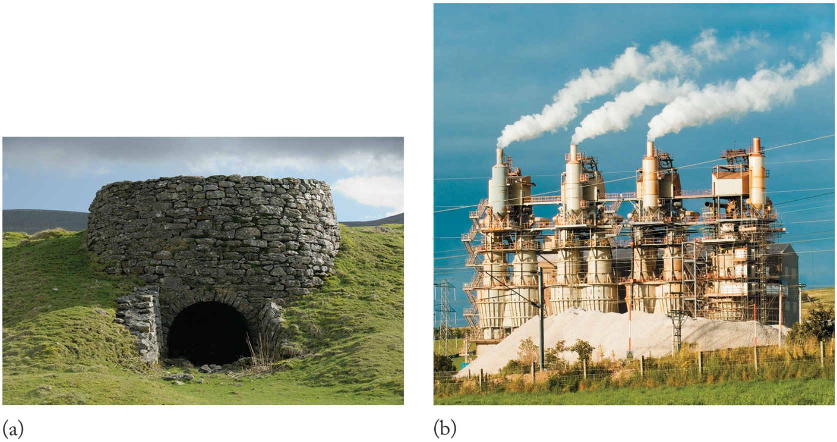

FIGURE 14.5 (a) For centuries, primitive kilns were used to decompose limestone ($CaCO_3$) into lime (CaO) and CO_2. These kilns were charged with layers of fuel (originally wood, later coal) and crushed limestone, and the fuel was ignited. Farmers use lime to “sweeten” (neutralize the acidity of) soil. It is also used to make mortar and cement. (b) A modern plant for converting limestone into lime.

$$K_c = \frac{[CaO][CO_2]}{[CaCO_3]}$$

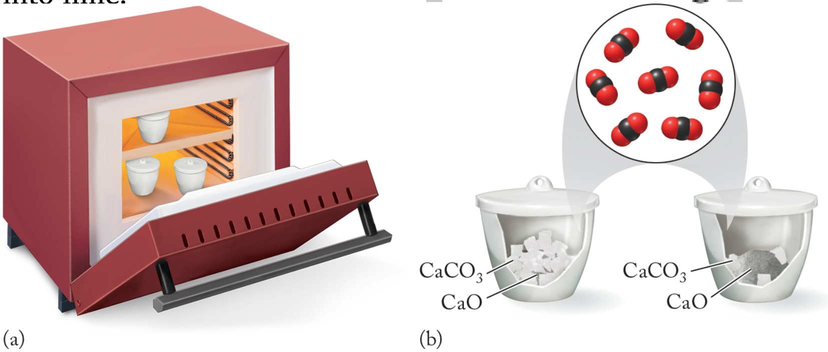

FIGURE 14.6 Two views of the thermal decomposition of $CaCO_3$ to CaO and CO_2. (a) Muffle furnace for heating crucibles containing $CaCO_3$ samples. (b) After heating and decomposition, the two crucibles now contain both $CaCO_3$ and CaO. Different crucibles with different amounts of $CaCO_3$ and CaO still have the same

equilibrium concentration of CO_2 gas.

14.6 Heterogeneous Equilibria

So far in Chapter 14 we have focused on reactions in the gas phase. However, the principles of chemical equilibrium also apply to reactions that contain solids and liquids, particularly reactions in solution. Equilibria in which products and reactants are all in the same phase are called homogeneous equilibria. Equilibria in which reactants and products are in different phases are heterogeneous equilibria.

Let’s consider a heterogeneous reaction that plays a key role in preventing SO_2 produced by coal-burning power plants from escaping into the atmosphere. The reaction occurs when tiny particles of solid calcium oxide are sprayed into exhaust gases that contain SO_2 gas:

$$CaO(s) + SO_2(g) \rightleftharpoons CaSO_3(s)$$

The large quantities of lime (CaO) needed for this reaction and for many other industrial and agricultural uses come from heating pulverized limestone, which is mostly $CaCO_3$, in kilns (**Figure 14.5**) operated at temperatures near 900°C. At these temperatures, $CaCO_3$ decomposes into solid lime and CO_2 gas in another reversible two-phase reaction:

$$CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$$

We might be tempted to write the concentration-based equilibrium constant expression for this reaction as follows:

This expression contains concentration terms for two solids: CaO and $CaCO_3$. However, the terms on the right side of an equilibrium concentration expression are reserved for reactants and products whose values change during a chemical reaction. The concentrations of the solids do not change: as long as these solids are present in the reaction mixture, their concentrations are defined by their densities, which do not change during the reaction. The constant concentration values of the solids are built into the value of K_c, so there is no need of terms for them in the right side of the equilibrium constant expression. This leaves us with

$$K_c = [CO_2]$$

This expression means that, if some CaO and $CaCO_3$ are present, the concentration of CO_2 gas does not vary at a given temperature, as shown in **Figure 14.6**. Instead, the concentration of CO_2 is the same as the value of K_c at that temperature.

The concept of constant concentration also applies to pure liquids involved in reversible chemical reactions. Assuming the liquid is present, its "concentration" is considered constant during the reaction and does not appear in the equilibrium constant expression. Similarly, most *K* expressions for reactions in aqueous solutions do not include a term for $[H_2O]$, even when water is a reactant or product, because its concentration is assumed to not change significantly. In summary, we follow the rules we learned earlier when writing equilibrium constant expressions for heterogeneous equilibria, with the additional rule that pure solids and liquids do not appear in the expression.

SAMPLE EXERCISE 14.9 Writing Equilibrium Constant Expressions for Heterogeneous Equilibria LO1

Write K_c expressions for the following reactions:

1. $CaO(s) + SO_2(g) \rightleftharpoons CaSO_3(s)$
2. $CO_2(g) + H_2O(\ell) \rightleftharpoons H_2CO_3(aq)$

Collect, Organize, and Analyze We are asked to write equilibrium constant expressions for equilibria involving reactants and products in more than one phase. We do not include terms for pure liquids and pure solids, nor do we include a concentration term for H_2O in reactions occurring in aqueous solutions because the value of $[H_2O]$ is assumed not to change significantly during the reaction. The first equilibrium involves two solids: CaO and $CaSO_3$. The second involves liquid H_2O.

Solve

1. An expression with terms for all reactants and products is

$$K_c = \frac{[CaSO_3]}{[CaO][SO_2]}$$

After removing the terms representing solids, we have

$$K_c = \frac{1}{[SO_2]}$$

2. In the equilibrium constant expression for reaction b, $[H_2O]$ is nearly constant and is not included, leaving

$$K_c = \frac{[H_2CO_3]}{[CO_2]}$$

Think About It Writing these equilibrium constant expressions is like writing those for homogeneous reactions, except we leave out terms for pure liquids and solids. When CO_2 dissolves in water, the water is, technically, no longer a *pure* liquid. However, its decrease in "concentration" is much too small to be considered a variable, so there is no $[H_2O]$ term in the K_c expression in part (b).

Practice Exercise Write K_p expressions for the following reactions:

1. $C(s) + CO_2(g) \rightleftharpoons 2\,CO(g)$
2. $CO_2(g) + H_2(g) \rightleftharpoons CO(g) + H_2O(\ell)$

Glossary

homogeneous equilibria
equilibria that involve reactants and products in the same phase.

heterogeneous equilibria
equilibria that involve reactants and products in more than one phase.

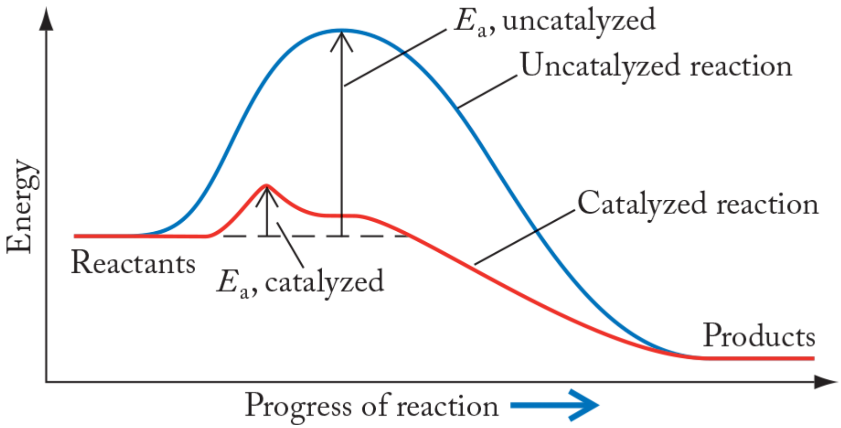

FIGURE 14.12 The effect of a catalyst on a reaction. A catalyst lowers the activation energy barrier, and as a result the rate of the reaction increases. Both the forward reaction and the reverse reaction occur more rapidly, however, so the position of equilibrium (i.e., the value of *K*) does not change. The system comes to equilibrium more rapidly, but the relative amounts of product and reactant present at equilibrium do not change.

14.7 Le Châtelier's Principle

Once a chemical re'ition of the system remains unchanged assuming no external forces perturb it. In this section we examine what happens when systems at equilibrium are perturbed. For example, the flask on the left in **Figure 14.7** contains an equilibrium mixture of two gases—NO_2 and its dimer, N_2O_4—at 25°C. NO_2 is a brown gas, whereas N_2O_4 is colorless. The corresponding dimerization reaction and its equilibrium constant are

The flask on the right in Figure 14.7 initially contained the same mixture of NO_2 and N_2O_4 as the one on the left, but was then placed in an ice bath at 0°C. Why did the temperature change cause a color change in the flask on the right? What other factors can perturb an equilibrium, and how do we explain any changes in the system?

One of the first scientists to study and then successfully predict how chemical equilibria respond to such perturbations was French chemist Henri Louis Le Châtelier (1850–1936). He articulated Le Châtelier’s principle, which states that, if a system at equilibrium is perturbed (or subjected to an external *stress*), the position of the equilibrium shifts in either the forward or reverse direction as a response to reduce that stress. We now consider the effects of several stresses, including changes in concentration, pressure, volume, and temperature.

Effects of Adding or Removing Reactants or Products

When a reactant or product is added or removed, a system at chemical equilibrium is perturbed. Following Le Châtelier’s principle, the system responds in such a way as to restore equilibrium. Through the years, chemists have used Le Châtelier’s principle to increase the yields of chemical reactions that would otherwise have provided very little of a desired product.

To explore how industrial chemists exploit Le Châtelier’s principle, let’s look again at the water–gas shift reaction for making hydrogen:

To perturb the equilibrium and shift the system toward the production of more H_2 (**Figure 14.8**), chemists pass the reaction mixture through a gas scrubber containing a concentrated aqueous solution of K_2CO_3. Doing this removes CO_2 from the gaseous mixture because of the following reaction:

$$CO_2(g) + H_2O(\ell) + K_2CO_3(aq) \rightleftharpoons 2\ KHCO_3(s)$$

Removing CO_2 means fewer molecules of it are available to collide with molecules of H_2 in the reverse reaction in Equation 14.2. As a result, the rate of the reverse reaction becomes slower than the rate of the forward reaction, and the system is no longer in equilibrium. The same conclusion is reached by calculating the value of the reaction quotient, Q_p:

---

after much of the CO_2 has been removed. The depleted term in the numerator results in a Q_p value that is less than K_p, which means that the reaction proceeds in the forward direction to restore equilibrium. Chemists say the reaction *shifts to the right*, making more CO_2 to replace some of what was removed in the reaction with K_2CO_3, and in the process more H_2 gas is made.

Another way to shift a reaction mixture at equilibrium is to add more reactant or product. If the goal is to form more products, then adding more reactants increases their concentration in the reaction mixture, which increases the rate of the forward reaction. Some of the added reactants are converted into additional products. This approach works even when only one of multiple reactants is added, as long as there are sufficient quantities of all the other reactants. This makes sense mathematically because adding one reactant increases the value of one of the terms in the denominator of the mass action expression. Therefore, Q is reduced to a value less than K and the reaction proceeds in the forward reaction, forming more products until equilibrium is restored.

SAMPLE EXERCISE 14.10 Adding or Removing Reactants or Products to Stress an Equilibrium LO6

Suggest three ways the production of ammonia via the reaction

$$N_2(g) + 3\ H_2(g) \rightleftharpoons 2\ NH_3(g)$$

can be increased without changing the reaction temperature.

Collect and Organize We are given the balanced chemical equation of a reversible reaction. We are asked to suggest three ways to increase its yield—that is, to shift its equilibrium to the right to form more product.

Analyze The mass action expression for this reaction is

Changes in the reaction system that reduce the value of Q_p, so that $Q_p < K_p$, will result in the formation of more NH_3.

Solve Interventions that (1) increase the partial pressure of N_2, (2) increase the partial pressure of H_2, or (3) remove NH_3 from the system will all shift the equilibrium to the right and increase the production of ammonia.

Think About It The industrial synthesis of ammonia relies on shifting the equilibrium to the right by (1) running the reaction at high partial pressures of the reactants and (2) removing the product NH_3 by passing the reaction mixture through chilled condensers. Chilling the mixture removes ammonia because it condenses at a higher temperature than N_2 or H_2, reducing the value of Q_p and shifting the equilibrium toward producing more ammonia.

Practice Exercise Describe the changes that occur in a gas-phase equilibrium according to the reaction

$$2\ H_2S(g) + 3\ O_2(g) \rightleftharpoons 2\ SO_2(g) + 2\ H_2O(g)$$

if (a) the reaction mixture is cooled, and water vapor condenses; (b) SO_2 gas dissolves in liquid water as it condenses; or (c) more O_2 is added.

Effects of Pressure and Volume Changes

A reaction involving gaseous reactants or products may be perturbed by altering the volume of the system, thereby changing the partial pressures of the reactants and products in accordance with Boyle’s law. To see how, let’s revisit the equilibrium between NO_2 and its dimer:

$$2\ NO_2(g) \rightleftharpoons N_2O_4(g)$$

CONNECTION Boyle’s law (Section 5.3) states that the volume of a given amount of a gas is inversely proportional to its pressure when kept at a constant temperature.

Suppose a syringe is filled with an equilibrium mixture of the two gases, as shown in **Figure 14.9a**. The plunger on the syringe is then depressed until the volume of the reaction mixture is half what it was initially, as shown in **Figure 14.9b**. At first the concentrations and partial pressures of the gases both double because the same number of molecules of each gas have been compressed into half their original volume. However, the composition of the mixture rapidly changes and some of the increase in brown color intensity fades, as shown in **Figure 14.9c**. This change happens because doubling the partial pressures of both gases perturbed the equilibrium of the reaction. To understand why, let's assume the initial equilibrium partial pressures of NO_2 and N_2O_4 are x and y, respectively. The value of K_p, therefore, is

When the volume of the gases is halved, then their partial pressures double to $P_{NO_2} = 2\times$ and $P_{N_2O_4} = 2y$. Inserting these pressures into the mass action expression gives us a reaction quotient that is half the value of K_p:

Because $Q_p < K_p$, the reaction proceeds in the forward direction, consuming reactants and forming products. The deeper brown color of the gas mixture in Figure 14.9b fades a little in Figure 14.9c, confirming that some of the brown NO_2 has dimerized, forming colorless N_2O_4.

Converting NO_2 into N_2O_4 reduces the total number of moles of gas in the reaction mixture because 2 moles of NO_2 are consumed for every 1 mole of N_2O_4 produced. Fewer moles of gas results in fewer collisions with the inner walls of the syringe, which means reduced pressure. Whenever a reaction mixture at equilibrium is compressed —and the partial pressures of its gas-phase reactants and products increase—the equilibrium shifts toward the side of the reaction equation with fewer moles of gases. In doing so, the reaction mixture relieves some of the stress induced by the increase in pressure resulting from compression. Conversely, increasing the volume of a system at equilibrium at constant temperature results in fewer collisions, lowers the partial pressures of all the gaseous reactants and products, and shifts the equilibrium toward the side of the reaction equation with more moles of gases (**Figure 14.10**).

CONCEPT TEST

Changing the overall volume of the reaction of the water–gas shift reaction at equilibrium:

$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$

does not shift the equilibrium. Why?

SAMPLE EXERCISE 14.11 Assessing the Impact of Compressing or Expanding the Volume of a Gas-Phase Reaction Mixture at Equilibrium LO6

In which of the following equilibria would compressing an equilibrium reaction mixture promote the formation of more product(s)?

1. $N_2(g) + O_2(g) \rightleftharpoons 2\ NO(g)$
2. $2\ NO(g) + O_2(g) \rightleftharpoons 2\ NO_2(g)$
3. $H_2O(\ell) + CO_2(g) \rightleftharpoons H_2CO_3(aq)$
4. $CaCO_3(s) \rightleftharpoons CaCO(s) + CO_2(g)$

Collect, Organize, and Analyze We are asked to identify the reactions for which higher pressure causes an increase in product formation. We know that compression shifts a chemical equilibrium involving gases toward the side of the reaction with fewer moles of gas.

Solve Summing the number of moles of gas on the reactant side and product side in each reaction, we have:

Reaction	Moles of Gaseous Reactants	Moles of Gaseous Products
1	2	2
2	3	2
3	1	0
4	0	1

The only two reactions with fewer moles of gaseous products than reactants are reactions b and c. Therefore, they are the only two in which compression increases product formation.

Think About It In reaction a, the number of moles of gas on the reactant side is the same as the number of moles on the product side, so changing pressure in either direction would not cause a shift in equilibrium. In reaction d, the number of moles on the product side is greater than on the reactant side, so compression favors the reverse of the reaction as written and decreases product formation.

Practice Exercise How does compressing a reaction mixture of CO, Cl_2, and $COCl_2$ affect the following equilibrium?

$$CO(g) + Cl_2(g) \rightleftharpoons COCl_2(g)$$

Effect of Temperature Changes

Let’s return now to Figure 14.7 and reconsider what happens when a volumetric flask containing an equilibrium mixture of NO_2 and N_2O_4 at 25°C is placed into an ice bath. The color of the gas mixture in Figure 14.7b becomes much lighter, indicating that the concentration of NO_2 has decreased. Why? For one thing, the boiling point of N_2O_4 is 21°C. Therefore, lowering the temperature from 25°C to 0°C removed most of the dimer from the gas phase, creating a pool of colorless N_2O_4 liquid in the bottom of the flask. The resulting decrease in the concentration and partial pressure of N_2O_4 makes $Q_p < K_p$, so the reaction shifts toward the formation of additional N_2O_4. This shift drives down the concentration of NO_2 and makes the gas phase in Figure 14.7b a lighter color.

CONNECTION According to Amontons’s law (Section 5.3), the pressure of a quantity of an ideal gas at constant volume is proportional to its absolute temperature.

In Section 14.1 we noted how important the production of ammonia is for the world's food supply. What is the effect of decreasing the temperature upon the synthesis of ammonia, which is an exothermic reaction in the forward direction?

If we think of energy as a product of an exothermic reaction, then lowering the temperature of the reaction mixture favors the forward reaction (because a product is effectively removed), whereas increasing the temperature favors the reverse reaction (because the amount of a product is increased). The situation is reversed for endothermic reactions, in which energy is treated as a reactant, so raising the temperature would favor the forward reaction, whereas lowering the temperature would favor the reverse reaction.

There is an important difference between applying Le Châtelier's principle to explain shifts in equilibrium position when changing concentrations or partial pressures of reactants or products versus applying Le Châtelier's principle to explain temperature changes: *changes in temperature change the value of K*. Increasing temperature reduces the yield of ammonia synthesis because increasing temperature reduces the value of K.

In general, the value of K decreases as temperature increases for exothermic reactions and increases as temperature increases for endothermic reactions. We revisit the influence of temperature on K values in Chapter 17, but for now this general analysis enables us to predict the direction of shifts in equilibria with changing temperature.

SAMPLE EXERCISE 14.12 Predicting Changes in Equilibrium with Changing Temperature LO6

The color of cobalt(II) chloride dissolved in dilute hydrochloric acid depends on temperature, as shown in **Figure 14.11**. The solution is pink at 0°C and royal blue at 75°C. Is the reaction that produces the pink-to-blue color change exothermic or endothermic?

Collect, Organize, and Analyze We are asked to determine whether the reaction in Figure 14.11 is exothermic or endothermic. If it is exothermic, then increasing its temperature should shift the reaction toward the formation of the pink reactant. If the reaction is endothermic, then increasing temperature should shift the reaction toward the formation of the blue product.

Solve The blue product is favored at higher temperatures, so the reaction as written must be endothermic.

Think About It The reaction mixture in this exercise is magenta at room temperature, indicating that both the pink and blue forms are present. As a result, the value of K at room temperature must be close to 1, but the concentration of $Cl^-(aq)$ is also an important factor because it is raised to the fourth power in the equilibrium constant expression.

Practice Exercise Does the value of the equilibrium constant of the reaction

increase or decrease with increasing temperature?

TABLE 14.4 Response of the Reaction $2\ A(g) \rightleftharpoons B(g)$ to Different Kinds of Stress

Kind of Stress	How System Responds	Shift
Add A	Consume A	Right
Remove A	Produce A	Left
Remove B	Produce B	Right
Add B	Consume B	Left
Compress the reaction mixture	Reduce moles of gas	Right
Increase the volume of the reaction mixture	Increase moles of gas	Left

Table 14.4 summarizes how a generic gas-phase reversible reaction in which 2 moles of reactants form 1 mole of product responds to various stresses.

Catalysts and Equilibrium

CONNECTION In Section 13.6 we learned that a catalyst simultaneously increases the rate of a reaction in both the forward and reverse directions, when we discussed the effect of temperature on the rates of reactions occurring in a catalytic converter.

The industrial production of ammonia was developed by the German chemists Fritz Haber (1868–1934) and Carl Bosch (1874–1940) in the early 20th century and is still widely referred to as the Haber–Bosch process. This process is commercially feasible because of the use of iron-based catalysts. As discussed in Section 13.6, a catalyst increases the rate of a chemical reaction by lowering its activation energy. The synthesis of ammonia involves both an equilibrium and a catalyst, so if a catalyst increases the rate of a reaction, does that catalyst affect the equilibrium constant of the reaction?

To answer this question, look at the energy profiles of the catalyzed and uncatalyzed reaction in **Figure 14.12**. The catalyst increases the rate of the reaction by decreasing the height of the energy barrier. However, the barrier height is reduced by the same amount whether the reaction proceeds in the forward direction or in reverse. As a result, the increase in reaction rate produced by the catalyst is the same in both directions. Therefore, a catalyst has *no* effect on the equilibrium constant of a reaction or on the composition of an equilibrium reaction mixture. A catalyst does, however, shorten the time needed for a system to reach equilibrium.

Glossary

Le Châtelier’s principle

the principle that a system at equilibrium responds to a stress in such a way that it relieves that stress.

$$K_p = \frac{(P_{HI})^2}{(P_{H_2})(P_{I_2})} = \frac{(2x)^2}{(1.00 - x)(1.03 - x)}$$

$$K_p = \frac{4x^2}{1.03 - 2.03\,x + x^2} = 50.2$$

$$K_p = \frac{(P_{CO_2})(P_{H_2})}{(P_{CO})(P_{H_2O})} = \frac{(x)(x)}{(2.00 - x)(2.00 - x)} = 11.8$$

$$\left(\frac{x}{2.00 - x}\right)^2 = 11.8$$

$$\left(\frac{x}{2.00 - x}\right) = \sqrt{11.8} = 3.435$$

$$(1 + 3.435)x = 6.870$$

$$x = \frac{6.870}{4.435} = 1.55\text{ atm}$$

$$K_p = \frac{(P_{CO_2})(P_{H_2})}{(P_{CO})(P_{H_2O})} = \frac{(1.55\text{ atm})(1.55\text{ atm})}{(0.45\text{ atm})(0.45\text{ atm})} = 11.8$$

$$PCl_3(g) + Cl_2(g) \rightleftharpoons PCl_5(g) \qquad K_p = 24.2$$

$$K_p = \frac{(P_{PCl_5})}{(P_{PCl_3})(P_{Cl_2})} = \frac{x}{(0.43 - x)(0.87 - x)} = 24.2$$

$$K_p = \frac{x}{0.3741 - 1.30x + x^2} = 24.2$$

$$K_p = \frac{(P_{PCl_5})}{(P_{PCl_3})(P_{Cl_2})} = \frac{0.40}{(0.03)(0.47)} = 28$$

$$K_p = \frac{0.3955}{(0.0345)(0.4745)} = 24.2$$

$N_2(g) + O_2(g) \rightleftharpoons 2\ NO(g) \qquad K_p = 1.0 \times 10^{-5}$

$$K_p = 1.0 \times 10^{-5} = \frac{(P_{NO})^2}{(P_{N_2})(P_{O_2})}$$

$$= \frac{(2x)^2}{(0.79 - x)(0.21 - x)} = \frac{4x^2}{(0.79 - x)(0.21 - x)}$$

$$\frac{4x^2}{(0.79)(0.21)} = 1.0 \times 10^{-5}$$

$$4x^2 = (0.79)(0.21)(1.0 \times 10^{-5}) = 1.659 \times 10^{-6}$$

$$x^2 = 4.148 \times 10^{-7}$$

$$x = 6.4 \times 10^{-4}\ \text{atm}$$

$$K_p = \frac{(P_{CO})(P_{Cl_2})}{(P_{COCl_2})} = \frac{(x)(x)}{(2.75 - x)} = 2.2 \times 10^{-10}$$

$$\frac{x^2}{(2.75)} = 2.2 \times 10^{-10}$$

$$K_p = \frac{(P_{CO})(P_{Cl_2})}{(P_{COCl_2})} = \frac{(2.5 \times 10^{-5})(2.5 \times 10^{-5})}{(2.75)} = 2.3 \times 10^{-10}$$

$$K_p = \frac{(P_{CO})(P_{Cl_2})}{(P_{COCl_2})} = \frac{(2.5 \times 10^{-5})(2.5 \times 10^{-5})}{(2.75)} = 2.3 \times 10^{-10}$$

Step 1: $4\ NH_3(g) + 5\ O_2(g) \rightleftharpoons 4\ NO(g) + 6\ H_2O(g)$

14.8 Calculations Based on *K*

Reference books and the tables in Appendix 5 of this book contain lists of equilibrium constants for chemical reactions. We can use these values in several kinds of calculations, including those in which:

1. We want to determine whether a reaction mixture has reached equilibrium (Sample Exercise 14.8).
2. We know the value of *K* and the starting concentrations or partial pressures of reactants or products, and we want to calculate their equilibrium concentrations or pressures.

In this section we focus on the second type of calculation and introduce a useful way of handling such problems: a table of reactant and product concentrations (or partial pressures) called a *RICE table*. The acronym RICE means that the table starts with the balanced chemical equation describing the **R**eaction followed by rows that contain **I**nitial concentration values, **C**hanges in those initial values as the reaction proceeds toward equilibrium, and **E**quilibrium values.

In our first example, we calculate how much hydrogen iodide forms from the reaction of hydrogen gas and iodine gas at 445°C. At this temperature, the K_p value of the reaction is 50.2:

$$H_2(g) + I_2(g) \rightleftharpoons 2\ HI(g)$$

The initial partial pressures are $P_{H_2} = 1.00$ atm and $P_{I_2} = 1.03$ atm, and no HI is present.

We start by writing the given (initial) information in our RICE table:

Reaction (R)						
[illegible]						
Initial (I)						
Change (C)						
Equilibrium (E)						

We know the reaction will proceed in the forward direction because there is no product initially present, so $Q_p = 0 < K_p$.

We need to use algebra to fill in rows C and E. We don't know how much H_2 or I_2 will be consumed or how much HI will be made. We can define the change in partial pressure of H_2 as $-x$ because H_2 is consumed during the reaction. Because the mole ratio of H_2 to I_2 in the reaction is 1:1, the change in P_{I2} is also $-x$. Two moles of HI are produced from each mole of H_2 and I_2, so the change in P_{HI} is $+2x$. Inserting these values in the C row, we have

Reaction (R)
[illegible]
Initial (I)
Change (C)
Equilibrium (E)

Combining the values in the I and C rows, we obtain the three partial pressures at equilibrium:

Reaction (R)
[illegible]
Initial (I)
Change (C)
Equilibrium (E)

The next step is to substitute the terms from the E row into the K_p expression for the reaction:

Expanding the terms in the numerator and denominator gives

Cross multiplying, we get

$$1.03 \times 50.2 - (2.03 \times 50.2)x + 50.2x^2 = 4x^2$$

Combining the x^2 terms and rearranging, we have

$$46.2x^2 - 101.9x + 51.7 = 0$$

This equation fits the general form of a quadratic equation:

$ax^2 + bx + c = 0$

We can solve for x with a scientific calculator or by using the quadratic formula as described in detail in Appendix 1 and illustrated here in the following steps:

1. Insert the three coefficients $a = 46.2$, $b = -101.9$, and $c = 51.7$ into the quadratic formula:
$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} = \frac{-(-101.9) \pm \sqrt{(-101.9)^2 - 4 \times 46.2 \times 51.7}}{2 \times 46.2}$$
2. Do the math within each of the terms:
$$x = \frac{101.9 \pm \sqrt{10383.61 - 9554.16}}{92.4} = \frac{101.9 \pm \sqrt{829.45}}{92.4}$$
3. Take the square root, combine the ± terms, and simplify:
$$x = \frac{101.9 \pm 28.8}{92.4} = \frac{130.7}{92.4} = 1.415 \quad \text{and} \quad \frac{73.1}{92.4} = 0.791$$

The ± sign yields two solutions for x: 0.791 atm and 1.415 atm. We focus on 0.791 atm because it is the only one that is physically possible. Recall that the algebraic terms for the equilibrium concentrations of H_2 and I_2 gas are $(1.00 - x)$ and $(1.03 - x)$. Inserting $x = 1.415$ atm into either of these produces an equilibrium partial pressure with a negative value, which is impossible. Therefore, we use $x = 0.791$ atm to calculate the equilibrium partial pressures:

$P_{H2} = 1.00 - x = 1.00 - 0.791 = 0.21$ atm

$P_{I2} = 1.03 - x = 1.03 - 0.791 = 0.24$ atm

$P_{HI} = 2\,x = 2(0.791) = 1.582 = 1.58$ atm

The value of x makes sense because it produces pressures of H_2 and I_2 that are less than their initial values but still positive. The sum of the partial pressures of the components in the system is $(0.21 + 0.24 + 1.58) = 2.03$ atm, which is the same as the starting pressure. This result is expected, because we have 2 moles of gas on the reactant side and 2 moles of gas on the product side, so we do not expect the pressure to change as the reaction proceeds. As a final check, we can use the calculated partial pressures in the expression for K_p and calculate its value. When we do so, we get $K_p = (1.58)^2/[(0.21)(0.24)] = 50$, which is not significantly different from the value given of 50.2.

SAMPLE EXERCISE 14.13 Calculating an Equilibrium Partial Pressure I LO7

Most of the H_2 used in the Haber–Bosch process for making ammonia is produced by the steam–gas reforming reaction followed by the water–gas shift reaction:

$$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$$

If a reaction vessel at 675 K is filled with an equimolar mixture of CO and steam, such that the partial pressure of each gas is 2.00 atm, what is the partial pressure of H_2 at equilibrium if $K_p = 11.8$ at 675 K?

Collect, Organize, and Analyze We are asked to find the partial pressure of a gaseous product in an equilibrium mixture, given the initial partial pressures of reactants and the value of K_p. The system initially contains no product, which means that the reaction quotient Q_p is equal to zero. A K_p value of 11.8 means that reactants should be converted into products, but there should be significant partial pressures of both reactants and products at equilibrium. The coefficients of the species in the chemical equation describing the reaction are all one, so in our RICE table we let $+x$ be the increase in the partial pressures of H_2 and CO_2 and $-x$ be the decreases in both reactants.

Solve

Reaction (R)	$CO(g)$	+	$H_2O(g)$	$\rightleftharpoons$	$CO_2(g)$	+	$H_2(g)$
	P_{CO} (atm)		P_{H_2O} (atm)		P_{CO_2} (atm)		P_{H_2} (atm)
Initial (I)	2.00		2.00		0		0
Change (C)	$-x$		$-x$		$+x$		$+x$
Equilibrium (E)	$2.00 - x$		$2.00 - x$		x		x

Inserting these equilibrium terms into the K_p expression:

Note that the algebraic terms for both products are equal to x, and the terms for both reactants are equal to $(2.00 - x)$. These equalities do not happen often, but solving for x is much easier when they do because the two terms can be written this way:

Taking the square root of both sides removes the exponent on the left:

Cross multiplying:

$x = 3.435\ (2.00 - x) = 6.870 - 3.435x$

Solving for x:

This is the equilibrium partial pressure of both products: H_2 and CO_2.

Think About It Our prediction that significant quantities of both reactants and products would be present at equilibrium is confirmed. Let's check the accuracy of our solution by inserting the equilibrium partial pressures of H_2 and CO_2 (1.55 atm) and of steam and CO ($2.00 - 1.55 = 0.45$ atm) into the equilibrium constant expression:

This result matches the K_p value we started with, confirming that our calculation is correct.

Practice Exercise The chemical equation for the reaction of chlorine and bromine to produce BrCl is

$Cl_2(g) + Br_2(g) \rightleftharpoons 2\ BrCl(g)$

If $K_p = 4.7 \times 10^{-2}$ for the reaction at a given temperature, what is the partial pressure of each reactant and product in a sealed reaction vessel at equilibrium? The initial partial pressures of Cl_2 and Br_2 are both 0.100 atm and no BrCl is present.

SAMPLE EXERCISE 14.14 Calculating an Equilibrium Partial Pressure II LO7

The K_p value for the reaction $PCl_3(g) + Cl_2(g) \rightarrow PCl_5(g)$ is 24.2 at 250°C. If the initial partial pressures of PCl_3 and Cl_2 are 0.43 and 0.87 atm, respectively, and no PCl_5 is initially present, what are the partial pressures of the three gases when equilibrium is achieved?

Collect and Organize We are asked to determine the equilibrium partial pressures of the three gases from the initial partial pressures of the reactants and the equilibrium constant. The chemical equation describing the reaction is

---

Analyze The system initially contains no product, so $Q < K_p$ and the reaction will proceed in the forward direction as written. We can construct a RICE table from the information given. If $+x$ is the increase in the partial pressure of the product formed, then, given the 1:1:1 stoichiometry of the reactants and product, the decreases in both reactants will be $-x$.

Solve Setting up the RICE table in which the equilibrium (E) terms are the sum of the (I) + (C) terms:

Reaction (R)
P (atm)
Initial (I)
Change (C)
Equilibrium (E)

Inserting the terms from row (E) into the K_p expression for the reaction:

There is only one partial pressure term in the numerator and the two terms in the denominator do not match, so solving for x will not be as simple as in Sample Exercise 14.13. Here we need to expand the terms in the denominator:

and cross multiply:

$0.3741 \times 24.2 - (1.30 \times 24.2)x + 24.2x^2 = x$

Combining the x terms and rearranging, we have

$24.2x^2 - 32.46x + 9.05322 = 0$

Using a scientific calculator or the quadratic formula to solve for x yields two values: 0.3955 and 0.9458. Only 0.3955 gives positive partial pressure values for all three gases, which are

$P_{PCl_3} = 0.43 - 0.3955 = 0.03$ atm

$P_{Cl_2} = 0.87 - 0.3955 = 0.47$ atm

$P_{PCl_5} = 0.3955 = 0.40$ atm

Think About It The values make sense because the partial pressures of both reactants have decreased and that of the product has increased. When we check our answers by substituting them into the equation for K_p:

we get a value that is reasonably close to the K_p value used in the calculation (24.2), given that the partial pressure of PCl_3 was rounded off to only one significant figure. To obtain a more useful accuracy check, let's *not* round off the calculated partial pressures to calculate K_p:

Practice Exercise Consider the reverse reaction in Sample Exercise 14.14 at the same temperature. If the vessel initially contains 1.35 atm PCl_5, what are the partial pressures of the three gases when equilibrium is achieved?

The equilibrium calculations we have done so far have been based on K_p values in the 10^{-2} to 10^2 range. As we noted in Section 14.2, reactions with these K_p values produce reaction mixtures with significant quantities of both reactants and products at equilibrium. When equilibrium constants are very small, however, we can frequently make an approximation at the outset that enables us to simplify our mathematical operations by considering the effect that the size of an equilibrium constant has on the values in our equation. For example, the K_p value for the following reaction at 1500 K is small:

If the initial partial pressures of N_2 and O_2 are 0.79 and 0.21 atm, respectively, and no NO is present, we can set up a RICE table and calculate the partial pressure of NO at equilibrium as we have done previously:

Reaction (R)					
P (atm)					
Initial (I)					
Change (C)					
Equilibrium (E)					

Inserting the equilibrium partial pressure terms in the K_p expression:

Before expanding the equation and solving for x, stop and think about the size of x. The equilibrium constant is very small, which means very little product will form. As a result, the value of x will probably be much smaller than the values of the initial partial pressures, so that $(0.79 - x)$ and $(0.21 - x)$ will be approximately the same as 0.79 and 0.21. If we assume that the $-x$ terms in the denominator are negligible and simply use the initial values of $P_{N2}$and P_{O2}instead, we obtain an equation that is much easier to solve:

This value is in fact the same as that obtained by solving for x without neglecting the $-x$ term, at least to two significant figures, which are all we are allowed in this problem.

In equilibrium calculations, we can ignore the $-x$ or $+x$ component of an equilibrium concentration or partial pressure term if the value of x is less than 5% of the initial value. In this problem the smaller initial partial pressure was 0.21 atm, and the ratio of $x/0.21\ \text{atm} = 6.4 \times 10^{-4}\ \text{atm}/0.21\ \text{atm} = 0.0030$ or 0.3%, which is well less than the 5% guideline.

SAMPLE EXERCISE 14.15 Calculating an Equilibrium Partial Pressure III LO7

The value of K_p for the decomposition of phosgene ($COCl_2$) gas:

$COCl_2(g) \rightleftharpoons CO(g) + Cl_2(g)$

is 2.2×10^{-10} at 100°C. If a sealed vessel contains only phosgene at a partial pressure of 2.75 atm, what are the partial pressures of the reactant and its decomposition products when the system comes to equilibrium?

Collect and Organize We are asked to find the partial pressures of $COCl_2$ and its decomposition products in a gas-phase equilibrium mixture. We know the initial value of P_{COCl_2} and the value of K_p.

Analyze The value of K_p is very small, so we may be able to assume that the $-x$ component of the P_{COCl_2} term at equilibrium is negligible.

Solve Setting up a RICE table for this reaction system:

Reaction (R)	$COCl_2(g)$
	P_{COCl_2} (atm)
Initial (I)	2.75
Change (C)	$-x$
Equilibrium (E)	$2.75 - x$

Using the equilibrium values in the mass action expression and then simplifying and solving for x:

Making the simplifying assumption that the $-x$ part of the P_{COCl2}term is negligible:

Cross multiplying and taking the square root to solve for x:

Therefore, at equilibrium P_{COCl2} is not significantly less than its initial value (2.75 atm) and $P_{CO} = P_{Cl2} = 2.5 \times 10^{-5}$ atm.

Think About It The ratio of x to the initial partial pressure of $COCl_2$ is 2.5×10^{-5} atm/2.75 atm $= 9.1 \times 10^{-6}$, which is much less than 5%, so our simplifying assumption was valid. To check on the accuracy of our arithmetic, let's insert the calculated partial pressures into the K_p expression:

This value is very close to the K_p value (2.2×10^{-10}) used in the calculation and supports the accuracy of the results.

Practice Exercise What effect will doubling the partial pressure of phosgene in the sample exercise have on the partial pressures of CO and Cl_2 at equilibrium?

SAMPLE EXERCISE 14.16 Integrating Concepts: Making Nitric Acid

About 15% of the ammonia produced industrially by the Haber–Bosch process is converted into nitric acid by the Ostwald process, named after Wilhelm Ostwald (1853–1932), the German chemist who developed it. In the Ostwald process, ammonia is burned in air at 900°C in the presence of a platinum–rhodium catalyst:

Under these conditions, about 90% of the starting ammonia is converted into NO.

1. Air is 21% O_2 by volume. Typical instructions for step 1

specify that the volume of air should be 10 times the volume of ammonia reacted. (i) Using this volume ratio, which is the limiting reactant? (ii) Write the K_p expression for step 1 and explain how the partial pressure of oxygen influences the position of the equilibrium.

2. In the second step of the process, the temperature is lowered, and more air is mixed with the products of step 1.

Step 2: $2\ NO(g) + O_2(g) \rightleftharpoons 2\ NO_2(g)$

$\Delta H^\circ_{rxn} = -114.0\ kJ/mol$

Predict what would happen to the yield in step 2 if the temperature were increased instead of lowered.

3. In the third and final step, NO_2 is passed through liquid water to form a solution of nitric acid (HNO_3); nitrogen monoxide gas is also produced. Write the K_c expression for this reaction.

Collect and Organize In part (a), we are provided with the balanced chemical equation describing a reversible gas-phase reaction and the volume ratio of the two reactants. We are asked to identify the limiting reactant, to write the K_p expression for the reaction, and to describe how altering the partial pressure of one of the reactants influences the equilibrium's position. In part (b), we are asked to predict the effect of raising reaction temperature on the yield of an exothermic reaction. In part (c), we need to write the K_c expression for a reaction happening in solution. We know at least some of the reactants and products, but we are not provided with a balanced chemical equation for this final step.

Analyze If we assume that both reactants in part (a) behave as ideal gases, then their volume ratio is the same as their mole ratio. Increasing the partial pressure of a reactant (O_2) shifts the equilibrium to the right (formation of more product). The reaction in part (b) is exothermic ($\Delta H^\circ < 0$), so the value of K_p and the yield of the reaction should decrease as temperature increases. The reaction in step 3 is a redox reaction because the oxidation state of nitrogen is initially $+4$ in NO_2, but it is $+5$ in HNO_3 and $+2$ in NO. Thus, nitrogen is both oxidized and reduced. To write a K_c expression we first need to write a balanced chemical equation, and that requires balancing the loss and gain of electrons by the N atoms in molecules of NO_2 as they form molecules of HNO_3 and NO. To do so, we need to use the procedure developed in Section 4.8.

Solve

1. (i) A volume ratio of 10:1 for air:ammonia translates into a mole ratio of $(10 \times 0.21) = 2.1$ mol O_2/mol NH_3. The stoichiometric ratio is 5 moles of O_2 for every 4 moles of NH_3, or 1.25 mol O_2/mol NH_3. Therefore, the reaction mixture contains excess O_2, making NH_3 the limiting reactant. (ii) The K_p expression (partial pressures of products over reactants each raised to a power equal to its stoichiometric coefficient) is

   $$K_p = \frac{(P_{NO})^4(P_{H_2O})^6}{(P_{NH_3})^4(P_{O_2})^5}$$

   The presence of excess O_2 at equilibrium shifts the position of the equilibrium toward the production of more NO.

2. The reaction is exothermic, so energy is a product of the reaction. If the temperature were increased, the reaction would shift in the direction of more reactants, and less NO_2 would be present at equilibrium.
3. The known reactants and products of the final reaction step are

   $NO_2(g) + H_2O(\ell) \rightleftharpoons NO(g) + HNO_3(aq)$

   During the reaction, the oxidation state of nitrogen simultaneously changes by +1 (from +4 in NO_2 to +5 in HNO_3) and by −2 (from +4 in NO_2 to +2 in NO). To balance the redox equation, we will use the guideline developed in Section 4.8. First, we divide the overall reaction into two half-reactions:

   Oxidation: $H_2O(\ell) + NO_2(g) \rightarrow HNO_3(aq)$

Reduction: $NO_2(g) \rightarrow NO(g) + H_2O(\ell)$

All of the elements are balanced except for hydrogen and oxygen. We balance the number of oxygen atoms in each half-reaction by adding water, and we balance the hydrogen atoms by adding protons, H^+, because the reaction takes place in acidic solution. To balance the charges, we add an appropriate number of electrons. Before adding the half-reactions, we need to multiply the oxidation half-reaction by 2 so that the number of electrons lost equals the number of electrons gained.

$$\begin{array}{l} \text{Oxidation: } 2[H_2O(\ell) + NO_2(g) \rightarrow HNO_3(aq) + H^+(aq) + e^-] \\ \text{Reduction: } 2\,H^+(aq) + 2\,e^- + NO_2(g) \rightarrow NO(g) + H_2O(\ell) \\ \hline \cancel{2\,H^+(aq) + 2\,e^- +} NO_2(g) + \cancel{2}\,H_2O(\ell) + 2\,NO_2(g) \rightarrow \\ \qquad NO(g) \cancel{+ H_2O(\ell)} + 2\,HNO_3(aq) \cancel{+ 2\,H^+(aq) + 2\,e^-} \end{array}$$

Cancelling out the protons, electrons, and water molecules that appear on both sides of the equation, we arrive at a balanced, overall equation:

$H_2O(\ell) + 3\,NO_2(g) \rightarrow NO(g) + 2\,HNO_3(aq)$

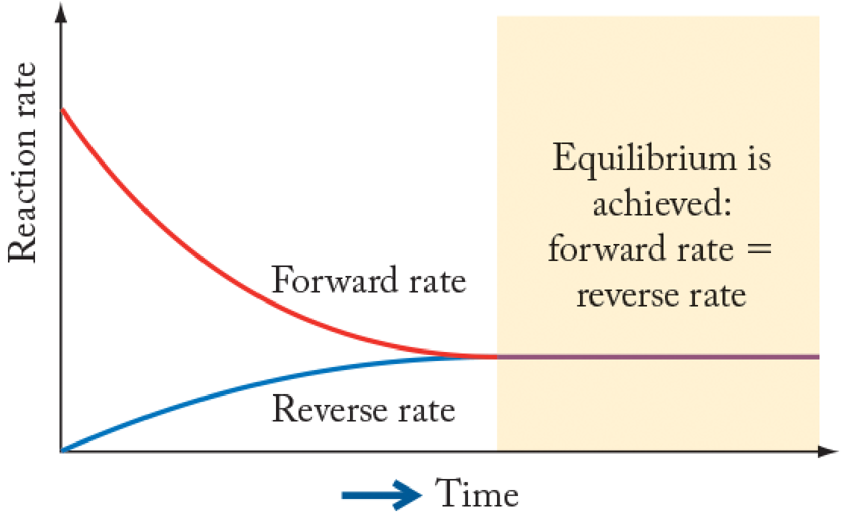
A check of the numbers of H and O atoms on both sides of the equation reveals that it is balanced. Because the concentration of H_2O is unlikely to decrease significantly during the reaction, there is no $[H_2O]$ term in the K_c expression:

$$K_c = \frac{[NO][HNO_3]^2}{[NO_2]^3}$$

Think About It Writing a chemical equation describing the conversion of NO_2 into HNO_3 and NO was simplified by recognizing that the reaction is a redox reaction that takes place in acidic solution.

Learning Objectives

- Relate the concentrations or partial pressures of reactants and products in a reaction mixture at equilibrium to their initial values and the value of K **Return to Sample Exercises 14.13, 14.14, 14.15**
- Relate the concentrations or partial pressures of reactants and products in a reaction mixture at equilibrium to their initial values and the value of K **Return to Sample Exercises 14.13, 14.14, 14.15**
- Relate the concentrations or partial pressures of reactants and products in a reaction mixture at equilibrium to their initial values and the value of K **Return to Sample Exercises 14.13, 14.14, 14.15**



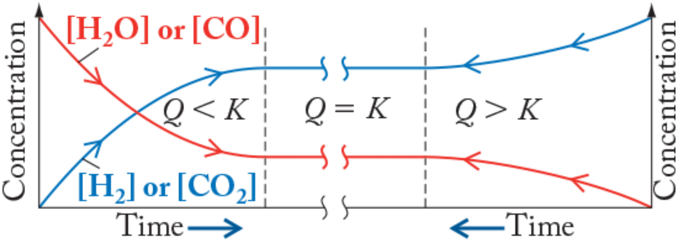
SUMMARY

LO1 According to the law of mass action, the ratio of the concentrations of the products of a reversible reaction divided by the concentrations of the reactants, with each raised to its stoichiometric coefficient from the balanced equation—a quantity called the mass action expression, or the equilibrium constant expression—has a characteristic value at a given temperature. The concentrations of pure liquids and solids that do not significantly change during a reaction are omitted from equilibrium constant expressions. (Sections 14.1, 14.2, 14.6)

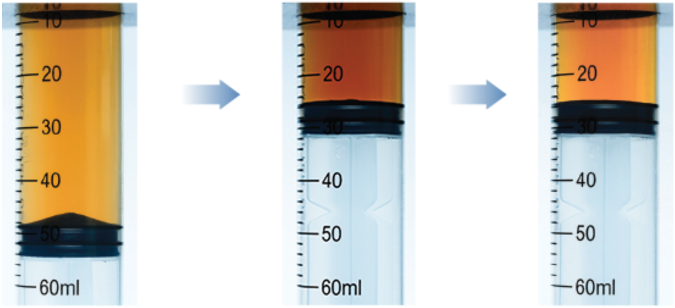
- LO2 The value of the equilibrium constant, K_c, of a reversible reaction can be calculated from the composition of a reaction mixture at equilibrium by inserting the molar concentrations of each reactant and product into the equilibrium constant expression, raising each value to the appropriate power and calculating the ratio of the product to reactant terms. Similarly, the equilibrium partial pressures of the reactants and products of a reversible gas–phase reaction can be used to calculate the K_p value of the reaction at that temperature.

(Section 14.2)

- LO3 The relationship between K_c and K_p for a reversible gas-phase reaction depends on the number of moles of gaseous reactants and products in the balanced chemical equation. (Section 14.3)
- LO4 The reverse of a reaction has an equilibrium constant that is the reciprocal of *K* for the forward reaction. If the balanced equation for a reaction is multiplied by some factor *n*, the value of *K* for that reaction is raised to the *n*th power. If reactions are summed to give an overall reaction, their equilibrium constants are multiplied together to obtain an overall equilibrium constant. (Section 14.4)



- LO5 The reaction quotient (*Q*) is the value of the mass action expression at any instant during a reaction. At equilibrium, $Q = K$, but for nonequilibrium conditions, *Q* indicates how a reaction is proceeding. (Sections 14.2, 14.5)



- LO6 According to Le Châtelier's principle, chemical reactions at equilibrium respond to stress by shifting the position of the equilibrium to relieve the stress. A catalyst decreases the time it takes a system to achieve equilibrium but does not change the value of the equilibrium constant. (Section 14.7)
- LO7 Equilibrium concentrations or partial pressures of reactants and products can be calculated from initial

concentrations or pressures, the reaction stoichiometry, and the value of the equilibrium constant. (Section 14.8)

PARTICULATE PREVIEW WRAP-UP

The chemical equation for both samples is

$$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$$

In sample A, the concentrations of the reactants are constant; in sample B, the concentrations of the reactants decrease. In sample A, the concentrations of the products are constant; in sample B, the concentrations of the products increase. Sample A is probably at equilibrium.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts and Equations	Sample Exercises
Writing equilibrium constant expressions	For the general equation $aA + bB \rightleftharpoons cC + dD$ $K_c = \frac{[C]^c[D]^d}{[A]^a[B]^b}$ (14.3) and $K_p = \frac{(P_C)^c(P_D)^d}{(P_A)^a(P_B)^b}$ (14.4)	
Calculating and interconverting K_c and K_p	Insert equilibrium concentrations or partial pressures into the equilibrium constant expression and use the relation $K_p = K_c(RT)^{\Delta n}$ (14.7) where $R = 0.08206$ L · atm/(mol · K), T is the absolute temperature, and Δn is the number of moles of product gas minus the number of moles of reactant gas in the balanced chemical equation.	14.2, 14.3, 14.4
Calculating K values for related reactions	$K_{reverse} = 1/K_{forward}$ for the forward and reverse reactions in an equilibrium system. If all the coefficients in a chemical equation are multiplied by n, the value of K increases by the power of n. If reactions are summed to give an overall reaction, their equilibrium constants are multiplied together to obtain an overall K.	14.5, 14.6, 14.7
Using Q and K values to predict the direction of a reaction	If $Q < K$, the net reaction proceeds in the forward direction to make more products; if $Q = K$, the reaction is at equilibrium;	14.8

		if $Q > K$, the reaction proceeds in the reverse direction to make more reactants.
Writing equilibrium constant expressions for heterogeneous equilibria	**14.9**	Pure liquids and solids are omitted from equilibrium constant expressions because their concentrations are constant.
Adding or removing reactants or products to stress an equilibrium	**14.10**	[illegible] shifts the equilibrium toward the production of more of that substance. Increasing the concentration of a substance shifts the equilibrium to react some of that substance.
Predicting the effect of changing volume on gas-phase equilibria	**14.11**	Equilibria involving different numbers of moles of gaseous reactants and products shift in response to an increase (or decrease) in volume caused by a decrease (or increase) in pressure toward the side with more (or fewer) moles of gases.
Predicting changes in equilibrium with temperature	**14.12**	The value of K for an endothermic reaction increases with increasing temperature; the value of K for an exothermic reaction decreases with increasing temperature.
Calculating concentrations or partial pressures of reactants and products at equilibrium	**14.13, 14.14, 14.15**	Use a RICE table to [illegible] reactant and product's partial pressure or concentration at equilibrium. Substitute these terms into the expression for K and solve.

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

Consider the graph of concentration versus time in Figure P14.1.

1. What is the mass action expression for the reaction?
2. What is the value of K_c?

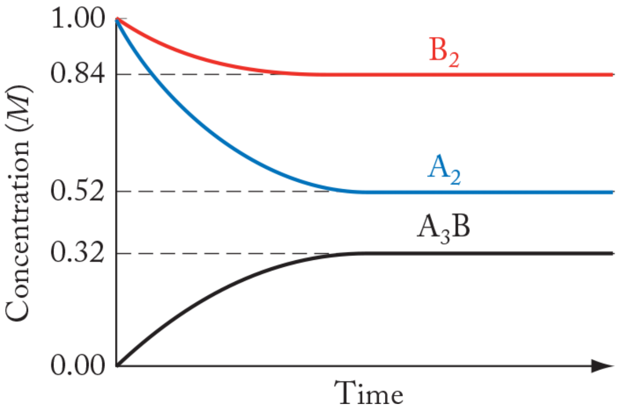


FIGURE P14.1

In Figure P14.2, the red spheres represent reactant A and the blue spheres represent product B in equilibrium with A.

1. Write a chemical equation that describes the equilibrium.
2. What is the value of the equilibrium constant K_c?

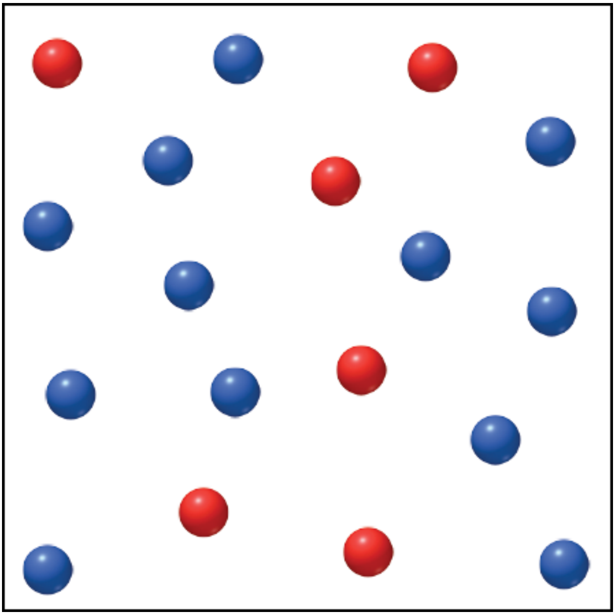

FIGURE P14.2

The equilibrium constant K_c for the reaction

A (red spheres) + B (blue spheres) $\rightleftharpoons$ AB

is 3.0 at 300.0 K. Does the situation depicted in Figure P14.3 correspond to equilibrium? If not, in what direction (to the left or to the right) will the system shift to attain equilibrium?

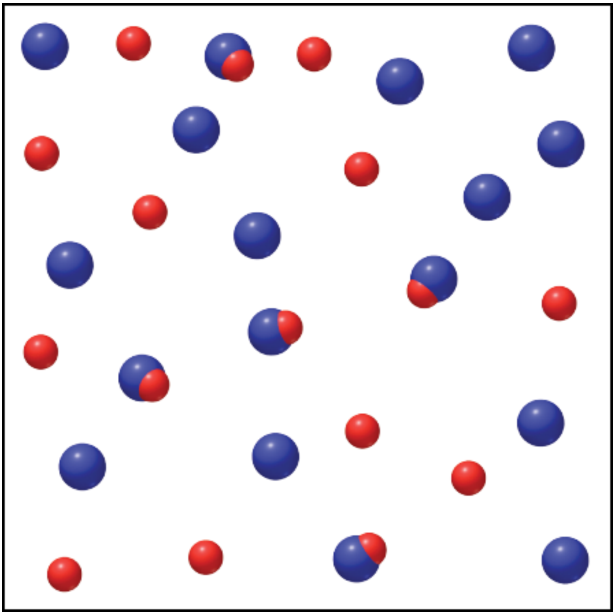

FIGURE P14.3

The diagrams in Figure P14.4 represent equilibrium states of the reaction

A (red spheres) + B (blue spheres) $\rightleftharpoons$ AB

at 300 K and 400 K, respectively. Is this reaction endothermic or exothermic? Explain.

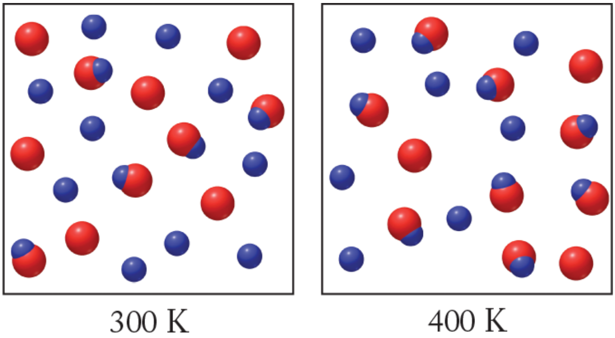

FIGURE P14.4

Does the reaction A → 2 B represented in Figure P14.5 reach equilibrium in 20 μs? Explain your answer.

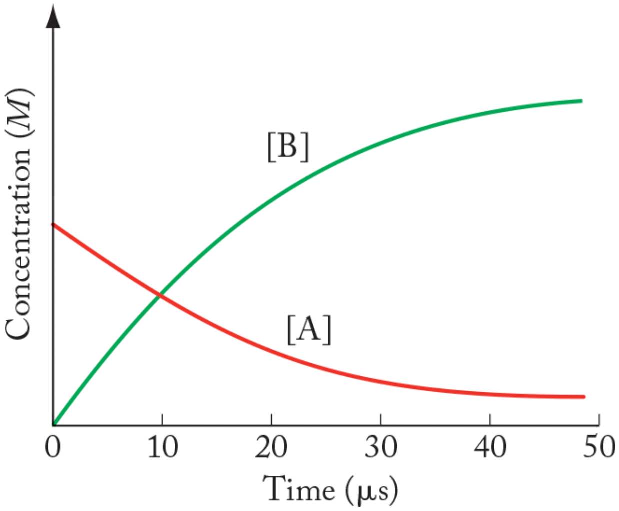

FIGURE P14.5

How does the cartoon in Figure P14.6 illustrate the concept of dynamic equilibrium?

THE SALT LAKE T

FIGURE P14.6

There is a temperature at which the equilibrium constant $K_p = 4$ for the dimerization of NO_2 to N_2O_4. Does the particle view (Figure P14.7) of a reaction mixture of these two gases at this temperature represent (a) $Q_p < K_p$, (b) $Q_p = K_p$, or (c) $Q_p > K_p$?

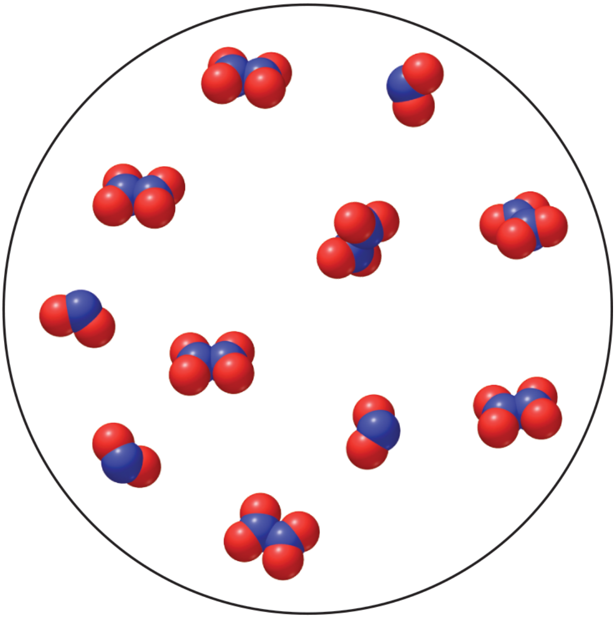

FIGURE P14.7

The graph in Figure P14.8 shows the results of an experiment in which the progress of the decomposition of NO_2 into NO and O_2 was monitored over time. (a) Which line corresponds to which gas? (b) Use the results shown in the graph to estimate the value of K_c for the decomposition reaction at the temperature used in the experiment.

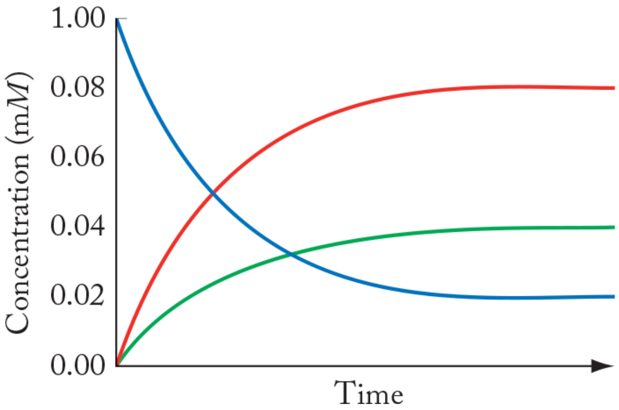

FIGURE P14.8

Sketch a graph similar to the one in Figure P14.8, but depicting the progress of the reaction $CaO(s) + SO_2(g) \rightleftharpoons CaSO_3(s)$ in which the initial partial pressure of SO_2 is 0.1 atm. Assume that the reaction mixture contains more than enough CaO to react with all of the SO_2 present and that the reaction occurs at a temperature at which its K_p value is exactly 50.

Use representations [A] through [I] in Figure P14.10 to answer questions (a)–(f). The center cell [E] represents an equilibrium mixture of $NO_2(g)$ and $N_2O_4(g)$. Assume that the temperature remains constant.

1. Write a balanced chemical equation describing the reversible reaction (NO_2 is the reactant) taking place in [E].
2. Identify one stress to the system that would transform [E] to [C].
3. Although [E] is an equilibrium mixture, the reaction mixture in [C] is not yet at equilibrium. Which representation depicts how [C] transforms to reestablish equilibrium?
4. Are [G] and [I] at equilibrium or not? How can you tell?
5. Given that N_2O_4 is colorless and NO_2 is brown, match the pictures of the syringes to their respective particulate images.
6. Does the syringe in [H] contain any N_2O_4?

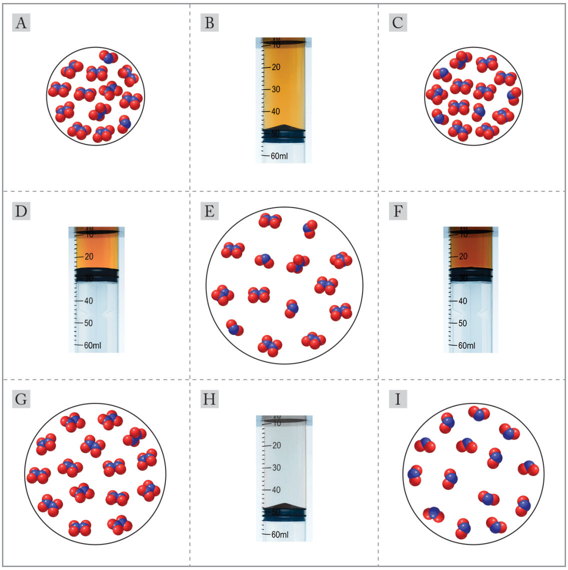

FIGURE P14.10

QUESTIONS AND PROBLEMS

The Dynamics of Chemical Equilibrium

Concept Review

Describe one way in which all the graphs used in Chapter 13 to illustrate the progress of chemical reactions differ from a graph of the progress of a reaction that has come to equilibrium.

What does the word *dynamic* mean when it is used to describe chemical equilibrium?

Do rapid reversible reactions always have greater yields of product than slow reversible reactions? Explain why or why not.

At equilibrium, is the sum of the concentrations of all the reactants always equal to the sum of the concentrations of the products? Explain why or why not.

How are forward and reverse reaction rates related in a system at chemical equilibrium?

Are ice cubes floating in 0°C water in an insulated container an example of a system in dynamic equilibrium? Explain why or why not.

Problems

Suppose the rate constant of the forward reaction $A(g) \rightleftharpoons B(g)$ is smaller than the rate constant of the reverse reaction. Do equilibrium mixtures of A and B have more A or more B in them? Explain your answer.

Suppose at 298 K the reaction $C(g) \rightleftharpoons D(g)$ has a forward rate constant of 5/s and a reverse rate constant of 10/s. What is the value of the equilibrium constant of the reaction at 298 K?

Suppose the rate of the forward reaction $N_2(g) + O_2(g) \rightleftharpoons 2\ NO(g)$ is $2.7 \times 10^{-3} M/s$. If the reaction mixture is at equilibrium, what is the rate of the reverse reaction?

Suppose the rate of consumption of N_2 in the reaction $N_2(g) + 3\ H_2(g) \rightleftharpoons 2\ NH_3(g)$ is $-\ 4.0 \times 10^{2} M/s$, whereas the rate of consumption of NH_3 in the reverse reaction is $-\ 1.6 \times 10^{3} M/s$. Is the reaction mixture at equilibrium? Explain why you think it is or is not.

In a study of the reaction

$$2\ N_2O(g) \rightleftharpoons 2\ N_2(g) + O_2(g)$$

volumes of all three gases were injected into a reaction vessel. The N_2O consisted entirely of isotopically labeled $^{15}N_2O$. Analysis of the reaction mixture after 1 day revealed the presence of compounds with molar masses 28, 29, 30, 32, 44, 45, and 46 g/mol. Identify the compounds and account for their appearance.

A mixture of ^{13}CO, $^{12}CO_2$, and O_2 in a sealed reaction vessel was used to follow the reaction

$2\ CO(g) + O_2(g) \rightleftharpoons 2\ CO_2(g)$

Analysis of the reaction mixture after 1 day revealed the presence of compounds with molar masses 28, 29, 32, 44, and 45 g/mol. Identify the compounds and account for their appearance.

The Equilibrium Constant; Relationships between K_c and K_p Values

Concept Review

What is the difference between an *equilibrium constant* and an *equilibrium constant expression*?

Does adding more reactant to a reaction mixture at equilibrium change the value of the equilibrium constant?

Under what conditions are the numerical values of K_c and K_p equal?

At 298 K, is K_p greater than or less than K_c if there is a net increase in the number of moles of gas in the reaction and if $K_c > 1$? Explain your answer.

Write K_c and K_p expressions for the following reversible reactions.

1. $4\ HCl(g) + O_2(g) \rightleftharpoons 2\ H_2O(g) + 2\ Cl_2(g)$
2. $CS_2(g) + 4\ H_2(g) \rightleftharpoons CH_4(g) + 2\ H_2S(g)$

Write K_c and K_p expressions for the following reversible reactions.

1. $2\ NOBr(g) \rightleftharpoons 2\ NO(g) + Br_2(g)$
2. $2\ C_2H_4(g) + 2\ H_2(g) \rightleftharpoons 2\ C_2H_6(g)$

SO_2 in the Air Combustion of fossil fuels that contain sulfur is an important source of sulfur dioxide in the atmosphere. Write the K_p and K_c expressions for the gas-phase combustion reaction:

$S(g) + O_2(g) \rightleftharpoons SO_2(g)$

How are the values of K_p and K_c related?

More SO_2 in the Air Sulfur dioxide released into the atmosphere during the combustion of fossil fuels may react with atmospheric oxygen, forming sulfur trioxide. Write the K_p and K_c expressions for this reaction. How are the values of K_p and K_c related?

Problems

At 1200 K the partial pressures of an equilibrium mixture of H_2S, H_2, and S are 0.020, 0.045, and 0.030 atm, respectively. Calculate the value of K_p at 1200 K for the reaction

$H_2S(g) \rightleftharpoons H_2(g) + S(g)$

At 1045 K the partial pressures of an equilibrium mixture of H_2O, H_2, and O_2 are 0.040, 0.0045, and 0.0030 atm, respectively. Calculate the value of the equilibrium constant K_p at 1045 K for the reaction

$2\ H_2O(g) \rightleftharpoons 2\ H_2(g) + O_2(g)$

At equilibrium, the concentrations of gaseous N_2, O_2, and NO in a sealed reaction vessel are $[N_2] = 3.3 \times 10^{-3} M$, $[O_2] = 5.8 \times 10^{-3} M$, and $[NO] = 3.1 \times 10^{-3} M$. What is the value of K_c for the reaction

$N_2(g) + O_2(g) \rightleftharpoons 2\ NO(g)$

at the temperature of the reaction mixture?

Exactly 2 moles of ammonia are heated in a sealed 1.00 L container to 650°C. At this temperature, ammonia decomposes to nitrogen and hydrogen gas:

$2\ NH_3(g) \rightleftharpoons N_2(g) + 3\ H_2(g)$

At equilibrium, the concentration of ammonia in the container is 1.00 *M*. What is the value of K_c for the decomposition reaction at 650°C?

Synthesis of Hydrogen (Step 1) Hydrogen gas production often begins with the steam–methane reforming reaction

$CH_4(g) + H_2O(g) \rightleftharpoons CO(g) + 3\ H_2(g)$

At 1000 K the partial pressures of the gases in an equilibrium mixture are 0.71 atm CH_4, 1.41 atm H_2O, 1.00 atm CO, and 3.00 atm H_2. What is the value of K_p for the reaction at 1000 K?

Synthesis of Hydrogen (Step 2) When the CO produced in the steam–methane reforming reaction is reacted with more steam at 450 K, the water–gas shift reaction:

$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$

produces more hydrogen. If the equilibrium partial pressures of the gases in the reactor are 0.35 atm H_2O, 0.24 atm CO, 4.47 atm H_2, and 4.36 atm CO_2, what is the value of K_p?

For which of the following reactions are the values of K_p and K_c equal?

$2\ NOCl(g) \rightleftharpoons 2\ NO(g) + Cl_2(g)$
$SO_2Cl_2(g) \rightleftharpoons SO_2(g) + Cl_2(g)$
$2\ CaSO_3(s) + O_2(g) \rightleftharpoons 2\ CaSO_4(s)$

For which of the following reactions are the values of K_c and K_p equal?

1. $2\ SO_2(g) + O_2(g) \rightleftharpoons 2\ SO_2(g)$
2. $O_3(g) + SO_2(g) \rightleftharpoons SO_3(g) + O_2(g)$
3. $4\ SO(g) \rightleftharpoons 2\ S_2O(g) + O_2(g)$

How is the K_c value of the reaction

$3\ NO(g) \rightleftharpoons NO_2(g) + N_2O(g)$

related to the K_p value for the reverse reaction?

$NO_2(g) + N_2O(g) \rightleftharpoons 3\ NO(g)$

If the value of the equilibrium constant K_c for the following reaction is 5×10^5 at 298 K, what is the value of K_p at 298 K?

$2\ CO(g) + O_2(g) \rightleftharpoons 2\ CO_2(g)$

Bulletproof Glass Phosgene ($COCl_2$) is used in the manufacture of foam rubber and bulletproof glass. It is formed from carbon monoxide and chlorine in the following reaction:

$Cl_2(g) + CO(g) \rightleftharpoons COCl_2(g)$

If $K_c = 5.0$ for this reaction at 327°C, then what is the value of K_p at 327°C?

If $K_p = 3.45$ at 298 K for the following reaction,

$SO_2(g) + NO_2(g) \rightleftharpoons NO(g) + SO_3(g)$

what is the value of K_c for the reverse reaction?

The K_c value for the reaction

$2\ NOBr(g) \rightleftharpoons 2\ NO(g) + Br_2(g)$

is 3.0×10^{-4} at 298 K. What is the value of K_p at 298 K for the following reaction?

$$NOBr(g) \rightleftharpoons NO(g) + \frac{1}{2} Br_2(g)$$

How is the value of the equilibrium constant K_c for the reaction

$2\ H_2O(g)\ +\ N_2(g) \rightleftharpoons 2\ H_2(g)\ +\ 2\ NO(g)$

related to the value of K_p for the following reaction at the same temperature?

$$H_2O(g) + \frac{1}{2} N_2(g) \rightleftharpoons H_2(g) + NO(g)$$

Manipulating Equilibrium Constant Expressions

Concept Review

Explain why representing the same reaction with different chemical equations, like this:

(1) $N_2(g) + 2\ O_2(g) \rightleftharpoons 2\ NO_2(g)$ K_1

(2) $\frac{1}{2} N_2(g) + O_2(g) \rightleftharpoons NO_2(g)$ K_2

results in different equilibrium constant values [i.e., $K_1 Z K_2$].

The reversible reaction $X(g)\ +\ Y(g) \rightleftharpoons Z(g)$ occurs in two reversible steps:

(1) $X(g) + Y(g) \rightleftharpoons Q(g) + R(g)$

(2) $Q(g) + R(g) \rightleftharpoons Z(g)$

How is the equilibrium constant for the overall reaction related to K_1 and K_2?

The thermal decomposition of NO_2 can be written as

(1) $2\ NO_2(g) \rightleftharpoons 2\ NO(g) + O_2(g)$

or it can be written as

$$(2) \qquad NO_2(g) \rightleftharpoons NO(g) + \tfrac{1}{2}O_2(g)$$

How is the value of K_2 related to the value of K_1?

How is the value of the equilibrium constant K_p for the reaction

$2\ H_2O(g) + N_2(g) \rightleftharpoons 2\ H_2(g) + 2\ NO(g)$

related to the value of K_p for the following reaction at the same temperature?

$$H_2O(g) + \tfrac{1}{2}N_2(g) \rightleftharpoons H_2(g) + NO(g)$$

Problems

If $K_c = 3.0 \times 10^{-4}$ at 298 K for

$2\ NOBr(g) \rightleftharpoons 2\ NO(g) + Br_2(g)$

what is the value of K_c at 298 K for the following reaction?

$$NOBr(g) \rightleftharpoons NO(g) + \tfrac{1}{2}Br_2(g)$$

Producing Ammonia At 450°C, $K_p = 4.5 \times 10^{-5}$ for the formation of ammonia:

$N_2(g) + 3\ H_2(g) \rightleftharpoons 2\ NH_3(g)$

What is the value of K_p at 450°C for the following reaction?

$2\ NH_3(g) \rightleftharpoons N_2(g) + 3\ H_2(g)$

At a particular temperature, $K_c = 2.4 \times 10^{-3}$ for the reaction

$2\ SO_2(g) + O_2(g) \rightleftharpoons 2\ SO_3(g)$

What is the value of the equilibrium constant K_c for each of the following reactions at the same temperature?

a. $SO_2(g) + \frac{1}{2}O_2(g) \rightleftharpoons SO_3(g)$
b. $2\ SO_3(g) \rightleftharpoons 2\ SO_2(g) + O_2(g)$
c. $SO_3(g) \rightleftharpoons SO_2(g) + \frac{1}{2}O_2(g)$

If the equilibrium constant K_c for the reaction

$2\ NO(g) + O_2(g) \rightleftharpoons 2\ NO_2(g)$

is 5×10^{12} at a given temperature, what is the value of the equilibrium constant K_c for each of the following reactions at the same temperature?

a. $NO(g) + \frac{1}{2}O_2(g) \rightleftharpoons NO_2(g)$
b. $2\ NO_2(g) \rightleftharpoons 2\ NO(g) + O_2(g)$
c. $NO_2(g) \rightleftharpoons NO(g) + \frac{1}{2}O_2(g)$

Calculate the value of the equilibrium constant K_p at 298 K for the reaction

$N_2(g) + 2\ O_2(g) \rightleftharpoons 2\ NO_2(g)$

from the following K_p values at 298 K:

$N_2(g) + O_2(g) \rightleftharpoons 2\ NO(g) \qquad K_p = 4.4 \times 40^{-31}$
$2\ NO(g) + O_2(g) \rightleftharpoons 2\ NO_2(g) \qquad K_p = 2.4 \times 40^{12}$

Calculate the value of the equilibrium constant K_p at 298 K for the reaction $\frac{1}{4}S_8(s) + 3\ O_2(g) \rightleftharpoons 2\ SO_3(g)$

from the following K_p values at 298 K:

$\frac{1}{8}\,S_8(g) + O_2(g) \rightleftharpoons SO_2(g)$	$K_p = 4.0 \times 10^{52}$
$2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g)$	$K_p = 7.8 \times 10^{24}$

Equilibrium Constants and Reaction Quotients

Concept Review

How is an equilibrium constant different from a reaction quotient?

Explain how comparing the values of reaction quotient Q and equilibrium constant K for a given reaction and temperature enables chemists to predict whether a reversible reaction will proceed in the forward direction, in the reverse direction, or in neither direction.

Problems

If $K_c = 22$ for the hypothetical reaction $A(g) \rightleftharpoons B(g)$ at a given temperature, and if $[A] = 0.10\ M$ and $[B] = 2.0\ M$ in a reaction mixture at that temperature, is the reaction at chemical equilibrium? If not, in which direction will the reaction proceed to reach equilibrium?

The equilibrium constant K_c for the hypothetical reaction

$2\,C(g) \rightleftharpoons D(g) + E(g)$

is 3×10^{-3}. If the composition of the reaction mixture is $[C] = [D] = [E] = 5 \times 10^{-4} M$, in which direction will the reaction proceed to reach equilibrium?

If $K_c = 1.5 \times 10^{-3}$ for the reaction

$N_2(g) + O_2(g) \rightleftharpoons 2\,NO(g)$

in which direction will the reaction proceed if the partial pressures of the three gases are all 1.00×10^{-3} atm?

At 650 K, $K_p = 4.3 \times 10^{-4}$ for the ammonia synthesis reaction:

$N_2(g) + 3\ H_2(g) \rightleftharpoons 2\ NH_3(g)$

If a vessel at 650 K contains a reaction mixture in which $[N_2] = 0.010\ M$, $[H_2] = 0.030\ M$, and $[NH_3] = 0.00020\ M$, will more ammonia form?

Use the information below to determine whether a reaction mixture in which the partial pressures of PCl_3, Cl_2, and PCl_5 are 0.20, 0.40, and 0.60 atm, respectively, is at equilibrium at 450 K. $PCl_3(g) + Cl_2(g) \rightleftharpoons PCl_5(g) \qquad K_p = 3.8$ at 450 K

If the reaction mixture is *not* at equilibrium, in which direction does the reaction proceed to achieve equilibrium?

If enough PCl_3 were injected into the reaction mixture in Problem 14.61 to double its partial pressure, would the mixture be closer to equilibrium? Explain why or why not.

Heterogeneous Equilibria

Concept Review

Write the K_c expression for the oxidation of calcium sulfite to gypsum (calcium sulfate):

$2\ CaSO_3(s) + O_2(g) \rightleftharpoons 2\ CaSO_4(s)$

Plaster of Paris The mineral gypsum, a hydrated form of calcium sulfate, is used to make casts for broken limbs. Gypsum can be converted to anhydrite ($CaSO_4$) by heating. Write the K_c and K_p expressions for the conversion reaction:

$CaSO_4 \cdot 2\ H_2O(s) \overset{\text{energy}}{\rightleftharpoons} CaSO_4(s) + 2\ H_2O(g)$

The brown residues that form on the surfaces of plumbing fixtures, such as inside toilet tanks, are the result of the oxidation of more soluble iron(II) compounds with dissolved oxygen, forming less soluble iron(III) compounds. Write the K_c expression for one such reaction:

$$4\ Fe(OH)_2(aq) + O_2(aq) + 2\ H_2O(\ell) \rightleftharpoons 4\ Fe(OH)_3(s)$$

Testing Minerals Write the K_c expression for this reaction, which is used to test whether a white, shiny mineral is marble (calcium carbonate):

$$2\ HCl(aq) + CaCO_3(s) \rightleftharpoons CaCl_2(aq) + H_2O(\ell) + CO_2(g)$$

Carbon Capture A process for removing CO_2 from the atmosphere is based on converting CO_2 to carbonate and then precipitating it as calcium carbonate. The following equilibria are relevant to this process:

$$CO_2(g) + 2\ OH^-(aq) \rightleftharpoons CO_3^{2-}(aq) + H_2O(\ell)$$

$$Ca(OH)_2(aq) + CO_3^{2-}(aq) \rightleftharpoons CaCO_3(s) + 2\ OH^-(aq)$$

Write K_c expressions for these equilibria and for the overall reaction of CO_2 with calcium hydroxide.

The calcium carbonate produced in the process described in Problem 14.67 is heated to a temperature at which it thermally decomposed:

$$CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$$

and the products are collected and stored. The CaO that is produced is mixed with room-temperature water to regenerate calcium hydroxide:

$$CaO(s) + H_2O(\ell) \rightleftharpoons Ca(OH)_2(aq)$$

The equilibrium constant for the second equilibrium is very large. Does this mean that the equilibrium constant for the overall reaction:

$$CaCO_3(s) + H_2O(\ell) \rightleftharpoons Ca(OH)_2(aq) + CO_2(g)$$

is also very large at room temperature? Explain why or why not.

Le Châtelier’s Principle

Concept Review

Does adding reactants to a system at equilibrium increase the value of the equilibrium constant? Why or why not?

Increasing the concentration of a reactant shifts the position of chemical equilibrium toward formation of more products. What effect does adding a reactant have on the rates of the forward and reverse reactions?

Carbon Monoxide Poisoning Patients suffering from carbon monoxide poisoning are treated with pure oxygen to remove CO from the hemoglobin (Hb) in their blood. The two relevant equilibria are

$Hb(aq) + 4\ CO(g) \rightleftharpoons Hb(CO)_4(aq)$

$Hb(aq) + 4\ O_2(g) \rightleftharpoons Hb(O_2)_4(aq)$

The value of the equilibrium constant for CO binding to Hb is greater than that for O_2. How, then, does this treatment work?

Is the equilibrium constant K_p for the reaction:

$2\ NO_2(g) \rightleftharpoons N_2O_4(g)$

in air the same in Los Angeles as in Denver if the atmospheric pressure in Denver is lower but the temperature is the same? Explain your answer.

Henry’s law predicts that the solubility of a gas in a liquid increases with its partial pressure. Explain Henry’s law in relation to Le Châtelier’s principle.

Why does adding an inert gas such as argon to an equilibrium mixture of CO, O_2, and CO_2 in a sealed vessel increase the total pressure of the system but not shift the following equilibrium?

$2\,CO(g) + O_2(g) \rightleftharpoons 2\,CO_2(g)$

Problems

Which of the following equilibria will shift toward formation of more products if an equilibrium mixture is compressed into half its volume?

1. $2\,N_2O(g) \rightleftharpoons 2\,N_2(g) + O_2(g)$
2. $2\,CO(g) + O_2(g) \rightleftharpoons 2\,CO_2(g)$
3. $N_2(g) + O_2(g) \rightleftharpoons 2\,NO(g)$
4. $2\,NO(g) + O_2(g) \rightleftharpoons 2\,NO_2(g)$

Which of the following equilibria will shift toward formation of more products if the volume of a reaction mixture at equilibrium increases by a factor of 2?

1. $2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g)$
2. $NO(g) + O_3(g) \rightleftharpoons NO_2(g) + O_2(g)$
3. $2\,N_2O_5(g) \rightleftharpoons 4\,NO_2(g) + O_2(g)$
4. $N_2O_4(g) \rightleftharpoons 2\,NO_2(g)$

How will the changes listed affect the equilibrium concentrations of reactants and products in the following reaction?

$2\,O_3(g) \rightleftharpoons 3\,O_2(g)$

1. O_3 is added to the system.
2. O_2 is added to the system.
3. The mixture is compressed to one-tenth its initial volume.

How will the changes listed affect the position of the following equilibrium?

$2\ NO_2(g) \rightleftharpoons NO(g) + NO_3(g)$

1. The concentration of NO is increased.
2. The concentration of NO_2 is increased.
3. The volume of the system expands to 5 times its initial value.

How will reducing the partial pressure of O_2 affect the position of the equilibrium in the following reaction?

$2\ SO_2(g) + O_2(g) \rightleftharpoons 2\ SO_3(g)$

Ammonia is added to a gaseous reaction mixture containing H_2, Cl_2, and HCl that is at chemical equilibrium. How will the addition of ammonia affect the relative concentrations of H_2, Cl_2, and HCl if the equilibrium constant of reaction 2 is much greater than the equilibrium constant of reaction 1?

(1) $H_2(g) + Cl_2(g) \rightleftharpoons 2\ HCl(g)$

(2) $HCl(g) + NH_3(g) \rightleftharpoons NH_4Cl(s)$

In which of the following equilibria does an increase in temperature produce a shift toward the formation of more product?

a. $PCl_3(g) + Cl_2(g) \rightleftharpoons PCl_5(g) \quad \Delta H^\circ < 0$
b. $CH_4(g) + H_2O(g) \rightleftharpoons CO(g) + 3\ H_2(g) \quad \Delta H^\circ > 0$
c. $CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g) \quad \Delta H^\circ < 0$

In which of the following equilibria does an increase in temperature produce a shift toward the formation of more product?

a. $N_2(g) + 3\ H_2(g) \rightleftharpoons 2\ NH_3(g) \quad \Delta H^\circ < 0$
b. $2\ NO_2(g) \rightleftharpoons 2\ NO(g) + O_2(g) \quad \Delta H^\circ > 0$
c. $C_2H_4(g) + H_2(g) \rightleftharpoons C_2H_6(g) \quad \Delta H^\circ < 0$

Calculations Based on K

Concept Review

Why are calculations based on *K* often simpler when the value of *K* is very small?

The following reaction is carried out in a sealed, rigid vessel at constant temperature.

$2\ NO(g) + O_2(g) \rightarrow 2\ NO_2(g)$

1. If the change in the partial pressure of O_2 is $-x$, what are the changes in the partial pressures of NO and NO_2?
2. As the reaction proceeds, what happens to the total pressure in the reaction vessel?

Problems

For the reaction $PCl_5(g) \rightleftharpoons PCl_3(g) + Cl_2(g) \qquad K_p = 23.6 \text{ at } 500\text{ K}$

1. Calculate the equilibrium partial pressures of the reactants and products at 500 K if the initial pressures are $P_{PCl5} = 0.560$ and $P_{PCl3} = 0.500$ atm.
2. If more chlorine is added after equilibrium is reached, how will the concentrations of PCl_5 and PCl_3 change?

Enough NO_2 gas is injected into a cylindrical vessel to produce a partial pressure, P_{NO2}, of 0.900 atm at 298 K. Calculate the equilibrium partial pressures of NO_2 and N_2O_4, given $2\ NO_2(g) \rightleftharpoons N_2O_4(g) \qquad K_p = 4 \text{ at } 298\text{ K}$

At 25°C, $K_c = 0.0900$ for the reaction between water vapor and dichlorine monoxide:

$H_2O(g) + Cl_2O(g) \rightleftharpoons 2\ HOCl(g)$

Determine the equilibrium concentrations of all three compounds at 25°C if the starting concentrations of both reactants are 0.00432 *M* and no HOCl is present.

At 648 K, $K_p = 4.3 \times 10^{-4}$ for the reaction

$3\ H_2(g) + N_2(g) \rightleftharpoons 2\ NH_3(g)$

Determine the equilibrium partial pressure of NH_3 in a reaction vessel that initially contained 0.900 atm N_2 and 0.500 atm H_2 at 648 K.

At 25°C, $K_p = 1.5 \times 10^{6}$ for the reaction

$$NO(g) + \tfrac{1}{2}\,O_2(g) \rightleftharpoons NO_2(g)$$

At equilibrium, what is the ratio of P_{O_2} to P_{NO} in air at 25°C? Assume that $P_{O_2} = 0.21$ and does not change.

The Water–Gas Reaction Passing steam over hot carbon produces a mixture of carbon monoxide and hydrogen known as water gas:

$H_2O(g) + C(s) \rightleftharpoons CO(g) + H_2(g)$

The value of K_c for the reaction at 1000°C is 3.0×10^{-2}.

1. Calculate the equilibrium partial pressures of the products and reactants at 1000°C if $P_{H_2O} = 0.442$ and $P_{CO} = 5.0$ atm at the start of the reaction. Assume that the carbon is in excess.
2. Determine the equilibrium partial pressures of the reactants and products after enough CO and H_2 are added to the equilibrium mixture in part (a) to initially increase the partial pressures of both gases by 0.075 atm.

At 700°C, $K_p = 1.5$ for the reaction

$CO_2(g) + C(s) \rightleftharpoons 2\ CO(g)$

Calculate the equilibrium partial pressures of CO and CO_2 at 700°C if initially $P_{CO2} = 5.0$ atm and CO is not present. Pure graphite is present initially and when equilibrium is achieved.

Composition of Jupiter's Atmosphere Ammonium hydrogen sulfide (NH_4SH) has been detected in the atmosphere of Jupiter. The equilibrium between ammonia, hydrogen sulfide, and NH_4SH is described by the following equation:

$NH_4SH(s) \rightleftharpoons NH_3(g) + H_2S(g)$

The value of K_p for the reaction at 24°C is 0.126. Suppose a sealed flask contains an equilibrium mixture of NH_4SH, NH_3, and H_2S at 24°C. At equilibrium, the partial pressure of H_2S is 0.355 atm. What is the partial pressure of NH_3?

A flask containing pure NO_2 was heated to 1000 K, a temperature at which $K_p = 158$ for the decomposition of NO_2:

$2\ NO_2(g) \rightleftharpoons 2\ NO(g) + O_2(g)$

The partial pressure of O_2 at equilibrium is 0.136 atm.

1. Calculate the partial pressures of NO and NO_2.
2. Calculate the total pressure in the flask at equilibrium.

At 830°C, $K_p = 7.69$ for the reaction

$2\ SO_3(g) \rightleftharpoons 2\ SO_2(g) + O_2(g)$

If a vessel at this temperature initially contains pure SO_3 and if the partial pressure of SO_3 at equilibrium is 0.100 atm, what is the partial pressure of O_2 in the flask at equilibrium?

NO_x Pollution In a study of the formation of NO_x in air pollution, a chamber heated to 2200°C was filled with air (0.79 atm N_2, 0.21 atm O_2). What are the equilibrium partial pressures of N_2, O_2, and NO if $K_p = 0.050$ for the following reaction at 2200°C?

$N_2(g) + O_2(g) \rightleftharpoons 2\ NO(g)$

At 450°C, $K_p = 6.5 \times 10^{-6}$ for the thermal decomposition of NO_2:

$2\ NO_2(g) \rightleftharpoons 2\ NO(g) + O_2(g)$

If a reaction vessel at this temperature initially contains only 0.500 atm NO_2, what will be the partial pressures of NO_2, NO, and O_2 in the vessel when equilibrium has been attained?

At 1400 K, $K_c = 2.2 \times 10^{-4}$ for the thermal decomposition of hydrogen sulfide:

$2\ H_2S(g) \rightleftharpoons 2\ H_2(g) + S_2(g)$

A sample of gas in which $[H_2S] = 6.00\ M$ is heated to 1400 K in a sealed high-pressure vessel. After chemical equilibrium has been achieved, what is the value of $[H_2S]$? Assume that no H_2 or S_2 was present in the original sample.

Urban Air On a very smoggy day, the equilibrium concentration of NO_2 in the air over an urban area reaches $2.2 \times 10^{-7} M$. If the temperature of the air is 25°C, what is the concentration of the dimer N_2O_4 in the air?

$$N_2O_4(g) \rightleftharpoons 2\ NO_2(g) \qquad K_c = 6.1 \times 10^{-3}$$

Chemical Weapon Phosgene ($COCl_2$) gained notoriety as a chemical weapon in World War I. Phosgene is produced by the reaction of carbon monoxide with chlorine:

$CO(g) + Cl_2(g) \rightleftharpoons COCl_2(g)$

If $K_c = 5.0$ at 600 K for this reaction, what are the equilibrium partial pressures of the three gases if a reaction vessel initially contains a mixture of the reactants in which $P_{CO} = P_{Cl2} = 0.265$ atm and there is no $COCl_2$?

At 2000°C, $K_c = 1.0$ for the reaction

$2\ CO(g) + O_2(g) \rightleftharpoons 2\ CO_2(g)$

What is the ratio of [CO] to $[CO_2]$ at 2000°C in an atmosphere in which $[O_2] = 0.0045\ M$ at equilibrium?

The water–gas shift reaction is an important source of hydrogen:

$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$

If $K_c = 5.1$ for this reaction at 700 K, calculate the equilibrium concentrations of the four gases at 700 K if the initial concentration of each of them is 0.050 *M*.

Sulfur dioxide reacts with NO_2, forming SO_3 and NO:

$SO_2(g) + NO_2(g) \rightleftharpoons SO_3(g) + NO(g)$

If $K_c = 2.50$ for the reaction at a given temperature, what are the equilibrium concentrations of the products when the reaction mixture was initially 0.50 *M* SO_2, 0.50 *M* NO_2, 0.0050 *M* SO_3, and 0.0050 *M* NO?

Additional Problems

CO as a Fuel Is carbon dioxide a viable source of the fuel CO? Pure carbon dioxide ($P_{CO2} = 1$ atm) decomposes at high temperatures. For the system

$2\ CO_2(g) \rightleftharpoons 2\ CO(g) + O_2(g)$

the percentage of decomposition of $CO_2(g)$ changes with temperature as follows:

Temperature (K)	Decomposition (%)
1500	0.048

[illegible]			
[illegible]			

Is the reaction endothermic? Calculate the value of K_p at each temperature and discuss the results. Is the decomposition of CO_2 an antidote for global warming?

Ammonia decomposes at high temperatures. In an experiment to explore this behavior, 2.00 moles of gaseous NH_3 is sealed in a rigid 1 liter vessel. The vessel is heated at 800 K and some of the NH_3 decomposes according to the following reaction:

$$2\ NH_3(g) \rightleftharpoons N_2(g) + 3\ H_2(g)$$

The system eventually reaches equilibrium and is found to contain 1.74 moles of NH_3. What are the values of K_p and K_c for the decomposition reaction at 800 K?

Elements of group 16 form hydrides with the generic formula H_2X. At a certain temperature, when gaseous H_2X is bubbled through a solution containing 0.3 *M* hydrochloric acid, the solution becomes saturated and $[H_2X] = 0.1\ M$. The following equilibria exist in this solution:

$$H_2X(aq) + H_2O(\ell) \rightleftharpoons HX^-(aq) + H_3O^+(aq) \qquad K_1 = 8.3 \times 10^{-8}$$

$$HX^-(aq) + H_2O(\ell) \rightleftharpoons X^{2-}(aq) + H_3O^+(aq) \qquad K_2 = 1 \times 10^{-14}$$

Calculate the concentration of X^{2-} in the solution.

Nitrogen dioxide reacts with SO_2 to form NO and SO_3:

$$NO_2(g) + SO_2(g) \rightleftharpoons NO(g) + SO_3(g)$$

An equilibrium mixture is analyzed at a certain temperature and found to contain $[NO_2] = 0.100\ M$, $[SO_2] = 0.300\ M$, $[NO] = 2.00\ M$, and $[SO_3] = 0.600\ M$. At the same temperature, extra $SO_2(g)$ is added to make $[SO_2] = 0.800\ M$. Calculate the composition of the mixture when equilibrium has been reestablished.

Controlling Air Pollution Calcium oxide is used to remove the pollutant SO_2 from smokestack gases. The overall reaction is $CaO(s) + SO_2(g) + \frac{1}{2} O_2(g) \rightleftharpoons CaSO_4(s)$

and $K_p = 2.38 \times 10^{73}$.

1. What is P_{SO_2} in equilibrium with air and solid CaO if P_{O_2} in air is 0.21 atm?
2. Consider a sample of gas that contains 100.0 moles of gas. How many molecules of SO_2 are in that sample?

A 100 mL reaction vessel initially contains 2.60×10^{-2} mol of NO and 1.30×10^{-2} mol of H_2. At equilibrium, the concentration of NO in the vessel is 0.161 *M*. The vessel also contains N_2, H_2O, and H_2 at equilibrium. What is the value of the equilibrium constant K_c for the following reaction?

$2\ H_2(g) + 2\ NO(g) \rightleftharpoons 2\ H_2O(g) + N_2(g)$

Thermal decomposition of the mineral dolomite (a mixture of calcium and magnesium carbonates) is described by the following equations:

$CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$

$MgCO_3(s) \rightleftharpoons MgO(s) + CO_2(g)$

1. Write K_p expressions for both reactions.
2. Write a chemical equation and K_p expression describing the decomposition of a sample of dolomite that contains 75% $CaCO_3$ and 25% $MgCO_3$ by mass.
3. Why is essentially all the $MgCO_3$ and $CaCO_3$ in a dolomite sample converted to the corresponding oxides when heated in an open container but not necessarily in a closed container?
4. Would the K_p values for these reactions depend on the volume of a closed reaction vessel?

Scrubbing Sulfur Dioxide from Power Plants Sulfur dioxide in the smokestack gases of power plants can be reduced by passing the gases through a spray of pulverized limestone ($CaCO_3$) suspended in water:

$$CaCO_3(s) + SO_2(g) \rightleftharpoons CaSO_3(s) + CO_2(g)$$

1. Are the values of K_p and K_c the same for this reaction?
2. The efficiency of scrubbing (the rate of SO_2 removal) increases with decreasing $CaCO_3$ particle size. Does this affect the value of K_p for the reaction?
3. Write a balanced chemical equation for the SO_2 sequestration reaction when a slurry of solid $Ca(OH)_2$ is used instead of $CaCO_3$.
4. Calcium hydroxide also has the capacity to remove CO_2 from stack gases, producing $CaCO_3$. Write a chemical equation describing the overall reaction for the removal of both SO_2 and CO_2.
5. How is the K_p value for the overall reaction related to the K_p values of the single-gas reactions?

Glossary

law of mass action

the principle relating the balanced chemical equation of a reversible reaction to its mass action expression (or equilibrium constant expression).

mass action expression

an expression equivalent in form to the equilibrium constant expression but applied to reaction mixtures that may or may not be at equilibrium.

equilibrium constant expression

the ratio of the concentrations or partial pressures of products to reactants at equilibrium, with each term raised to a power equal to the coefficient of that substance in the balanced chemical equation for the reaction.

equilibrium constant

the ratio of the concentrations or partial pressures of products to reactants at equilibrium, with each term raised to a power equal to the coefficient of that substance in the balanced chemical equation for the reaction.

reaction quotient (Q)

the numerical value of the mass action expression based on the concentrations or partial pressures of the reactants and products present at any time during a reaction; at equilibrium, $Q = K$.

Le Châtelier’s principle

the principle that a system at equilibrium responds to a stress in such a way that it relieves that stress.

Acid–Base Equilibria Proton Transfer in Biological Systems

PARTICULATE REVIEW

Donating H^+ Ions

In this chapter we use the principles of chemical equilibrium from Chapter 14 to explore the structure and properties of acids and bases. Consider these models of four molecules that each contain at least one hydrogen atom.

- Which molecules produce H^+ ions when dissolved in water? Identify the acidic hydrogen atoms.
- Which molecule dissociates completely in water, meaning that each molecule in a sample produces a H^+ ion?
- Which molecule partially dissociates in water, meaning that only a small fraction of molecules in solution releases H^+ ions, whereas most do not?

(Review Section 4.5 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Accepting H^+ Ions

Bases form covalent bonds as they accept H^+ ions donated by acids. As you read Chapter 15, look for ideas that will help you answer these questions:

- Which of the three species depicted form covalent bonds as they accept H^+ ions?
- When each species accepts a proton, does it produce a cation? An anion? A neutral molecule?
- What feature do these particles have in common to form bonds to H^+ ions?

Learning Outcomes

- LO1 Relate the strengths of acids and bases to their concentrations and to their K_a and K_b values

  Sample Exercise 15.1

- LO2 Relate the strengths of acids and bases to their molecular structures

  Sample Exercise 15.2

- LO3 Recognize conjugate acid–base pairs, and predict their formulas and complementary acidic and basic strengths

  Sample Exercises 15.3, 15.4

- LO4 Interconvert $[H_3O^+]$, $[OH^-]$, pH, and pOH

Sample Exercises 15.5, 15.6, 15.7

- LO5 Relate the pH of solutions of weak acids and bases to their percent ionization and to their K_a and K_b values

  Sample Exercises 15.8, 15.9

- LO6 Calculate the pH of solutions of strong and weak acids and bases

  Sample Exercises 15.10, 15.11, 15.12, 15.13

- LO7 Calculate the pH of solutions of polyprotic acids

  Sample Exercises 15.14, 15.15

- LO8 Predict whether a salt is acidic, basic, or neutral, and calculate the pH of a salt solution

  Sample Exercises 15.16, 15.17, 15.18

$$CO_2(g) + H_2O(\ell) \rightleftharpoons H_2CO_3(aq) \qquad (15.1)$$

$$H_2CO_3(aq) + H_2O(\ell) \rightleftharpoons HCO_3^-(aq) + H_3O^+(aq) \qquad (15.2)$$

15.1 Acids and Bases: A Balancing Act

The pink and blue colors of the hydrangea blossoms in the chapter-opening photograph are produced by the same species of plant grown in the same garden, but in soils having slightly different composition. The colors of hydrangea blossoms are controlled by the availability of aluminum ions (Al^{3+}) in the soil in which they grow. Aluminum ions are soluble in acidic soils, and hydrangeas grown in acidic soils form blue blossoms. In soils that are neutral or slightly basic, however, aluminum ions precipitate as aluminum hydroxide [$Al(OH)_3$] and are unavailable. As a result, hydrangea blossoms grown in those soils lack blue pigment and are pink.

For many biological systems, including the human body, acid–base balance is vital to normal function and good health. Our blood, for example, is normally slightly basic, regulated by the proportions of CO_2 gas and bicarbonate (HCO_3^-) ions dissolved in it. This regulation happens because of the following reversible chemical reactions:

Note how molecules of CO_2 and H_2O combine, forming molecules of carbonic acid (H_2CO_3), which react with more water molecules, donating H^+ ions to them and forming bicarbonate and hydronium (H_3O^+) ions.

CONNECTION When describing aqueous solutions, the terms *hydrogen ion*, *proton*, and *hydronium ion* all refer to the same species (Section 4.5). Thus, the symbols H^+ and $H^+(aq)$ are simply abbreviated forms of H_3O^+.

Compounds that produce hydronium ions when dissolved in water are acids, whereas compounds that produce hydroxide ions (OH^-)

in aqueous solution are bases. More precisely, such compounds are referred to respectively as Arrhenius acids and Arrhenius bases in honor of Svante Arrhenius, whose research on the behavior of electrolytic solutions was recognized with the 1903 Nobel Prize in Chemistry.

In Section 4.5 we introduced the *Brønsted–Lowry* model of acids and bases, in which acids are defined as substances that *donate* H^+ ions, and bases are defined as substances that *accept* H^+ ions. We also learned in Chapter 4 that acids and bases are classified as strong or weak, depending on the degree to which their molecules either donate or accept electrons. Here in Section 15.1 we use the concept of chemical equilibrium to further explore what it means to be a weak or strong acid or base.

If the concentration of H_2CO_3 in Equation 15.2 increases, then Le Châtelier's principle predicts that the concentration of H_3O^+ ions in a solution that contains carbonic acid and bicarbonate ions will increase (as will the acidity of the solution). The equilibrium described in Equation 15.1 indicates, moreover, that the concentration of H_2CO_3 increases when the concentration of dissolved CO_2 increases. Therefore, an increase in the concentration of dissolved CO_2 shifts the equilibria in *both* Equations 15.1 and 15.2 to the right, increasing the concentration of H_3O^+ ions and making the solution more acidic. On the other hand, Le Châtelier's principle also predicts that an increase in the concentration of HCO_3^- ions shifts both equilibria to the left, decreasing the concentration of H_3O^+ ions and reducing the acidity of the solution.

CONNECTION In Section 4.5 we learned that the greater the concentration of H_3O^+ ions in a solution, the more acidic the solution.

The equilibria in Equations 15.1 and 15.2 play a key role in human health. Normally, the concentration of HCO_3^- ions in our blood is about 20 times the dissolved concentration of CO_2 because the dissociation of carbonic acid is not our blood's only source of HCO_3^-. The abundance of HCO_3^- ions drives down the concentration of H_3O^+ ions in our blood below 10^{-7} M. As we discuss later in this chapter, a $[H_3O^+]$ value this small means that our blood is slightly basic.

Unfortunately, some people suffer from medical problems that alter the normal balance of CO_2 and HCO_3^- in their blood. For example, chronic lung disease impairs not only a patient's ability to inhale O_2 but also the ability to exhale CO_2. As a result, CO_2 builds up in the blood and in the tissues where it is produced. The result is a condition called *respiratory acidosis*. Its symptoms include fatigue, lethargy, and shortness of breath. In severe cases, the condition can be fatal.

CONCEPT TEST

When people hyperventilate, they breathe too rapidly. Hyperventilation results in carbon dioxide being removed from the bloodstream more quickly than the body produces it through metabolism. What effect does this have on the equilibria in Equations 15.1 and 15.2?

(Answers to Concept Tests are in the back of the book.)

In this chapter we examine acid–base balance, both in environmental samples and in our bodies. We study why changes in this balance occur, some of the consequences of these changes, and what we can do to control them.

Glossary

Arrhenius acid	a compound that produces H_3O^+ ions in aqueous solution
Arrhenius base	a compound that produces OH^- ions in aqueous solution

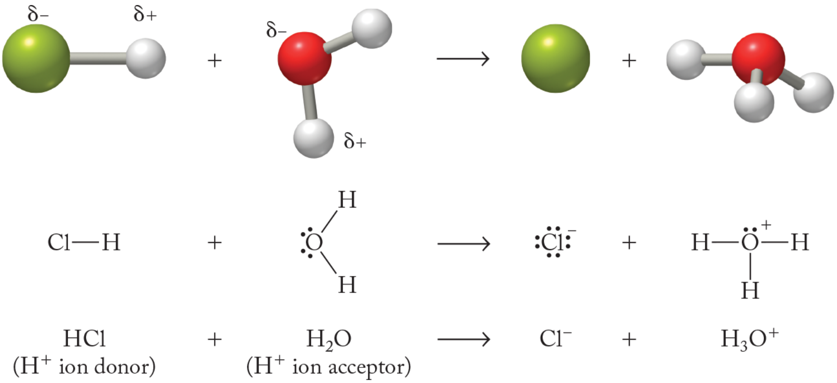

FIGURE 15.1 When hydrogen chloride dissolves in water, each molecule of HCl ionizes by reacting with a molecule of H_2O, forming Cl^- and H_3O^+ ions.

$$K_a = \frac{[H_3O^+][CH_3COO^-]}{[CH_3COOH]}$$

$$HNO_3(aq) + H_2O(\ell) \rightarrow NO_3^-(aq) + H_3O^+(aq) \qquad (15.3)$$

$$HNO_2(aq) + H_2O(\ell) \rightleftharpoons NO_2^-(aq) + H_3O^+(aq) \qquad (15.4)$$

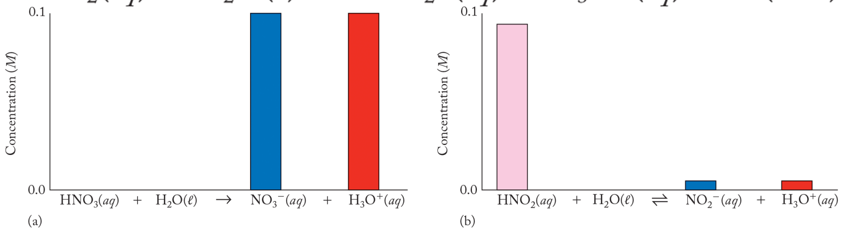

FIGURE 15.2 Degrees of ionization of a strong acid versus a weak acid. (a) The strong acid HNO_3 is ionized completely, existing only as H_3O^+ and NO_3^- ions. (b) The weak acid HNO_2 ionizes very little. [*Note*: Although $H_2O(\ell)$ is part of the balanced chemical equation in both (a) and (b), the amount is quite large relative to the other species and has been omitted from these graphs.]

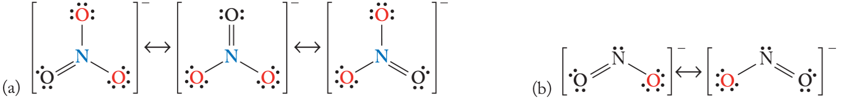

FIGURE 15.3 Nitric acid (HNO_3) is a stronger acid than nitrous acid (HNO_2) in part because more resonance structures more effectively delocalize the negative charge on a nitrate ion shown in (a)

compared to a nitrite ion shown in (b). This delocalization leads to greater chemical stability and promotes the acid ionization reaction in which molecules of HNO_3 donate H^+ ions and form NO_3^- ions.

Acid	Resonance Structures of Oxoanion	K_a
Hypochlorous HClO		2.9×10^{-8}
Chlorous $HClO_2$		1.1×10^{-2}
Chloric $HClO_3$		· 1
Perchloric $HClO_4$		Strong acid

FIGURE 15.4 In the oxoacids of chlorine, acid strength increases with increasing number of O atoms bonded to the Cl atom and the greater ability of the oxoanions they form to delocalize their negative charge.

Acid	Structure	Electronegativity of Halogen Atom	K_a
Hypochlorous HClO		3.0	2.9×10^{-8}
Hypobromous HBrO		2.8	2.3×10^{-9}
Hypoiodous HIO		2.5	2.3×10^{-11}

FIGURE 15.5 The strengths of these three hypohalous acids increase with the increasing electronegativities of their halogen atoms. Thus, the relative acidities are HClO > HBrO > HIO.

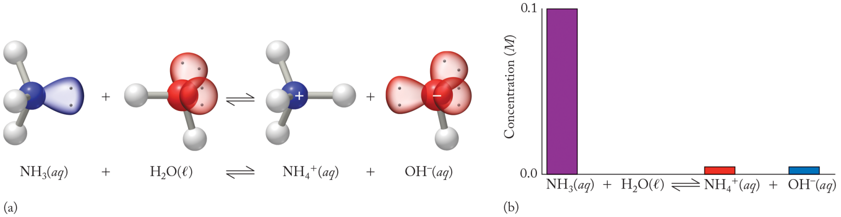

FIGURE 15.6 (a) Molecules of ammonia can react with molecules of water, producing NH_4^+ and OH^- ions. (b) In a 0.1 *M* solution, ammonia exists mostly as molecules of NH_3 in equilibrium with much smaller concentrations of NH_4^+ and OH^- ions.

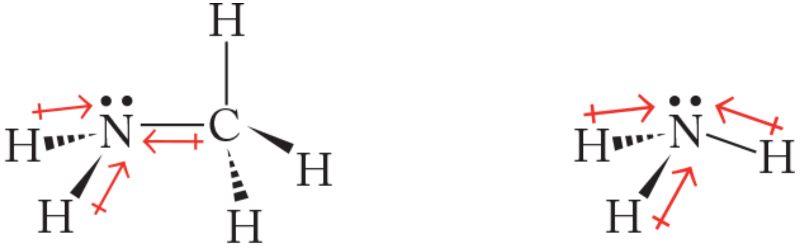
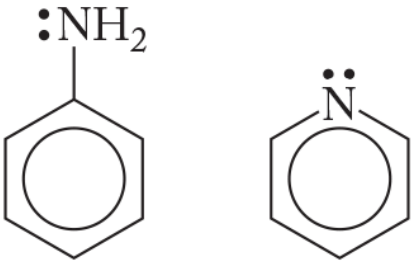


(a) Methylamine (b) Ammonia



(c) Aniline Pyridine

FIGURE 15.7 (a) The greater number of valence electrons in the methyl group of a molecule of CH_3NH_2 produces a greater density of electrons that are drawn toward its N atom as compared to the electron density in a molecule of NH_3 (b), which makes methylamine a stronger base than ammonia. The electron density surrounding the N atoms in the aromatic compounds (c) aniline and pyridine is much less than that around the N atom in ammonia, because the electrons are delocalized around the aromatic rings.

15.2 The Molecular Structures and Strengths of Acids and Bases

In this section we explore how and why molecules of acids dissociate when they dissolve in water, producing hydrogen ions and anions with $1-$ charges. We also examine why the molecules of a few of these compounds completely ionize in this way, making them strong acids, whereas those of many others only partially ionize, making them weak acids. Later in the section we examine the capacity of molecules of basic compounds to accept hydrogen ions, and we compare their strengths as bases to their molecular structures. We start by taking a molecular view of the process of acid ionization in aqueous solutions.

Strong and Weak Acids

To understand why molecules of acidic substances ionize when they dissolve in water, we need to consider the structures of their molecules and the nature and strength of the intermolecular forces they experience. The molecular structures of the common strong acids are shown in **Table 15.1**. The H atoms that can be released as H^+ ions are highlighted in red. In each of these strong acids one or more hydrogen atoms is bonded to the atom of an electronegative element: O, Cl, Br, or I. The bonds that these pairs of atoms form are polar covalent, which results in strong dipole–dipole interactions between the H atoms in these bonds and the O atoms of H_2O molecules. In aqueous solutions of HCl, for example, the strength of these dipole–dipole interactions results in every H—Cl bond breaking in such a way that the bonding pair of electrons moves to the Cl atom, forming a Cl^- ion. The H^+ ion that is simultaneously produced is drawn to the water molecule's O atom, where it uses one of the lone pairs of electrons on O to form a covalent bond. The product of this union is an H_3O^+ ion as shown in **Figure 15.1**.

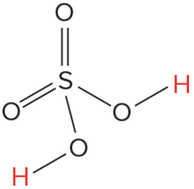
CONNECTIONElectronegativity was introduced in Section 8.3 and intermolecular forces were described in Chapter 10.

As with gas-phase equilibria (Chapter 14), the extent to which an acid ionization reaction takes place is reflected in the value of its equilibrium constant, *K*: the greater the value of *K*, the higher the concentrations of products and the lower the concentrations of reactants at equilibrium. The equilibrium constants that describe acid ionization reactions are given the symbol K_a, where the subscript “a” indicates that the equilibrium involves ionization of an *a*cid.

Table 15.2 shows the molecular structures of a few of the many compounds that are weak acids and lists their K_a values at 25°C. All these values are much smaller than 1, which means that only a fraction of their molecules donate H^+ ions in most aqueous solutions. Let’s write the equilibrium constant expressions for the first acid in the table—acetic acid—following the same process used in Chapter 14 for gas-phase reactions. The numerator contains concentration terms for the products each raised to a power equal to its coefficient in the acid ionization reaction (both are one), and the denominator contains the concentration value of the reactant: un-ionized acetic acid. Its coefficient is also one.

TABLE 15.1 Strong Acids and Their Ionization Reactions in Water

Strong Acid	Molecular Structure	Reaction with Water
Hydrobromic		$HBr(aq) + H_2O(\ell) \rightarrow Br^-(aq) + H_3O^+(aq)$
Hydrochloric		$HCl(aq) + H_2O(\ell) \rightarrow Cl^-(aq) + H_3O^+(aq)$
Hydroiodic		$HI(aq) + H_2O(\ell) \rightarrow I^-(aq) + H_3O^+(aq)$
Nitric		$HNO_3(aq) + H_2O(\ell) \rightarrow NO_3^-(aq) + H_3O^+(aq)$
Perchloric		$HClO_4(aq) + H_2O(\ell) \rightarrow ClO_4^-(aq) + H_3O^+(aq)$
Sulfuric		$H_2SO_4(aq) + H_2O(\ell) \rightarrow HSO_4^-(aq) + H_3O^+(aq)$ $HSO_4^-(aq) + H_2O(\ell) \rightleftharpoons SO_4^{2-}(aq) + H_3O^+(aq)$



Note that the K_a expression does not contain a term for the concentration of water, even though molecules of H_2O reacted to form H_3O^+ ions. The reason for this is that ionization reactions such as this one consume an insignificant fraction of the water molecules present in most aqueous solutions.

TABLE 15.2 Some Common Weak Acids and Their Ionization Reactions in Water

Weak Acid	Molecular Structure	Reaction in Water	K_a
Acetic		$CH_3COOH(aq) + H_2O(\ell) \rightleftharpoons CH_3COO^-(aq) + H_3O^+(aq)$	1.76×10^{-5}
Formic		$HCOOH(aq) + H_2O(\ell) \rightleftharpoons HCOO^-(aq) + H_3O^+(aq)$	1.77×10^{-4}
Hydrofluoric		$HF(aq) + H_2O(\ell) \rightleftharpoons F^-(aq) + H_3O^+(aq)$	6.8×10^{-4}
Hypochlorous		$HClO(aq) + H_2O(\ell) \rightleftharpoons ClO^-(aq) + H_3O^+(aq)$	2.9×10^{-8}
Nitrous		$HNO_2(aq) + H_2O(\ell) \rightleftharpoons NO_2^-(aq) + H_3O^+(aq)$	4.0×10^{-4}

SAMPLE EXERCISE 15.1 Relating K_a and Acid Strength LO1

Suppose 0.100 *M* aqueous solutions of each of the acids in Table 15.2 are prepared. Rank them from most acidic to least acidic.

Collect, Organize, and Analyze The acidity of an aqueous solution is proportional to the concentration of H_3O^+ ions in it. The larger the value of K_a, the greater the concentration of H_3O^+ ions produced by a given concentration of acid.

Solve Ranking the acids in order of decreasing K_a values, we have:

hydrofluoric acid > nitrous acid > formic acid > acetic acid > hypochlorous acid.

Think About It It makes sense that concentrations of H_3O^+ ions in the samples should be proportional to the K_a values of the acids because larger K_a values mean larger numerator values of the acids' K_a expressions (assuming the denominators of these 0.100 *M* solutions were essentially the same), and the numerators contain the $[H_3O^+]$ terms.

Practice Exercise Rank the weak acids in the table shown here in order of decreasing acid strength.

Weak Acid	K_a
HN_3	1.9×10^{-5}
$CH_2BrCOOH$	2.0×10^{-3}
$HClO_2$	1.1×10^{-2}
Lactic	1.4×10^{-4}
C_6H_5COOH	6.5×10^{-5}

(Answers to Practice Exercises are in the back of the book.)

Now let's compare the molecular formulas and structures of nitric acid (HNO_3), a strong acid from Table 15.1, and nitrous acid (HNO_2), a weak acid from Table 15.2. The bar graphs in **Figure 15.2** show the degree to which 0.1 *M* solutions of these two acids ionize when they dissolve in water. Molecules of HNO_3 ionize completely, each one donates a H^+ ion to a molecule of H_2O as all the HNO_3 molecules become $NO_3{}^-$ ions:

On the other hand, only a small fraction of the molecules of HNO_2 ionize (Figure 15.2b) as described by the following chemical equation:

At equilibrium, molecules of HNO_2 donate H^+ ions to molecules of

H_2O at the same rate that H_3O^+ ions donate H^+ ions to nitrite (NO_2^-) ions, reforming HNO_2 and H_2O.

Why do these two acids, with such similar formulas and molecular structures, have such different acid strengths? The key is in the number of O atoms bonded to their central N atoms. Recall from Section 8.3 (see Figure 8.9) that oxygen is the second-most-electronegative element (after fluorine). This means that oxygen atoms bonded to the central atoms in molecules of oxoacids attract electron density toward themselves and away from the H atoms in the molecules' O—H groups. This allows these H atoms to interact more strongly with the O atoms in molecules of H_2O.

In addition, the presence of more O atoms in an oxoacid allows the negative charge of the oxoanion it forms when it ionizes to be spread out (or *delocalized*) over a greater number of O atoms, as shown by the resonance structures in **Figure 15.3**. Single-bonded O atoms (highlighted in red) have formal charges of -1. The three resonance structures of the nitrate ions (Figure 15.3a) each have two single-bonded O atoms and a central N atom (highlighted in blue) with a formal charge of $+1$, for a net ionic charge of $1-$. Thus, the nitrate ion has *three* ways to distribute its charge. The nitrite ion, on the other hand, has only *two* (Figure 15.3b). Greater delocalization of the charge on a nitrate ion helps make nitric acid stronger than nitrous acid.

In a similar fashion, SO_4^{2-} ions are more stable than SO_3^{2-} ions, helping to make H_2SO_4 a stronger acid than H_2SO_3. This trend of increasing acid strength with increasing numbers of oxygen atoms bonded to the central atom (i.e., with increasing oxidation number of the central atom) is true for all groups of oxoacids with the same central atom, as illustrated by the strengths of the oxoacids of chlorine (**Figure 15.4**).

CONNECTION Introduced in Section 4.8, oxidation numbers are positive or negative numbers assigned to an atom based on the number of electrons that it gains or loses when it forms an ion or that it shares when it forms covalent bonds with the atoms of other elements.

The strength of an oxoacid is also related to the electron-withdrawing power of the central atom. Consider, for example, the relative strengths of the three hypohalous acids in **Figure 15.5**. The most electronegative of the three halogen atoms (Cl) has the greatest attraction for the pair of electrons it shares with oxygen. This attraction helps draw electron density toward chlorine and away from the hydrogen end of the already polar O—H bond. These greater shifts in electron density also mean that the negative charge on a hypochlorite (ClO^-) ion is more delocalized than on other hypohalite ions. Thus, hypochlorous acid [$HClO(aq)$] is the strongest of the three acids, followed by hypobromous acid [$HBrO(aq)$] and then hypoiodous acid [$HIO(aq)$].

CONNECTION Figure 8.9 depicts the electronegativities of the elements.

Acid Strength and Molecular Structure

SAMPLE EXERCISE 15.2 Ranking Oxoacid Strength LO2

Rank the following compounds in order of decreasing acid strength: phosphoric acid (H_3PO_4), arsenic acid (H_3AsO_4), and antimonic acid (H_3SbO_4).

Collect and Organize Each of these oxoacids contains a different group 15 element. In each acid, this central atom is bonded to the same number of O atoms and has the same oxidation number ($+5$). The electronegativities of these elements decrease with increasing atomic number and row number.

Analyze In oxoacids, more electronegative central atoms draw electron density away from the H ends of the O—H bonds and help disperse the negative charges that form when oxoacids release H^+ ions to form oxoanions.

Solve Ranking the oxoacids in order of decreasing acid strength is a matter of ranking them in order of decreasing electronegativity of the central atom—that is, in order of increasing atomic number (and row number) in the periodic table: $H_3PO_4 > H_3AsO_4 >$

H_3SbO_4.

Think About It The trend of decreasing oxoacid strength with increasing atomic number (decreasing electronegativity) of their central atoms is confirmed by the K_a values of these acids as each of their molecules loses one H^+ ion, that is, $K_{a,H3PO4} = 6.9 \times 10^{-3}$; $K_{a,H3AsO4} = 5.5 \times 10^{-3}$; $K_{a,H3SbO4} = 1.9 \times 10^{-3}$.

Practice Exercise Of the following acids, which is the strongest and which is the weakest? Sulfuric acid (H_2SO_4), sulfurous acid (H_2SO_3), and selenous acid (H_2SeO_3)

Strong and Weak Bases

Most strong bases are not molecular compounds, but rather are the soluble hydroxides of the group 1 and 2 elements. **Table 15.3** lists the ions present when these ionic compounds completely dissociate as they dissolve in water. Note that a mole of a group 1 hydroxide such as NaOH produces 1 mole of OH^- ions, but a mole of a group 2 hydroxide such as $Ba(OH)_2$ produces 2 moles of OH^- ions. Their complete dissociation makes these hydroxides strong bases because OH^- ions are the strongest H^+ ion acceptors that can exist in aqueous solutions. We explore why this is true in Section 15.4.

TABLE 15.3 Strong Bases and Their Dissociation in Water

Strong Base	Ions in Aqueous Solutions
Lithium hydroxide	$Li^+(aq) + OH^-(aq)$
Sodium hydroxide	$Na^+(aq) + OH^-(aq)$
Potassium hydroxide	$K^+(aq) + OH^-(aq)$
Calcium hydroxide	$Ca^{2+}(aq) + 2OH^-(aq)$
Barium hydroxide	$Ba^{2+}(aq) + 2OH^-(aq)$
Strontium hydroxide	$Sr^{2+}(aq) + 2OH^-(aq)$

TABLE 15.4 Some Common Weak Bases and Their Ionization

Reactions in Water

Weak Base	K_b	Reaction in Water
Ammonia	1.8×10^{-5}	$NH_3(aq) + H_2O(\ell) \rightleftharpoons NH_4^+(aq) + OH^-(aq)$
Aniline	4.0×10^{-10}	$C_6H_5NH_2(aq) + H_2O(\ell) \rightleftharpoons C_6H_5NH_3^+(aq) + OH^-(aq)$
Dimethylamine	5.9×10^{-4}	$(CH_3)_2NH(aq) + H_2O(\ell) \rightleftharpoons (CH_3)_2NH_2^+(aq) + OH^-(aq)$
Methylamine	4.4×10^{-4}	$CH_3NH_2(aq) + H_2O(\ell) \rightleftharpoons CH_3NH_2^+(aq) + OH^-(aq)$
Pyridine	1.7×10^{-9}	$C_5H_5N(aq) + H_2O(\ell) \rightleftharpoons C_5H_5NH^+(aq) + OH^-(aq)$

Molecular bases such as those listed in **Table 15.4** are weakly basic. To understand how they function as bases, let's focus on what happens when a 0.1 *M* solution of ammonia is prepared. Collisions between water and ammonia molecules sometimes result in the transfer of a proton from a water molecule (functioning as a Brønsted–Lowry acid) to an ammonia molecule (a Brønsted–Lowry base). The transferred proton bonds to the lone pair on the nitrogen atom, producing NH_4^+ and OH^- ions as shown in **Figure 15.6a**. Many other weak bases also contain nitrogen atoms with lone pairs of electrons that can use these electrons to form covalent bonds with H^+ ions (see Table A5.3 in Appendix 5).

Only a small fraction of the ammonia molecules in a 0.1 *M* solution react with molecules of water, as shown by the bar graph in **Figure 15.6b**. This tells us that the equilibrium constant for the reaction between NH_3 and H_2O, which has the symbol K_b to indicate that it is an ionization reaction involving a basic compound and water, must be very small. In fact, it is only 1.76×10^{-5} at 25°C.

The other nitrogen-containing bases in Table 15.4 have K_b values that are either an order of magnitude or more greater than that of ammonia (methylamine and dimethylamine) or several orders of magnitude less (aniline and pyridine). As with the strengths of acids, differences in base strength are related to molecular structures. Molecules of methylamine and dimethylamine resemble molecules of ammonia in which methyl groups have replaced one or two of the H atoms in NH_3. These replacements mean there are more valence electrons in the two amines than in ammonia, and these electrons are in polar covalent bonds whose electrons are drawn to the electronegative N atoms of the amines (**Figure 15.7**).

This shift means there is more electron density surrounding the N atoms, which enhances the strength of their interactions with the H atoms of water molecules, which makes them better H^+ ion acceptors and, therefore, stronger bases.

There are many more valence electrons in aniline and pyridine, compared to ammonia, but these electrons are *not* drawn to the N atoms in these molecules. Why? One reason is that both aniline and pyridine are aromatic compounds (Figure 15.7c), which means they have six-atom rings of highly delocalized π electrons. The enhanced stability of these delocalized electrons draws electron density away from the N atoms and into the rings.

15.3 Conjugate Pairs and Their Complementary Strengths as Acids and Bases

In this section we explore the relationship between acidic compounds and the anions they form when they undergo acid ionization. If these ionization reactions are reversible, then the anions must have the capacity to accept H^+ ions as they reform the parent acid. In other words, the anions are bases!

Recognizing Conjugate Pairs

Let's revisit the nitrous acid equilibrium in Equation 15.4. In the forward direction, HNO_2 functions as a Brønsted–Lowry acid by donating H^+ ions to molecules of H_2O (**Figure 15.8a**). In the reverse reaction, NO_2^- ions accept H^+ ions and function as a Brønsted–Lowry base. Structurally, the difference between HNO_2 and NO_2^- is the H^+ ion that a molecule of HNO_2 donates, resulting in the formation of a NO_2^- ion, and that a NO_2^- ion accepts in the reverse reaction to reform a molecule of HNO_2. An acid and a base that are related in this way are called a conjugate acid–base pair, or *conjugate pair.* An acid forms its conjugate base when it donates a H^+ ion, and a base forms its conjugate acid when it accepts a H^+ ion.

Figure 15.8b depicts the base ammonia and its conjugate acid. As we saw in Figure 15.6, when ammonia is added to water, some molecules of NH_3 accept H^+ ions from molecules of H_2O. In this way NH_3 functions as a Brønsted–Lowry base. In the reverse reaction, NH_4^+ ions donate H^+ ions and function as Brønsted–Lowry acids. Because the structure of NH_3 molecules and the structure of NH_4^+ ions differ only by the H^+ ion that a molecule of NH_3 accepts and that an NH_4^+ ion donates, NH_3 and NH_4^+ are also a conjugate acid–base pair.

Now let's consider the acid–base behavior of the water molecules in the reactions in Figure 15.8. H_2O functions as a *base* in the nitrous acid reaction, accepting a H^+ ion and forming its conjugate acid, H_3O^+. This behavior makes H_2O and H_3O^+ a conjugate pair. In the ammonia reaction, however, H_2O functions as an *acid* by donating a H^+ ion to form its conjugate base, the OH^- ion. These two reactions illustrate that water can act as an acid or a base, depending on the acid–base properties of the substance dissolved in it. We revisit this acid–base duality of water in Section 15.4.

The following generic chemical equations summarize the relationships between conjugate pairs in aqueous solutions.

$$\text{Acid}(aq) + H_2O(\ell) \rightleftharpoons \text{conjugate base}(aq) + H_3O^+(aq)$$

$$\text{Base}(aq) + H_2O(\ell) \rightleftharpoons \text{conjugate acid}(aq) + OH^-(aq)$$

The difference within each conjugate acid–base pair is the H^+ ion that the acid donates to form its conjugate base and that the base accepts to form its conjugate acid.

SAMPLE EXERCISE 15.3 Identifying a Conjugate Acid–Base Pair LO3

Identify the conjugate acid–base pair in the ionization reactions that occur when (a) perchloric acid ($HClO_4$) and (b) formic acid (HCOOH) dissolve in water.

Collect, Organize, and Analyze Brønsted–Lowry acids form their conjugate bases when they donate H^+ ions to molecules of H_2O. Therefore, the formulas of their conjugate bases are the formulas of the original acids, minus a H^+ ion.

Solve (a) Perchloric acid ($HClO_4$) has only one H atom per molecule, which must be the one that it loses as a H^+ ion:

(b) Formic acid (HCOOH) has two H atoms per molecule, but only the one bonded to an O atom in the carboxylic acid group (see Table 15.2) is ionizable in water:

In both reactions, H_3O^+ and H_2O are also a conjugate acid–base pair: H_2O is the base and H_3O^+ is its conjugate acid.

Think About It The formulas of the two conjugate bases make sense because each has one fewer H atom than the parent acid molecule and each is an anion with a 1− charge. These properties are consistent with an acid molecule losing one H^+ ion.

Practice Exercise Identify the conjugate acid–base pairs in the reaction that occurs when acetic acid (CH_3COOH) dissolves in water.

Relative Strengths of Conjugate Acids and Bases

HCl is a strong acid (see Table 15.1), and like $HClO_4$ in Sample Exercise 15.3, its acid ionization reaction goes to completion:

As a result, the reverse reaction essentially does not happen at all, which means that the Cl^- ion (the conjugate base of HCl) must be a very weak base. This contrast in relative strengths applies to all conjugate pairs: strong acids have very weak conjugate bases and strong bases have very weak conjugate acids, as shown in **Figure 15.9**.

Between these extremes exist many weak acids with weak conjugate bases. For example, HNO_2 is a weak acid ($K_a = 4.0 \times 10^{-4}$), which means that its conjugate base, NO_2^-, is a weak base. This pairing of weak acids and weak bases applies to most of the conjugate acids and bases that occur in nature and in ourselves.

All the strong acids in Figure 15.9 ionize completely in water; that is, every molecule transfers one H^+ ion to a molecule of H_2O. In this context, water is said to *level* the strengths of these acids; they all are equally strong in water because they cannot be more than 100% ionized. This leveling effect means that H_3O^+, the conjugate acid of H_2O, is the strongest acid that can exist in water. An acid that is stronger than H_3O^+ simply donates all its ionizable H atoms to water molecules, forming H_3O^+ ions, when it dissolves in water. On the other hand, weak acids are differentiated by the fact that only a small fraction of the molecules donate their ionizable H atoms to water molecules. The weak acids higher on the list in Figure 15.9 form more acidic aqueous solutions than do acids lower on the list because the larger the K_a, the greater the fraction of molecules that dissociate at a given concentration.

A similar leveling effect exists for strong bases. The strongest base that can exist in water is the OH^- ion, the conjugate base of H_2O. Any base that is stronger than OH^- hydrolyzes in water to produce OH^- ions. The oxide ion (O^{2-}), for example, is a very strong base, and it reacts with water to produce two OH^- ions:

$$O^{2-}(aq) + H_2O(\ell) \rightarrow 2\ OH^-(aq)$$

The strengths of bases weaker than OH^- ions can be differentiated by the fraction of their molecules that accept H^+ ions from water molecules in aqueous solutions. Weaker bases are higher on the list in Figure 15.9; stronger bases are lower on the list.

SAMPLE EXERCISE 15.4 Relating the Strengths of a Conjugate Pair LO3

List the following anions in order of decreasing strength as Brønsted–Lowry bases: F^-, Cl^-, OH^-, $HCOO^-$, and $NO_2{}^-$.

Collect, Organize, and Analyze All five anions are listed among the bases in Figure 15.9. Therefore, all we must do is rank them according to their location in the figure: the strongest one will be the closest to the bottom and the weakest will be the closest to the top.

Solve The anions in decreasing order of strength as bases (H^+ ion acceptors) are OH^-, $HCOO^-$, $NO_2{}^-$, F^-, and Cl^-.

Think About It According to Figure 15.9, we have also sorted the anions in *increasing* order for the strength of their conjugate acids. The complementary sorting makes sense because the stronger the acid, the weaker its conjugate base, and vice versa.

Practice Exercise List the following anions in order of decreasing strength as Brønsted–Lowry bases: Br^-, S^{2-}, ClO^-, CH_3COO^-, and HSO_3^-.

Glossary

conjugate acid–base pair

a Brønsted–Lowry acid and base that differ from each other only by a H^1 ion: acid 4 conjugate base + $H1$.

conjugate base

the base formed when a Brønsted–Lowry acid donates a H^1 ion.

conjugate acid

the acid formed when a Brønsted–Lowry base accepts a H^1 ion.

leveling effect

the observation that all strong acids have the same strength in water and are completely converted into solutions of H_3O^1 ions; strong bases are likewise leveled in water and are completely converted into solutions of OH2 ions.

$$= 4.74 \qquad = 3.36$$

15.4 pH and the Autoionization of Water

The acidity of an aqueous solution is directly related to its concentration of H_3O^+ ions. In Section 15.4 we examine another way to quantify acidity. To understand this alternative approach, we begin with the autoionization of water, which is the process that can happen when two water molecules collide to produce equal and very small concentrations of H_3O^+ and OH^- ions in pure water:

One water molecule, acting as an acid, donates a H^+ ion to another water molecule that functions as a base (**Figure 15.10**). The donor H_2O molecule forms its conjugate base (OH^-), and the acceptor H_2O molecule forms its conjugate acid (H_3O^+). We have already encountered this dual nature of water: molecules of H_2O act as H^+ ion acceptors in solutions of acidic solutes and as H^+ ion donors in solutions of basic solutes. The autoionization of water is an example of amphiprotic behavior.

CONNECTION *Amphiprotic* compounds (Section 4.5) can behave as either a proton acceptor (a Brønsted–Lowry base) or a proton donor (a Brønsted–Lowry acid).

The equilibrium constant expression for the autoionization of water might be written

Water is a pure liquid, however, so we do not include its concentration in equilibrium constant expressions. This reduces Equation 15.7 to an equilibrium constant expression that is given the symbol K_w:

In pure water at 25°C $[H_3O^+] = [OH^-] = 1.0 \times 10^{-7}$ *M*. Inserting these values into Equation 15.8 gives us

This tiny K_w value confirms that only a very small fraction of water molecules undergoes autoionization at room temperature. The reverse of autoionization—the reaction between $[H_3O^+]$ and $[OH^-]$ to produce H_2O—has an equilibrium constant of $1/K_w = 1.0 \times 10^{14}$ at 25°C and essentially goes to completion:

Equation 15.8 means that an inverse relationship exists between $[H_3O^+]$ and $[OH^-]$ in any aqueous sample—namely, as the concentration of one increases, the concentration of the other must decrease so that the product of the two is always 1.0×10^{-14}. A solution in which $[H_3O^+] > [OH^-]$ is acidic, a solution in which $[H_3O^+] < [OH^-]$ is basic, and a solution in which $[H_3O^+] = [OH^-] = 1.0 \times 10^{-7}$ *M* is neutral (neither acidic nor basic).

The tiny value of K_w means that autoionization of water does not contribute significantly to $[H_3O^+]$ in solutions of most acids or to $[OH^-]$ in solutions of most bases, so we can ignore the contribution of autoionization in most calculations of acid or base strength. If acids or bases are extremely weak, however, or if their concentrations are extremely low, then H_2O autoionization may need to be considered.

The pH Scale

pH Scale

In the early 1900s scientists developed a device called the *hydrogen electrode* to determine the concentrations of hydronium ions in solutions. The electrical voltage, or *potential*, produced by the hydrogen electrode is a linear function of the logarithm of $[H_3O^+]$. This relationship led Danish biochemist Søren Sørensen (1868–1939) to propose a scale for expressing acidity based on what he termed "the potential of the hydrogen ion," abbreviated pH. Mathematically, we define pH as the base-10 negative logarithm of $[H_3O^+]$:

For example, the pH of a solution in which $[H_3O^+] = 5.0 \times 10^{-3}$ *M* is

$$\text{pH} = -\log(5.0 \times 10^{-3}) = -(-2.30) = 2.30$$

Sørensen's pH scale has several attractive features. Because it is logarithmic, there are no exponents, as are commonly encountered in values of $[H_3O^+]$. The logarithmic scale also means that a change of one pH unit corresponds to a 10-fold change in $[H_3O^+]$, so that a solution with a pH of 5.0 has 10 times the concentration of H_3O^+ ions and is 10 times as acidic as a solution with a pH of 6.0. Similarly, the concentration of H_3O^+ ions in a solution with a pH of 12.0 is 1/10 that of a solution with a pH of 11.0. Conversely, the concentration of OH^- ions in a solution with a pH of 12.0 is 10 times that of a solution with a pH of 11.0.

The negative sign in front of the logarithmic term in Equation 15.10 means that pH values of most aqueous solutions, except for very concentrated solutions of strong acids or bases, are positive numbers between 0 and 14. It also means that *large* pH values correspond to *small* values of $[H_3O^+]$. Acidic solutions have pH values less than 7.00 ($[H_3O^+] > 1.0 \times 10^{-7}$ *M*), and basic solutions have pH values greater than 7.00 ($[H_3O^+] < 1.0 \times 10^{-7}$ *M*). A solution with a pH of exactly 7.00 is neutral. The pH values for some common aqueous solutions are shown in **Figure 15.11**.

CONCEPT TEST

Match the pH values on the left with the descriptors on the right.

13.77	strongly acidic
10.02	weakly acidic
7.00	weakly basic
4.37	strongly basic
0.22	neutral

SAMPLE EXERCISE 15.5 Relating pH and [H_3O^+] LO4

Suppose the pH of solution A is 8.0 and the pH of solution B is 4.0. Which of the following statements about the two solutions are true and which are false?

1. Solution A is 2 times as acidic as solution B.
2. Solution B is 10,000 times as acidic as solution A.
3. The concentration of OH^- ions in solution A is half their concentration in solution B.
4. The values of [OH^-] and [H_3O^+] are closer to each other in solution A than in solution B.

Collect, Organize, and Analyze The pH scale is logarithmic, so a decrease (or increase) of one pH unit corresponds to a 10-fold increase (or a 90% decrease) in [H_3O^+]. The negative sign in the pH formula ($\text{pH} = -\log[H_3O^+]$) means that a higher pH value corresponds to a (much) lower [H_3O^+].

Solve

1. False, because pH is a log scale, and because higher pH values mean lower [H_3O^+].
2. True; a decrease of 4 pH units corresponds to a 10^4 increase in [H_3O^+] and acidity.
3. False, because pH is a log scale. Actually, [OH^-] in solution A is 10^4 times that of solution B.
4. True, because a pH of 8.0 is only one unit away from the pH (7.0) where $[H_3O^+] = [OH^-]$, so $[OH^-] = 10 \times [H_3O^+]$ in solution A. A pH of 4.0 is 3 units below 7.0, so $[H_3O^+] = 1000 \times [OH^-]$ in solution B.

Think About It There are two key aspects of the equation pH =

$-\log[H_3O^+]$ that affect which of the four statements are true: (1) the negative sign means that the higher the pH of a solution, the lower its $[H_3O^+]$; (2) the log scale means that a decrease in pH of one unit corresponds to a 10-fold increase in $[H_3O^+]$.

Practice Exercise Which of the following changes in pH corresponds to the greatest percent increase in $[H_3O^+]$? Which change corresponds to the greatest percent decrease in $[H_3O^+]$? (a) pH 1 → pH 3; (b) pH 7 → pH 4; (c) pH 12 → pH 14; (d) pH 5 → pH 9; (e) pH 2 → pH 0

When we convert $[H_3O^+]$ to pH values and pH values to $[H_3O^+]$, we need to express the resulting values with the appropriate number of significant digits. Because a pH value is the negative logarithm of a hydronium ion concentration, the digit or digits before the decimal point in the pH value define the location of the decimal point in the $[H_3O^+]$ value. They do *not* define how precisely we know the concentration value, so they are not considered significant digits. For example, $[H_3O^+] = 2.7 \times 10^{-4}$ has two significant digits: the 2 and 7. The corresponding pH value should also have two significant digits, but those two should come after the decimal point, which means the pH value is 3.57, not 3.6. The 3 in pH 3.57 is not a significant digit because it serves only to indicate that the corresponding $[H_3O^+]$ value falls between 10^{-3} and 10^{-4} *M*.

CONNECTION The general rules for the use of significant figures in calculations involving measured quantities are explained in Section 1.10.

SAMPLE EXERCISE 15.6 Converting $[H_3O^+]$ to pH and pH to $[H_3O^+]$ LO4

Cells located in the upper region of the human stomach called the *fundus* secrete gastric acid (about 0.16 *M* HCl) during digestion. After this acid mixes with the food being digested, the pH of the contents of the stomach is often between 3 and 5.

1. How much more acidic is 0.16 *M* HCl than stomach contents with a pH of 3.20?
2. Which of the two samples in part (a) has the lower $[H_3O^+]$?

Collect and Organize We are asked to compare the acidities (the ratio of the $[H_3O^+]$ values) of two solutions that both contain hydrochloric acid. We know the pH of one and the HCl concentration of the other. We must also determine which sample has the lower $[H_3O^+]$.

Analyze Hydrochloric acid is a strong acid that is 100% ionized in aqueous solutions. Therefore, the $[H_3O^+]$ value of a solution of HCl is the same as the concentration of the acid. We can use Equation 15.10 to calculate the pH of 0.16 *M* HCl and to convert pH 3.20 into its corresponding $[H_3O^+]$ value. The result of the second calculation, when divided into 0.16 *M*, will give us the desired ratio of acidities.

Solve

1. To convert pH to $[H_3O^+]$, we need to solve Equation 15.10 for $[H_3O^+]$:

   $$\text{pH} = -\log[H_3O^+]$$

   or,

   $$\log[H_3O^+] = -\text{pH}$$

   Taking the antilog (10^x) of both sides:

   $$[H_3O^+] = 10^{-\text{pH}}$$

   Inserting pH = 3.20:

   $$[H_3O^+] = 10^{-3.20} = 6.3 \times 10^{-4}\ M$$

   Calculating the ratio of acidities ($[H_3O^+]$ values):

$$\frac{[H_3O^+](\text{gastric acid})}{[H_3O^+](\text{stomach contents})} = \frac{0.16\ M}{6.3 \times 10^{-4}\ M} = 2.5 \times 10^2$$

Thus, secreted gastric acid is 2.5×10^2 times more acidic than the digestion mixture in the stomach.

2. Using the values calculated in part (a), the stomach contents have a lower $[H_3O^+]$.

Think About It The results of the two parts to this sample exercise are consistent: 0.16 *M* HCl is 2.5×10^2 times more acidic than the stomach content sample, and its pH is $3.20 - 0.8 = 2.4$ units lower. Note how this seemingly small change in pH corresponds to a more than 200-fold difference in acidity.

Practice Exercise The results of several oceanographic studies indicate that the average pH of Earth's oceans is now 8.07. The hydrogen ion concentration of the oceans at the start of the industrial revolution was 6.61×10^{-9} *M*. How much more acidic is the ocean now than then?

CONCEPT TEST

Is the pH of a 1.00 *M* solution of a weak acid higher or lower than the pH of a 1.00 *M* solution of a strong acid?

pOH, pK_a, and pK_b Values

The letter *p* as used in pH is also used with other symbols to mean *the negative logarithm* of the variable that follows it. For example, just as every aqueous solution has a pH value, it also has a pOH value, defined as

We can use the K_w expression (Equation 15.9) to relate pOH to pH. We start by taking the negative logarithm of both sides of the equation and then rearrange the terms:

Many tables of equilibrium constants list p*K* values rather than *K* values because doing so does not require the use of exponential notation and saves space. The tables in Appendix 5 of this book contain both sets of values. Use them whenever you need a *K* or p*K* value that is not provided in a problem. For example, we can define both pK_a and pK_b values for acetic acid and methylamine, respectively, and for the other acids and bases in Tables 15.2 and 15.4:

SAMPLE EXERCISE 15.7 Interconvert $[H_3O^+]$, $[OH^-]$, pH, and pOH LO4

Digested food travels from your stomach, where the pH is 4.50, and moves to your small intestine, where the pH increases to 7.50. Convert these pH values to pOH, $[H_3O^+]$, and $[OH^-]$ values.

Collect, Organize, and Analyze We are given two pH values, and we want to determine the corresponding pOH, $[H_3O^+]$, and $[OH^-]$ values.

- We can use Equation 15.10 to convert from pH to $[H_3O^+]$, as we did in Sample Exercise 15.6.
- We can use Equation 15.12 to convert from pH to pOH.
- We can use Equation 15.11 to convert from pOH to $[OH^-]$.

The $[H_3O^+]$ value we calculate for pH 4.50 should be 10^3, or 1000, times the $[H_3O^+]$ value we calculate for pH 7.50 (because $7.50 - 4.50 = 3.00$). Correspondingly, the $[OH^-]$ value we calculate for pH 7.50 should be 10^3, or 1000, times the $[OH^-]$ value we calculate for pH 4.50. The inverse relationship between pH and pOH means that the pOH value we calculate for pH 4.50 should be 3 units larger than the one we get for pH 7.50.

Solve

1. Converting pH to $[H_3O^+]$:

$$pH = -\log[H_3O^+] \tag{15.10}$$

or

$$[H_3O^+] = 10^{-pH}$$

Stomach: $[H_3O^+] = 10^{-4.50} = 3.2 \times 10^{-5}\ M$

Small intestine: $[H_3O^+] = 10^{-7.50} = 3.2 \times 10^{-8}\ M$

2. Converting pH to pOH:

$$pH + pOH = 14.00 \tag{15.12}$$

$$pOH = 14.00 - pH$$

Stomach: $pOH = 14.00 - 4.50 = 9.50$

Small intestine: $pOH = 14.00 - 7.50 = 6.50$

3. Converting pOH to $[OH^-]$:

$$pOH = -\log[OH^-] \tag{15.11}$$

or

$$[OH^-] = 10^{-pOH}$$

Stomach: $[OH^-] = 10^{-9.50} = 3.2 \times 10^{-10}\ M$

Small intestine: $[OH^-] = 10^{-6.50} = 3.2 \times 10^{-7}\ M$

Think About It As predicted, the $[H_3O^+]$ in the stomach is 1000 times that of the small intestine. The differences in pOH values are also as predicted, as are the differences in $[OH^-]$. All calculated concentration values were rounded off to two significant digits because each starting pH value had only two digits after the decimal point.

Practice Exercise What are the values of $[H_3O^+]$ and $[OH^-]$ in household ammonia, an aqueous solution of NH_3 that has a pH of 11.70?

Glossary

autoionization	the process that produces equal and very small concentrations of H_3O^1 and OH2 ions in pure water.
pH	the negative logarithm of the hydronium ion concentration in an aqueous solution.
pOH	the negative logarithm of the hydroxide ion concentration in an aqueous solution.

15.5 K_a, K_b, and the Ionization of Weak Acids and Bases

Most of the acids and bases in nature are weak acids and bases. In Sections 15.5 and 15.6 we explore how to quantify the degree to which these molecules react with molecules of water to form either H_3O^+ or OH^- ions.

Weak Acids

Nitrous acid (HNO_2) is a weak acid (see Section 15.2), which means it is only partially ionized when it dissolves in water:

To what degree does this reaction proceed before it reaches equilibrium? We begin by translating Equation 15.4 into an equilibrium constant expression, with products in the numerator and reactants in the denominator:

As noted in Section 15.2, there is no concentration term for water in the denominator because it is the solvent in this reaction and a pure liquid.

We can generalize this K_a expression for the ionization of any weak acid, HA:

The corresponding K_a expression is

Equation 15.14 can be used to calculate the K_a value of an unknown weak acid if we know the concentration of the acid, [HA], in a solution and the pH of the solution. Suppose, for example, we determine that a 0.100 *M* solution of HA has a pH of 2.20. To calculate K_a, we first convert the pH value to $[H_3O^+]$:

$$[H_3O^+] = 10^{-2.20} = 6.3 \times 10^{-3}\,M$$

Next, we assume that the only source of H_3O^+ ions is the ionization of HA. If so, then $[A^-]$ must also be $6.3 \times 10^{-3}\,M$ because each mole of HA that ionizes produces 1 mole of H_3O^+ and 1 mole of A^-. Moreover, if $[H_3O^+]$ increases by $6.3 \times 10^{-3}\,M$, then [HA] must have decreased by $6.3 \times 10^{-3}\,M$. Therefore, the concentration of HA once equilibrium has been achieved is

$$[HA] = (0.100 - 6.3 \times 10^{-3})\,M = 0.094\,M$$

Using the three calculated equilibrium concentrations in the K_a

expression gives us:

The small value of K_a confirms that HA is a weak acid.

The ratio of the equilibrium $[A^-]$ value to the initial [HA] value represents the degree of ionization of HA, which is usually expressed as a percentage of the initial acid concentration. For this reason it is also called *percent ionization*. In equation form, this relationship is

Inserting the data from the previous calculation into Equation 15.15 yields the percent ionization of 0.100 *M* HA:

CONCEPT TEST

Describe how the percent ionization of a weak acid is related to its K_a value.

Now let’s examine how the degree of ionization of a weak acid depends on its concentration in solution. A plot of percent ionization as a function of the initial concentration of nitrous acid at 25°C is shown in **Figure 15.12**. Note that the degree of ionization *increases* as the concentration of the acid *decreases*. This same pattern is observed for all weak acids.

Suppose, for example, we have a 1.0 *M* solution of a generic weak acid, HA, in which the concentrations of A^- and H_3O^+ ions at equilibrium are both 0.0010 *M*. Using these concentrations in Equation 15.14 to solve for K_a, we have:

Now suppose that more water is added to the HA solution, increasing its volume by a factor of 10. If no change in the degree of ionization occurred, then [HA] would be 0.10 *M* and the concentrations of A^- and H_3O^+ ions would both be 1.0×10^{-4} *M*. However, if we insert these values into the equilibrium constant expression, we get a reaction quotient (Q) value of:

This Q value is only 1/10 the value of K_a, so the acid ionization reaction is no longer at equilibrium. Because $Q < K_a$, the reaction proceeds in the forward direction. When this happens, the concentrations of A^- and H_3O^+ ions increase, and so does the percentage of HA molecules that ionize. Further dilutions would produce even greater percent ionization values, following the trend we see for nitrous acid in Figure 15.12.

SAMPLE EXERCISE 15.8 Relating pH, K_a, and Percent Ionization of a Weak Acid LO5

The pH of a 1.00 *M* solution of formic acid (HCOOH) is 1.88.

1. What is the percent ionization of 1.00 *M* HCOOH?
2. What is the K_a value of formic acid?

Collect, Organize, and Analyze We are asked to determine the K_a value of formic acid and its percent ionization in a solution of known concentration and pH. There are two H atoms in a molecule of formic acid, but only one is in a carboxylic acid group and can ionize in an aqueous solution. As a result, the acid ionization reaction is

$$HCOOH(aq) + H_2O(\ell) \rightleftharpoons HCOO^-(aq) + H_3O^+(aq)$$

The 1:1:1 stoichiometry of the ionization reaction indicates that $[HCOO^-] = [H_3O^+]$ in a solution of HCOOH at equilibrium, so using Equation 15.10 (i.e., $pH = -\log[H_3O^+]$) will give us the values of $[H_3O^+]$ and $[HCOO^-]$ at equilibrium and will allow us to calculate the degree of ionization by using Equation 15.15. At equilibrium, [HCOOH] is equal to its initial concentration minus the portion that ionized, or

$$[HCOOH]_{equilibrium} = [HCOOH]_{initial} - [H_3O^+]_{equilibrium}$$

We can then calculate the value of K_a by using the following equilibrium constant expression:

The pH of the 1.00 *M* solution is close to 2, which corresponds to $[H_3O^+] = 10^{-2}\ M$. Therefore, the percent ionization of formic acid in this solution should be about $[(10^{-2}\ M)/(1\ M)](100\%) = 1\%$.

Solve

1. The pH of the 1.00 *M* solution is 1.88. The corresponding $[H_3O^+] = [HCOO^-]$ is

   $$10^{-1.88} = 1.32 \times 10^{-2}\ M$$

   Inserting this value and the initial concentration of HCOOH in Equation 15.15:

   $$\begin{aligned}\text{Percent ionization} &= \frac{[HCOO^-]_{\text{equilibrium}}}{[HCOOH]_{\text{initial}}} \times 100\% \\ &= \frac{1.32 \times 10^{-2}\ M}{1.00\ M} \times 100\% = 1.3\%\end{aligned}$$

---

2. A RICE table can be used to determine the value of K_a, though not quite in the way these tables were used to calculate equilibrium concentrations in Chapter 14. In this exercise we are given $[HCOOH]_{\text{initial}}$ and, before any acid ionization occurs: $[HCOO^-]_{\text{initial}} = [H_3O^+]_{\text{initial}} = 0$. We've already determined the value of $[H_3O^+]$ at equilibrium: $1.32 \times 10^{-2}\ M$. In other words, we have already solved for *x*. The ionization reaction produces equal numbers of moles of H_3O^+ and $HCOO^-$, so $[HCOO^-]$ must also be $1.32 \times 10^{-2}\ M$. Also, *the change* in the concentrations of $HCOO^-$ and H_3O^+ must be $+x$, or $+1.32 \times 10^{-2}\ M$, and the change in [HCOOH] must be $-x$, or $-1.32 \times 10^{-2}\ M$. Filling in the RICE table with these concentration values and calculating $[HCOOH]_{\text{equilibrium}}$:

Reaction	$HCOOH(aq) + H_2O(\ell)$	$H_3O^+(aq)$
	$[HCOOH]\ (M)$	$[H_3O^+]\ (M)$
Initial (I)	1.00	0
Change (C)	-1.32×10^{-2}	
Equilibrium (E)	0.987	1.32×10^{-2}

Inserting the equilibrium concentration values in the K_a expression for HCOOH and doing the math:

Think About It The result of the percent ionization calculation is close to our estimate of about 1%, and the calculated K_a value matches the K_a value for formic acid listed in Table 15.2. In calculating the value of K_a, we used equilibrium concentrations of the products to calculate their change in concentration during the ionization reaction, then reversed the sign on that value to calculate the change in [HCOOH], which was subtracted from $[\text{HCOOH}]_{\text{initial}}$ to calculate $[\text{HCOOH}]_{\text{equilibrium}}$.

Practice Exercise The value of $[H_3O^+]$ in a 0.050 *M* solution of an organic acid is 5.9×10^{-3} *M*. What is the pH of the solution, the percent ionization of the acid, and its K_a value?

CONCEPT TEST

Three weak acids have the following K_a values:

Acid	K_a
A	3.6×10^{-5}
B	1.9×10^{-4}
C	9.2×10^{-4}

Which acid is the most extensively ionized in a 0.10 *M* solution of the acid? Which acid has the lowest percent ionization in a 1.00 *M* solution of the acid?

Weak Bases

Now let's examine the degree of ionization of weakly basic compounds when they dissolve in water. For example, ammonia bonds to hydrogen ions transferred from water:

$NH_3(aq) + H_2O(\ell) \rightleftharpoons NH_4^+(aq) + OH^-(aq)$

The limited strength of ammonia as a base is reflected in its small K_b value at 25°C:

As with K_a expressions, there is no $[H_2O]$ term in this K_b expression because the concentration of water does not change significantly during the reaction.

More generally, the transfer of a proton to any Brønsted–Lowry weak base in aqueous solution can be written as:

$B(aq) + H_2O(\ell) \rightleftharpoons HB^+(aq) + OH^-(aq)$

with a corresponding equilibrium constant expression:

Just as with weak acids, we can calculate the degree of ionization of a weak base and its K_b value if we know the pH and the initial concentration of a solution of the base, $[B]_{initial}$. We first need to convert pH into pOH using Equation 15.12, then pOH into $[OH^-]$ using Equation 15.11, and then, assuming $[OH^-] = [HB^+]$ at equilibrium, use $[HB^+]_{equilibrium}$ to calculate percent ionization:

SAMPLE EXERCISE 15.9 Relating pH, K_b, and Percent Ionization of a Weak Base LO5

Trimethylamine, $(CH_3)_3N$, is a particularly foul-smelling volatile organic compound that forms during the decay of plant and animal matter. Its base ionization reaction in water is

$(CH_3)_3N(aq) + H_2O(\ell) \rightleftharpoons (CH_3)_3NH^+(aq) + OH^-(aq)$

The pH of a 0.500 *M* solution of trimethylamine is 11.75 at 25°C.

1. What is the percent ionization of trimethylamine in a 0.500 *M* solution?
2. What is the K_b value of trimethylamine?

Collect and Organize We are asked to determine the K_b value of trimethylamine and its percent ionization in a solution of known concentration and pH. We can use Equation 15.12 to convert pH into pOH and Equation 15.11 to convert pOH into $[OH^-]$. Equation 15.17 relates percent ionization to the equilibrium concentration of $(CH_3)_3NH^+$ ions and the initial concentration of $(CH_3)_3N$.

Analyze The stoichiometry of the ionization reaction indicates that $[(CH_3)_3NH^+] = [OH^-]$ at equilibrium assuming the initial concentrations of both were essentially zero. After using Equations 15.12 and 15.11 to calculate these conentrations we can use them in a RICE table (see Sample Exercise 15.8) to calculate $[(CH_3)_3N]$ at equilibrium. The equilibrium concentrations of the three reaction components can be used in the K_b expression to calculate the value of K_b. The pH of the 0.500 *M* solution is a little less than 12, which corresponds to a pOH that is a little more than $(14 - 12) = 2$ and a value for $[OH^-]$ that is a little less than 10^{-2} *M*. Therefore, the percent ionization of trimethylamine in this solution should be 1%–2%.

Solve

1. The pH of the 0.500 *M* solution is 11.75. Calculating the corresponding pOH:

   $$\text{pH} + \text{pOH} = 14.00 \qquad \text{or} \qquad \begin{aligned}\text{pOH} &= 14.00 - \text{pH}\\ &= 14.00 - 11.75 = 2.25\end{aligned}$$

   Calculating $[OH^-]$:

   $$[OH^-] = 10^{-\text{pOH}} = 10^{-2.25} = 5.6 \times 10^{-3}\ M$$

   Assuming $[(CH_3)_3NH^+] = [OH^-]$, then the percent ionization of $(CH_3)_3N$ is

   $$\begin{aligned}\text{Percent ionization} &= \frac{[(CH_3)_3NH^+]_{\text{equilibrium}}}{[(CH_3)_3N]_{\text{initial}}} \times 100\%\\ &= \frac{5.6 \times 10^{-3}\ M}{0.500\ M} \times 100\% = 1.1\%\end{aligned}$$

2. Setting up a RICE table based on the base ionization reaction and inserting $[(CH_3)_3NH^+] = [OH^-] = 5.6 \times 10^{-3}\ M$ at equilibrium, we use this value to calculate the changes in concentration of the products and reactant and the equilibrium $[(CH_3)_3N]$ value:

Reaction $(CH_3)_3N(aq)$ $H_2O(\ell)$					
$[(CH_3)_3N]\ (M)$ $[OH^-]\ (M)$					
Initial (I) 0.500					
Change (C) 5.6×10^{-3}					
Equilibrium (E) 0.494 $\times 10^{-3}$					

Inserting these equilibrium concentration values in the K_b expression:

Think About It The result of the percent ionization calculation is in our estimated range of 1%–2%, and the calculated K_b is close to the value listed in Appendix 5: 6.46×10^{-5}. The calculated K_b value was rounded to only 2 significant figures (as was the calculated percent ionization value) because there were only 2 digits to the right of the decimal point in the initial pH value.

Practice Exercise The pH of a 0.100 *M* aqueous solution of ethylamine ($CH_3CH_2NH_2$) is 11.86 at 25°C. What percentage of the $CH_3CH_2NH_2$ molecules in this solution are ionized as described in the chemical equation below, and what is the K_b value of ethylamine?

$$CH_3CH_2NH_2(aq) + H_2O(\ell) \rightleftharpoons CH_3CH_2NH_3^+(aq) + OH^-(aq)$$

Figure 15.13 summarizes the ways we can interconvert $[H_3O^+]$, $[OH^-]$, pH, and pOH. The diagram may leave you wondering which path to follow to make cross-corner (two-step) conversions, such as $[OH^-]$ to pH. Many students find the math simpler if they travel the "northern" route—that is, via a pOH-to-pH conversion.

Glossary

degree of ionization

the ratio of the quantity of a substance that is ionized to the concentration of the substance before ionization; when expressed as a percentage, it is often called *percent ionization*.

Learning Objectives

- Relate the pH of solutions of weak acids and bases to their percent ionization and to their K_a and K_b values **Return to Sample Exercises 15.8, 15.9**
- Relate the pH of solutions of weak acids and bases to their percent ionization and to their K_a and K_b values **Return to Sample Exercises 15.8, 15.9**

15.14 Cleaners used to remove grease and hair clogs from water pipes typically contain large amounts of sodium hydroxide.

Calculating pOH: $\quad \mathrm{pOH} = -\log[\mathrm{OH^-}] = -\log(1.2) = -0.079$

Calculating pH: $\quad \mathrm{pH} = 14.00 - \mathrm{pOH} = 14.00 - (-0.079) = 14.08$

FIGURE 15.15 The carabid beetle secretes formic acid (HCOOH) as a defense against predators.

$$K_a = \frac{[HCOO^-][H_3O^+]}{[HCOOH]} = 1.77 \times 10^{-4}$$

$$K_a = \frac{[HCOO^-][H_3O^+]}{[HCOOH]} = \frac{(x)(x)}{(0.040 - x)} = 1.77 \times 10^{-4}$$

$$K_b = \frac{[NH_4{}^+][OH^-]}{[NH_3]} = \frac{(x)(x)}{3.0} = \frac{x^2}{3.0} = 1.76 \times 10^{-5}$$

$$x = [OH^-] = \sqrt{5.28 \times 10^{-5}} = 7.3 \times 10^{-3}\,M$$

$$\frac{7.3 \times 10^{-3}\,M}{3.0\,M} \times 100\% = 0.24\%$$

15.6 Calculating the pH of Acidic and Basic Solutions

In this section we calculate the pH values of solutions of acids and bases. We begin with solutions of strong acids and strong bases.

Strong Acids and Strong Bases

Strong acids have large K_a values and ionize essentially completely in aqueous solutions. In nearly all their solutions, then, the concentration of H_3O^+ ions is the same as the initial concentration of the strong acid. For example, the pH of muriatic acid (7.4 *M* HCl), which is sold in hardware and building supply stores to clean concrete surfaces, is

$$\text{pH} = -\log[H_3O^+] = -\log(7.4) = -0.87$$

Strong bases are ionic compounds that dissociate completely in aqueous solutions. For a group 1 hydroxide such as NaOH, then, $[OH^-]$ will be the same as the strong base's initial concentration. For a group 2 hydroxide such as $Ca(OH)_2$, $[OH^-]$ will be twice the strong base's initial concentration. To calculate the pH of a solution of a strong base, therefore, we need to calculate the concentration of OH^- ions given the initial concentration of the base and then convert $[OH^-]$ to pOH, and then to pH. Sample Exercise 15.10 illustrates the steps involved.

SAMPLE EXERCISE 15.10 Calculating the pH of a Solution of a Strong Base LO6

Liquids such as the one in the bottle in **Figure 15.14** are used to remove clogs from bathroom and kitchen drains. They contain sodium hydroxide at concentrations as high as 1.2 *M*. What is the pH of 1.2 *M* NaOH?

Collect, Organize, and Analyze NaOH is a strong base that produces 1 mole of hydroxide ions per mole of NaOH in solution, so $[OH^-]$ is the same as the initial concentration of the base. Therefore, $[OH^-] = 1.2\ M$. We can convert this value to pOH and then to pH following the steps shown in Figure 15.13.

Solve

Think About It The calculated pH is slightly above 14 because $[OH^-]$ is slightly greater than 1 *M*.

Practice Exercise *Kalkwasser* is the German word for "lime water," which is the common name for saturated solutions of $Ca(OH)_2$. It has many uses, including being added to water in aquarium tanks to adjust their pH (and to provide Ca^{2+} ions for the plants and animals living in the tank). What is the pH of a Kalkwasser solution whose concentration is 0.0225 *M* $Ca(OH)_2$?

Weak Acids and Weak Bases

In Section 15.5 we learned how pH and concentration can be used to calculate the percent ionization and the K_a or K_b of a weak acid or weak base, respectively. If we know the concentration of a weak acid solution and its K_a value (or a weak base and its K_b value), can we determine the pH of that solution? Sample Exercises 15.11 and 15.12 take us through these calculations.

CONNECTION RICE tables were introduced in Section 14.8 to help us calculate the changes (C) from initial (I) to equilibrium (E) concentrations for a given reaction (R).

SAMPLE EXERCISE 15.11 Calculating the pH of a Solution of a Weak Acid LO6

Most of the acids on our planet and in our bodies are weak acids, including all carboxylic acids. Formic acid (HCOOH) is one of the more common carboxylic acids and the one with the simplest molecular structure. Secretions of the carabid beetle shown in **Figure 15.15** contain 0.040 *M* HCOOH. What is the pH of 0.040 *M* formic acid? The K_a value for formic acid is 1.77×10^{-4}.

Collect and Organize We are asked to determine the pH of a known concentration of a weak acid. We also know its K_a value. The molecular structure of formic acid in Table 15.2 indicates that only one H atom per molecule is ionizable in aqueous solution.

Analyze The acid ionization reaction is

$$HCOOH(aq) + H_2O(\ell) \rightleftharpoons HCOO^-(aq) + H_3O^+(aq)$$

and the corresponding equilibrium constant expression is

Calculating pH involves first solving for $[H_3O^+]$, which we can do by setting up a RICE table based on the above reaction, as we did for several equilibrium calculations in Chapter 14.

Solve First we set up a RICE table based on the acid ionization reaction. The object of the table is to solve for $[H_3O^+]$ at equilibrium, so we give it the symbol x. Filling in the other cells in the table according to the 1:1:1 stoichiometry of the reaction gives us

Reaction (R)	$HCOOH(aq) + H_2O(\ell)$	$H_3O^+(aq)$
	$[HCOOH]$ (M)	$[H_3O^+]$ (M)
Initial (I)	0.040	
Change (C)	$-x$	
Equilibrium (E)	$0.040 - x$	x

Inserting the equilibrium terms into the K_a expression,

Solving for x by first cross multiplying:

$$x^2 = 7.08 \times 10^{-6} - (1.77 \times 10^{-4})x$$

and rearranging the terms:

$$x^2 + (1.77 \times 10^{-4})x - 7.08 \times 10^{-6} = 0$$

gives us a quadratic equation with two solutions:

$$x = -0.00275 \text{ and } 0.00257$$

The negative x value has no physical meaning because it results in negative concentration values, so $[H_3O^+] = 0.00257\ M$.

Solving for pH:

$$\text{pH} = -\log[H_3O^+] = -\log(0.00257) = 2.59$$

CONNECTION Directions for using the quadratic formula to solve quadratic equations are given in Appendix 1.

Think About It We did not attempt to simplify the calculation of $[H_3O^+]$ by eliminating "$-x$" from the denominator of the equilibrium constant expression. This was a sensible decision because the value of x is 0.00257/0.040, or 6.4%, of the initial concentration of formic acid. Put another way, the formic acid in the sample was 6.4% ionized. This value of x should be less than 5% of the initial value of [HA] to use the simplification.

Practice Exercise Acetic acid, the main ingredient in vinegar, is a carboxylic acid. What is the pH of a 0.035 *M* solution of acetic acid, given that its $K_a = 1.76 \times 10^{-5}$?

SAMPLE EXERCISE 15.12 Calculating the pH of a Solution of a Weak Base LO6

The concentration of NH_3 in the household ammonia used to clean windows ranges between 50 and 100 g/L, or from about 3 *M* to almost 6 *M*. What is the pH of 3.0 *M* NH_3? The K_b value for ammonia is 1.76×10^{-5}.

Collect and Organize We are asked to determine the pH of a 3.0 *M* solution of ammonia. Figure 15.6 described the basic behavior of ammonia in aqueous solutions.

Analyze The hydrolysis of ammonia produces OH^- ions. We can calculate the equilibrium concentration of OH^- ions by using the K_b value and expression and then convert $[OH^-]$ to pOH and finally to pH. Given the 1:1:1 stoichiometry of NH_3, $NH_4{}^+$, and OH^-, we know that $[NH_4{}^+] = [OH^-]$ at equilibrium. If that equilibrium value is *x*, then the change in $[NH_3]$ during the reaction is $-x$. The pH value of a concentrated solution of a base with a K_b value near 10^{-5} should be well above 7 but below 14.

Solve We begin by setting up a RICE table in which we let $[NH_4{}^+] = [OH^-] = x$ at equilibrium:

Reaction $NH_3(aq)$ $H_2O(\ell)$				
$[NH_3]$ (*M*) $[NH_4{}^+]$ (*M*) $[OH^-]$ (*M*)				
Initial (I) 3.0				
Change (C) $-x$				
Equilibrium (E) $3.0 - x$ x				

Because K_b is small (1.76×10^{-5}) in comparison with the initial concentration of base (3.0 *M*), we can make the simplifying assumption that *x* will be less than 5% of 3.0 *M*, so the concentration term in the denominator can be simplified from (3.0 − x) to 3.0. With this assumption, our equilibrium constant expression is

so

$x^2 = 5.28 \times 10^{-5}$

Solving for x gives us

Taking the negative logarithm of $[OH^-]$ to calculate pOH:

$\text{pOH} = -\log[OH^-] = -\log(7.3 \times 10^{-3}\ M) = 2.14$

Then we subtract this value from 14.00 to obtain the pH:

$\text{pH} = 14.00 - \text{pOH} = 14.00 - 2.14 = 11.86$

CONNECTION As noted in Section 14.8, the $-x$ or $+x$ component of an equilibrium concentration or partial pressure term can be ignored if x is less than 5% of the initial concentration or partial pressure.

Think About It The calculated pH value falls in the range we predicted given the small K_b value but relatively high initial concentration of ammonia. To check our simplifying assumption, let's compare the value of x with the initial $[NH_3]$ value of 3.0 M:

This percentage is much less than 5%, which means our simplifying assumption was justified. Moreover, substituting $x = 7.3 \times 10^{-3}$ into the expression for K_b yields 1.78×10^{-5}, which is very close to the value given.

Practice Exercise What is the pH of a 0.200 M solution of methylamine (CH_3NH_2, $K_b = 4.4 \times 10^{-4}$)?

pH of Very Dilute Solutions of Strong Acids

Despite the autoionization of water (Section 15.4), water typically contributes very little to equilibrium concentrations of H_3O^+ or OH^- ions because K_w is only 1.00×10^{-14} at 25°C. Now that we have developed the concept of pH and explored how it helps us quantify the acidity of a solution, let's consider a very dilute solution of acid, a situation where the concentration of hydronium ions produced by the autoionization of water is greater than the concentration of hydronium ions produced by the acid.

SAMPLE EXERCISE 15.13 pH Calculations Involving the Autoionization of Water LO6

What is the pH of 1.0×10^{-8} *M* HCl?

Collect and Organize We are asked to calculate the pH of a very dilute solution of HCl, which is a strong acid and ionizes completely. The autoionization of pure water at 25°C produces an equilibrium $[H_3O^+] = 1.0 \times 10^{-7}$ *M*.

Analyze In a 1.0×10^{-8} *M* HCl solution $[H_3O^+] = 1.0 \times 10^{-8}$ *M*, and the pH should be

$$\text{pH} = -\log[H_3O^+] = -\log(1.0 \times 10^{-8}) = 8.00$$

This answer is not reasonable because a solution of a strong acid, no matter how dilute it is, cannot be basic (pH > 7). To calculate pH, we must also consider the autoionization of water. Let's set up a RICE table based on the autoionization equilibrium in which *x* represents the increase in $[H_3O^+]$ resulting from autoionization and in which the initial value of $[H_3O^+]$ is 1.0×10^{-8} *M*.

Solve Set up the RICE table and fill in the rows as described above:

[illegible] $H_2O(\ell)$				
[illegible] (*M*)				
[illegible] $^{-8}$				

Change (C)	$+x$
Equilibrium (E)	$(1.0 \times 10^{-8}) + x$

Substituting equilibrium values into Equation 15.8, and solving for x:

$$K_w = [H_3O^+][OH^-]$$

$$1.0 \times 10^{-14} = (1.0 \times 10^{-8} + x)(x)$$

Rearranging this equation to solve for x gives:

$$x^2 + (1.0 \times 10^{-8})x - 1.0 \times 10^{-14} = 0$$

There are two solutions to this quadratic equation:

$$x = 9.5 \times 10^{-8}\ M \text{ or } x = -1.1 \times 10^{-7}\ M$$

Only the first of these numbers makes physical sense, because a negative value for x would mean a negative concentration of hydroxide ions at equilibrium. Thus, the total concentration of hydrogen ions in the solution is

$$[H_3O^+] = (9.5 \times 10^{-8}\ M) + (1.0 \times 10^{-8}\ M) = 10.5 \times 10^{-8}\ M = 1.05 \times 10^{-7}\ M$$

and pH is

$$pH = -\log(1.05 \times 10^{-7}\ M) = 6.98$$

Think About It This value agrees with our prediction that the solution should be (very) slightly acidic.

Practice Exercise What is the pH of $1.5 \times 10^{-7}\ M$ $Ca(OH)_2$?

CONCEPT TEST

In the pH calculations in this chapter, we routinely ignore the concentrations of H_3O^+ and OH^- ions produced by the autoionization of water. Suppose calculations of the pH of six different solutions produced the results shown in the following table. Which, if any, of the calculations should have taken into account the autoionization of water to obtain an accurate result?

Solution	pH
A	2.66
B	4.12
C	6.39
D	7.27
E	9.10
F	12.88

$H_2CO_3(aq) + H_2O(\ell) \rightleftharpoons HCO_3^-(aq) + H_3O^+(aq) \qquad K_{a_1} = 4.3 \times 10^{-7}$

$$K_{a_1} = \frac{[HCO_3^-][H_3O^+]}{[H_2CO_3]} = \frac{(x)(x)}{1.4 \times 10^{-5}} = 4.3 \times 10^{-7}$$

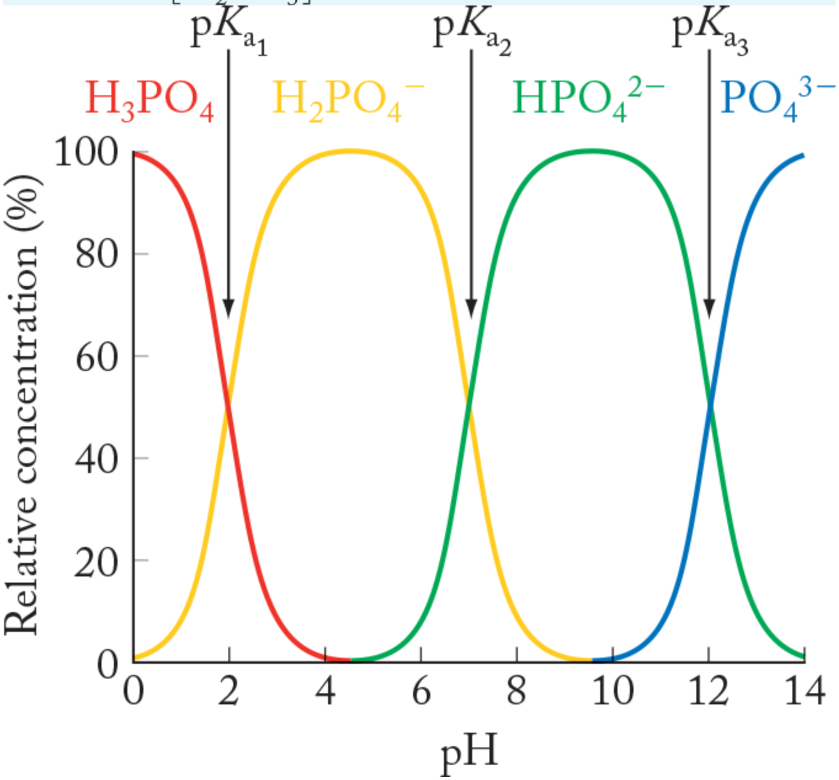

FIGURE 15.16 The relative concentrations of H_3PO_4 and the oxoanions it forms at different pH values.

$$K_{a_2} = \frac{[HPO_4^{2-}][H_3O^+]}{[H_2PO_4^-]}$$

15.7 Polyprotic Acids

Up to this point we have dealt with monoprotic acids, which have only one ionizable hydrogen atom per molecule. Acids that contain more than one ionizable hydrogen atom—such as sulfuric acid (H_2SO_4) and phosphoric acid (H_3PO_4)—are called polyprotic acids. For molecules with two and three ionizable hydrogen atoms, we use the more specific terms *diprotic acids* and *triprotic acids*, respectively. Let's consider the acidic properties of a strong diprotic acid, sulfuric acid.

Acid Rain

Coal naturally contains sulfur impurities, which combustion releases into the atmosphere as SO_2. For this reason, burning coal for energy production has significant environmental consequences: in the atmosphere, some SO_2 is oxidized to SO_3, which then combines with water vapor to form particles of sulfuric acid (H_2SO_4), a principal component of acid rain in many parts of the world. Sulfuric acid is a strong acid (see Table 15.1) because it is completely ionized in water:

$$H_2SO_4(aq) + H_2O(\ell) \rightarrow HSO_4^-(aq) + H_3O^+(aq)$$

However, the second ionization step may not be complete:

The equilibrium constant symbol K_{a2} corresponds to the donation of the second H^+ ion.

The combination of one complete and one incomplete ionization reaction means that many solutions of H_2SO_4 contain more than 1 mole but less than 2 moles of H_3O^+ ions for every mole of H_2SO_4 dissolved. One such solution is the subject of Sample Exercise 15.14.

SAMPLE EXERCISE 15.14 Calculating the pH of a Solution of a Strong Diprotic Acid LO7

What is the pH of a 0.100 *M* solution of H_2SO_4?

Collect and Organize We are given the concentration of a solution of sulfuric acid and asked to calculate its pH. Sulfuric acid is a strong diprotic acid in that one hydrogen atom ionizes completely but a second hydrogen atom may not be ionized for every molecule ($K_{a2} = 0.012$).

Analyze We start with the assumption that the ionization of H_2SO_4 is complete:

$$H_2SO_4(aq) + H_2O(\ell) \rightarrow HSO_4^-(aq) + H_3O^+(aq)$$

As a result, the second ionization step begins with $[HSO_4^-] = [H_3O^+] = 0.100\ M$. Ionization of HSO_4^- then produces additional H_3O^+ ions:

$$HSO_4^-(aq) + H_2O(\ell) \rightleftharpoons SO_4^{2-}(aq) + H_3O^+(aq)$$

We can use a RICE table to calculate the increase in $[H_3O^+]$ (represented by x). The second ionization adds to the total $[H_3O^+]$ value. This increase in $[H_3O^+]$ will have a value between 0 and 0.1 *M*, which means the total $[H_3O^+]$ value will be between 0.1 and 0.2 *M* and the pH of the solution at equilibrium should be a little less than 1.

Solve We begin by setting up a RICE table in which initially $[HSO_4^-] = [H_3O^+] = 0.100\ M$. We let the change in $[H_3O^+]$ during the second ionization step be $+x$. Filling in the other cells of the table according to the stoichiometry of the second ionization step:

[illegible] + $H_2O(\ell)$						
[illegible]						

Initial (I)	0.100				
Change (C)	+x				
Equilibrium (E)	0.100+x				

Inserting the equilibrium concentrations in the equilibrium constant expression for K_{a2}:

Cross multiplying and rearranging the terms:

$x^2 + 0.112x - 1.2 \times 10^{-3} = 0$

Solving this quadratic equation for x yields these two values:

$x = 0.00985$ and -0.122

The negative value of x represents a negative $[SO_4{}^{2-}]$ value and has no physical meaning. Therefore, we use only the positive x value to calculate the total $[H_3O^+]$ at equilibrium:

$[H_3O^+] = (0.100 + x) = (0.100 + 0.00985) = 0.10985 = 0.110$ M

The corresponding pH is

$\text{pH} = -\log[H_3O^+] = -\log(0.110) = 0.96$

Think About It As predicted, the value of $[H_3O^+]$ is between 0.1 and 0.2 *M* and the pH of the solution is a little less than one. The degree of ionization of $HSO_4{}^-$ is

---

This value exceeds 5%, so ignoring the decrease in $HSO_4{}^-$ to avoid solving a quadratic equation would have been a bad idea.

Practice Exercise What is the pH of a 0.200 *M* solution of H_2SO_4? How did doubling the concentration of H_2SO_4 affect the pH when compared with the 0.100 *M* solution of H_2SO_4 in Sample Exercise 15.14?

CONCEPT TEST

List all the phosphorus-containing species present in an aqueous solution of phosphoric acid (H_3PO_4) in decreasing order of concentration.

Normal Rain

Rainwater falling from the sky is naturally acidic. The fourth-most-abundant gas in the atmosphere is CO_2, which dissolves in water to form a small amount of carbonic acid, as we discussed in Section 15.1:

The equilibrium constant for this reaction is only about 10^{-3}, so most of the dissolved carbon dioxide remains in the form of hydrated molecules of CO_2. However, some molecules of H_2CO_3 then go on to release H^+ ions:

When using this K_{a1}value, keep in mind that its value is based on the total concentration of dissolved CO_2 present in a sample. To simplify these calculations, $[H_2CO_3]$ is used to represent the total concentration of CO_2 dissolved in the sample. The second ionization constant, K_{a2}, has an even smaller value:

It turns out that calculating the pH of a solution of carbonic acid is simpler than the pH calculation for sulfuric acid. The reason is that K_{a1}, although small, is still much larger than K_{a2}. We can explain this difference based on electrostatic attractions between oppositely charged ions. The first ionization step produces a negatively charged oxoanion (HCO_3^-). The second requires a H^+ ion to dissociate from HCO_3^- to produce an even more negative oxoanion (CO_3^{2-}). Separating oppositely charged ions that are naturally attracted to each other is not a process that we would expect to be favored, and the much smaller value of K_{a2}confirms our expectation.

In general, the K_{a2} value of any diprotic acid is smaller—often much smaller—than its K_{a1} value. A consequence of these large differences is that essentially all the limited strength of many weak diprotic acids is derived from the first ionization reaction. For those acids whose K_{a1} value is at least a thousand times greater than its K_{a2} value, we can ignore the second ionization reaction.

SAMPLE EXERCISE 15.15 Calculating the pH of a Solution of a Weak Diprotic Acid LO7

What is the pH of rainwater at 25°C in equilibrium with atmospheric CO_2, producing a total dissolved CO_2 concentration of $1.4 \times 10^{-5} M$?

Collect and Organize We are asked to determine the pH of a dilute solution of dissolved CO_2. There are two ionizable H atoms in H_2CO_3. The K_{a1} and K_{a2} values are 4.3×10^{-7} and 4.7×10^{-11}, respectively. Any H_2CO_3 that dissociates to produce bicarbonate and hydronium ions will be replaced by more CO_2 dissolving from the atmosphere, so the value of $[H_2CO_3]$ in the denominator in the K_{a1} expression will be constant at $1.4 \times 10^{-5} M$.

Analyze The value of K_{a1} is more than 1000 times the K_{a2} value, so the second ionization step can be ignored in calculating the pH of a solution of dissolved CO_2. Therefore, we focus on the first ionization equilibrium:

Because of the small value of K_{a1} and the small concentration of dissolved CO_2, we should obtain a pH value that is less than 7, but a lot closer to 7 than 0.

Solve First we set up a RICE table in which $x = [H_3O^+] = [HCO_3^-]$ at equilibrium and the value of $[H_2CO_3]$ is a constant $1.4 \times 10^{-5} M$.

$H_2CO_3(aq)$ + $H_2O(\ell)$										
$[H_2CO_3]$ (M)										
Initial (I) 1.4×10^{-5}										
Change (C)										

Equilibrium (E) 1.4×10^{-5}				

so

$$x^2 = 6.0 \times 10^{-12}$$

Therefore,

$$x = [H_3O^+] = 2.4 \times 10^{-6} M$$

Taking the negative logarithm of $[H_3O^+]$ to calculate pH:

$$\text{pH} = -\log[H_3O^+] = -\log(2.4 \times 10^{-6} M) = 5.62$$

Think About It Carbonic acid is a weak acid, and its concentration here is small, so obtaining a pH value that is only about 1.4 units below neutral pH is reasonable.

Practice Exercise The proximity of the calculated pH value to 7.00 raises the question of whether the autoionization of water contributes significantly to $[H_3O^+]$ in the rainwater sample. Recalculate the pH of the rainwater sample in Sample Exercise 15.15, assuming the initial concentration of $H_3O^+ = 1.00 \times 10^{-7} M$.

Some acids have three ionizable H atoms per molecule. Two important triprotic acids are phosphoric acid (H_3PO_4) and citric acid, the acid responsible for the tart flavor of citrus fruits. According to **Table 15.5**, $K_{a1} > K_{a2} > K_{a3}$ for both acids. This pattern is much like that for the $K_{a1} > K_{a2}$ values of diprotic acids. The reason is the same, too—namely, it is more difficult to remove a second H^+ ion from the negatively charged ion formed after the first H^+ ion is removed, and it is even more difficult to remove a third H^+ ion from an ion with a 2− charge.

Figure 15.16 illustrates the separations between the pK_a values of phosphoric acid and their impact on the relative concentrations of H_3PO_4 and the oxoanions it forms at different pH values. At pH values below about 4.5, the principal species present in solution are H_3PO_4 and $H_2PO_4^-$. The concentrations of HPO_4^{2-} and PO_4^{3-} that are produced in the second and third acid ionization reactions (see Table 15.5) are insignificant, which is why we can ignore them in calculating the pH of a solution of phosphoric acid.

The pH values at the three cross-over points in the concentration curves in Figure 15.16 correspond to the three p*K* values of phosphoric acid. This makes sense when we consider, for example, phosphoric acid's second ionization step:

$$H_2PO_4^-(aq) + H_2O(\ell) \rightleftharpoons HPO_4^{2-}(aq) + H_3O^+(aq)$$

TABLE 15.5 Ionization Equilibria of Two Triprotic Acids

Phosphoric Acid		
(1)  $\mathrm{HO{-}P(=O)(OH){-}OH + H_2O \rightleftharpoons HO{-}P(=O)(OH){-}O^- + H_3O^+}$	$K_{a_1} = 7.1 \times 10^{-3}$	$pK_{a_1} = 2.15$
(2)  $\mathrm{HO{-}P(=O)(OH){-}O^- + H_2O \rightleftharpoons {}^-O{-}P(=O)(OH){-}O^- + H_3O^+}$	$K_{a_2} = 6.3 \times 10^{-8}$	$pK_{a_2} = 7.20$
(3)  $\mathrm{{}^-O{-}P(=O)(OH){-}O^- + H_2O \rightleftharpoons {}^-O{-}P(=O)(O^-){-}O^- + H_3O^+}$	$K_{a_3} = 4.5 \times 10^{-13}$	$pK_{a_3} = 12.35$
Citric Acid		
(1)  $\mathrm{HO{-}C(CH_2COOH)(CH_2COOH){-}COOH + H_2O \rightleftharpoons HO{-}C(CH_2COO^-)(CH_2COOH){-}COOH + H_3O^+}$	$K_{a_1} = 7.4 \times 10^{-4}$	$pK_{a_1} = 3.13$
(2)  $\mathrm{HO{-}C(CH_2COO^-)(CH_2COOH){-}COOH + H_2O \rightleftharpoons HO{-}C(CH_2COO^-)(CH_2COOH){-}COO^- + H_3O^+}$	$K_{a_2} = 1.7 \times 10^{-5}$	$pK_{a_2} = 4.76$
(3)  $\mathrm{HO{-}C(CH_2COO^-)(CH_2COOH){-}COO^- + H_2O \rightleftharpoons HO{-}C(CH_2COO^-)(CH_2COO^-){-}COO^- + H_3O^+}$	$K_{a_3} = 4.1 \times 10^{-7}$	$pK_{a_3} = 6.39$

The equilibrium constant expression for this reaction is

At the point where the yellow and green curves cross over, $[H_2PO_4^-] = [HPO_4^{2-}]$, which means these two terms cancel out of the K_{a2} expression and we are left with $K_{a2} = [H_3O^+]$. Taking the negative log values of this equality gives us $pK_{a2} = -\log[H_3O^+]$. In other words, the pH at which the yellow and green curves intersect in Figure 15.16 should equal the value of pK_{a2} (7.20), and indeed it does. To test your understanding of these interesting curves, do a similar analysis of the pH at the intersection of the green and blue curves in Figure 15.16.

CONCEPT TEST

Do you expect the second or third acid ionization steps in phosphoric acid and citric acid to influence the pH of 0.100 *M* solutions of either acid?

Glossary

monoprotic acid	an acid that has one ionizable hydrogen atom per molecule.
polyprotic acid	an acid that has two or more ionizable hydrogen atoms per molecule.

$NH_3(aq) + H_2O(\ell) \rightleftharpoons NH_4^+(aq) + OH^-(aq) \qquad K_b = 1.76 \times 10^{-5}$

$$K_a = \frac{[NH_3][H_3O^+]}{[NH_4^+]} \qquad K_b = \frac{[NH_4^+][OH^-]}{[NH_3]}$$

$$K_a \times K_b = \frac{\cancel{[NH_3]}[H_3O^+]}{\cancel{[NH_4^+]}} \times \frac{\cancel{[NH_4^+]}[OH^-]}{\cancel{[NH_3]}} = [H_3O^+][OH^-]$$

$$K_a \times K_b = K_w \qquad (15.18)$$

$$K_b = \frac{K_w}{K_a} = \frac{1.0 \times 10^{-14}}{2.9 \times 10^{-8}} = 3.4 \times 10^{-7}$$

$$\frac{82.5\ \cancel{g}}{L} \times \frac{1\ mol}{74.44\ \cancel{g}} = 1.11\ mol/L$$

$$K_b = \frac{[HClO][OH^-]}{[ClO^-]} = \frac{(x)(x)}{1.11 - x} \approx \frac{x^2}{1.11} = 3.4 \times 10^{-7}$$

$$x = [OH^-] = 6.1 \times 10^{-4}$$

$$\frac{6.1 \times 10^{-4}\ M}{1.11\ M} \times 100\% = 0.055\%$$

$$K_a = \frac{[NH_3][H_3O^+]}{[NH_4^+]}$$

$$K_a = \frac{K_w}{K_b} = \frac{1.0 \times 10^{-14}}{1.76 \times 10^{-5}} = 5.68 \times 10^{-10} = \frac{[NH_3][H_3O^+]}{[NH_4^+]}$$

$$K_a = 5.68 \times 10^{-10} = \frac{[NH_3][H_3O^+]}{[NH_4^+]} = \frac{(x)(x)}{0.25 - x}$$

$$\frac{x^2}{0.25} = 5.68 \times 10^{-10}$$

$$x^2 = 1.42 \times 10^{-10}$$

$$x = 1.19 \times 10^{-5} = [\mathrm{H_3O^+}]$$

$$\mathrm{pH} = -\log[\mathrm{H_3O^+}] = -\log(1.19 \times 10^{-5}) = 4.92$$

$$\frac{1.19 \times 10^{-5}\ M}{0.25\ M} \times 100\% = 0.0048\%$$

$$K = \frac{[\mathrm{H_2CO_3}]}{[\mathrm{CO_2}]} = \frac{x}{2.7 \times 10^{-3}} = 3.4 \times 10^{-2}$$

$$K_{\mathrm{a_1}} = \frac{[\mathrm{HCO_3}^-][\mathrm{H_3O^+}]}{[\mathrm{H_2CO_3}]} = \frac{(0.028 + x)(x)}{2.7 \times 10^{-3}} \approx \frac{0.028x}{2.7 \times 10^{-3}}$$

$$= 4.3 \times 10^{-7}$$

$$x = 4.15 \times 10^{-8}$$

15.8 Acidic and Basic Salts

Seawater and the freshwater in many rivers and lakes have pH values that range from weakly basic to weakly acidic. How can these waters be more basic than the acidic rainwater (pH ≤ 5.6) that serves, directly or indirectly, as their water supply? When rain soaks into the ground, its pH changes as it flows through soils that contain basic components. To understand the chemical processes that produce neutral or slightly basic groundwater, we first need to examine the acid–base properties of some common ionic compounds present in these waters.

As we discussed in Chapter 4, soluble ionic compounds separate into their component ions when they dissolve in water. For example, a 0.01 M solution of NaCl contains 0.01 M $\mathrm{Na^+}$ ions and 0.01 M $\mathrm{Cl^-}$ ions. It is also a neutral solution. Neither $\mathrm{Na^+}$ ions nor

Cl^- ions hydrolyze (react with water) to form H_3O^+ or OH^- ions when they dissolve in water. The Cl^- ion is the conjugate base of a strong acid (HCl); therefore, the strength of the Cl^- ion as a base can be considered negligible.

When NaF, another sodium salt, dissolves in water, it produces F^- ions, which are the conjugate base of the weak acid, HF. Therefore F^- ions are weakly basic. When they dissolve in water some of them react with molecules of water forming molecules of HF and OH^- ions:

or,

$$F^-(aq) + H_2O(\ell) \rightleftharpoons HF(aq) + OH^-(aq)$$

The small concentrations of OH^- ions produced by this reaction make NaF solutions weakly basic.

If the salts that contain the conjugate bases of weak acids are basic, it is only reasonable that salts that contain the conjugate acids of weak bases are acidic. An example of such a salt is NH_4Cl. The Cl^- ions that are produced when NH_4Cl dissolves have negligible strengths as Brønsted–Lowry bases, but NH_4^+ ions are the conjugate acid of NH_3, a weak base. As a result, NH_4^+ ions are weakly acidic, producing at least some H_3O^+ ions as ammonium ions dissociate: donating one of their H atoms as an H^+ ion to a molecule of water, forming a hydronium ion and leaving behind a neutral molecule of ammonia:

or,

$$NH_4^+(aq) + H_2O(\ell) \rightleftharpoons NH_3(aq) + H_3O^+(aq)$$

Consequently, solutions of NH_4Cl are weakly acidic.

Table 15.6 summarizes how salts can be acidic, basic, or neutral depending on whether they include cations that are the conjugate acids of weak bases, anions that are the conjugate bases of weak acids, or both. Salts that contain both the conjugate base of a weak acid *and* the conjugate acid of a weak base may be acidic, basic, or neutral, depending on the relative strengths of the acid and base. Ammonium acetate represents the rare example of a salt in which the strengths of the conjugate acid (acetic acid) and the base (ammonia) happen to be *exactly the same*: the K_a of acetic acid $=$ K_b of ammonia 1.76×10^{-5}. As a result, ammonium acetate is a neutral salt.

TABLE 15.6 Acid–Base Properties of Salts

Source of Cation	Source of Anion	pH of Solution	Example
Strong base	Strong acid	7	NaCl
Weak base	Strong acid	<7	NH_4Cl
Strong base	Weak acid	>7	NaF
Weak base	Weak acid	Neutral, acidic, or basic	NH_4CH_3COO[a], NH_4F[b], NH_4HCO_3[c]

SAMPLE EXERCISE 15.16 Predicting Whether a Salt Is Acidic, Basic, or Neutral LO8

NaClO is the active ingredient in chlorine bleach such as Clorox (**Figure 15.17**). Is an aqueous solution of NaClO acidic, basic, or neutral?

Collect, Organize, and Analyze Sodium ions do not hydrolyze and do not affect the pH of aqueous solutions. However, ClO^- ions are the conjugate base of HClO, which is a weak acid (Table 15.2). Therefore, ClO^- ions are weak bases that partially hydrolyze, forming OH^- ions:

$$ClO^-(aq) + H_2O(\ell) \rightleftharpoons HClO(aq) + OH^-(aq)$$

Solve Because hydrolysis of ClO^- ions produces OH^- ions, solutions of NaClO are weakly basic.

Think About It Any sodium salt that contains an anion that is the conjugate base of a weak acid produces weakly basic aqueous solutions.

Practice Exercise Write a chemical equation for the hydrolysis reaction that explains why an aqueous solution of K_2SO_4 is slightly basic.

Having established that salts can be acidic, basic, or neutral, let's now address how to calculate the pH of their aqueous solutions. Our approach is much like that used to calculate the pH of solutions of weak acids and bases, but there is an extra step. For example, if we want to calculate the pH of a solution of ammonium chloride, we need to know the equilibrium constant of the reaction in which NH_4^+ ion functions as a Brønsted–Lowry acid:

$$NH_4^+(aq) + H_2O(\ell) \rightleftharpoons NH_3(aq) + H_3O^+(aq)$$

K_a values are typically *not* listed for the conjugate acids of weak bases, but K_b values for the corresponding weak bases are (see Appendix 5). For ammonia,

---

The strengths of conjugate acids and bases are complementary—that is, the stronger one is, the weaker the other. Therefore, we can derive the K_a value for ammonium ions from the K_b value for ammonia. To see how, we first write the K_a and K_b equilibrium constant expressions for NH_4^+ and NH_3:

These expressions are similar, although any shared terms that appear in the numerator of one expression are found in the denominator of the other. We can take advantage of this situation by multiplying the two expressions together:

The simplified product is the K_w expression for the autoionization of water. Thus,

---

This is a very handy equation because (1) it works for all conjugate acid–base pairs, and (2) it allows us to calculate either the K_b of the anion in a basic salt from the K_a of its conjugate acid, or the K_a of the cation in an acidic salt from the K_b of its conjugate base.

SAMPLE EXERCISE 15.17 Calculating the pH of a Solution of a Basic Salt LO8

The chlorine bleach shown in Figure 15.17 contains 82.5 g/L of NaClO. What is the pH of this solution?

Collect and Organize We know the concentration of an aqueous solution of hypochlorite (NaClO) and we are asked to calculate its pH. We determined in Sample Exercise 15.16 that NaClO is a basic salt because the ClO^- ion is the conjugate base of HClO, a weak acid. Sodium ions do not hydrolyze and play no role in the acid–base properties of sodium salts. The K_a value for HClO is 2.9×10^{-8} (see Figure 15.5 and Appendix 5).

Analyze We need to first convert the K_a value for HClO into the K_b value for the ClO^- ion by using Equation 15.18: $K_a \times K_b = K_w$. We also need to convert the concentration of NaClO from g/L to molarity. That value will be the initial value of the reactant in a RICE table based on its hydrolysis reaction:

$$ClO^-(aq) + H_2O(\ell) \rightleftharpoons HClO(aq) + OH^-(aq)$$

We will solve for $[OH^-]$, then pOH, and then pH. The concentration of the solution should be about 1 *M*, and K_b should be a little more than 10^{-7}. Therefore, $[OH^-]$ of a ~1 *M* solution should be near the square root of that value, or ~10^{-3}, making pOH ≈ 3 and pH ≈ 11.

Solve Calculating K_b:

---

and then calculating the molar concentration of NaClO to use in the following RICE table:

[illegible] $H_2O(\ell)$				
[illegible] (*M*)				

Initial (I)			
Change (C)			
Equilibrium (E)			

To solve for x, we make the simplifying assumption that x will be small compared with 1.11 M because the value of K_b is so small ($<<10^{-5}$):

Calculating pOH:

$$\text{pOH} = -\log[\text{OH}^-] = -\log(6.1 \times 10^{-4}) = 3.21$$

and pH:

$$\text{pH} = 14.00 - \text{pOH} = 14.00 - 3.21 = 10.79$$

Think About It The calculated pH (10.79) matches our estimate of 11. Also, the calculated [OH^-] value is much less than 5% of the initial [ClO^-] value:

Our assumption that we could ignore the $-x$ term in the denominator of the K_b expression was justified.

Practice Exercise The pH of swimming pools is made slightly basic by spreading solid Na_2CO_3 across the surface. Another approach involves preparing concentrated solutions of Na_2CO_3 and slowly adding them to the water circulating through the pool pump and filter. What is the pH of an aqueous solution of 0.100 M Na_2CO_3?

SAMPLE EXERCISE 15.18 Calculating the pH of a Solution of an Acidic Salt LO8

What is the pH of 0.25 M NH_4Cl?

Collect and Organize We are asked to calculate the pH of a solution of NH_4Cl. When NH_4Cl dissolves in water, NH_4^+ and Cl^- ions are released into solution. The NH_4^+ ion is the conjugate acid of NH_3, which is a weak base. The Cl^- ion is the conjugate base of HCl, which is a strong acid.

Analyze The Cl^- ion has negligible strength as a Brønsted–Lowry base, so it does not contribute to the acid–base properties of NH_4Cl. Ammonia is a weak base ($K_b = 1.76 \times 10^{-5}$), which means that its conjugate acid, NH_4^+, is a weak acid, and the pH of the solution will be controlled by its hydrolysis:

$$NH_4^+(aq) + H_2O(\ell) \rightleftharpoons NH_3(aq) + H_3O^+(aq)$$

The K_a value of NH_4^+ can be calculated by dividing K_w by the K_b of ammonia (i.e., by using Equation 5.18). The K_b value of ammonia is close to 10^{-5}, so the K_a value of the ammonium ion will be close to 10^{-9}. Therefore, $[H_3O^+]$ of a 0.25 M solution should be near the square root of about 10^{-10}, or about 10^{-5}, giving a pH $\approx$ 5.

Solve The simplified K_a expression for the NH_4^+ ion is

Rearranging Equation 15.18 to solve for K_a:

We set up a RICE table in which we make the usual assumptions that the reaction is the only significant source of H^+ and that $x = [H_3O^+] = [NH_3]$ at equilibrium:

Reaction (R) $NH_4^+(aq)$ +		$H_2O(\ell)$						
$[NH_4^+]$ (M) $[H_3O^+]$ (M)								
Initial (I) 0.25								
Change (C) $-x$								
Equilibrium (E) $0.25 - x$								

Given the very small value of K_a, we can make the simplifying assumption that $(0.25\ M - x) < 0.25\ M$, which gives us

Think About It This result matches our prediction quite closely.

The calculated $[H_3O^+]$ is much less than 5% of the initial concentration of NH_4^+,

---

so our simplifying assumption was valid.

Practice Exercise What is the pH of a 0.25 *M* solution of methylamine hydrochloride (CH_3NH_3Cl)?

SAMPLE EXERCISE 15.19 Integrating Concepts: The pH of Human Blood

We began this chapter by noting how essential it is that our circulation and respiration systems efficiently remove from our bodies the CO_2 produced in our cells. An enzyme, carbonic anhydrase, plays a key role in this process by speeding up the rate at which CO_2 hydrolyzes:

$$CO_2(g) + H_2O(\ell) \rightleftharpoons H_2CO_3(aq)$$

and the rate at which H_2CO_3 ionizes:

$$H_2CO_3(aq) + H_2O(\ell) \rightleftharpoons HCO_3^-(aq) + H_3O^+(aq)$$

1. Does carbonic anhydrase increase the acid strength of dissolved CO_2—that is, the K_{a1} of carbonic acid based on the total concentration of CO_2 in solution?
2. Suppose that, during strenuous exercise, the total concentration of dissolved CO_2 in the blood flowing through muscle tissues is 2.7×10^{-3} *M*. If the equilibrium constant of the hydrolysis reaction is 3.4×10^{-2}, what is the equilibrium concentration of carbonic acid in the blood?
3. Suppose the concentration of HCO_3^- ions in the blood in part (b) is 0.028 *M*. What is the pH of the blood?

Collect and Organize We are asked whether the presence of an enzyme that increases the rates at which CO_2 is hydrolyzed and undergoes acid ionization makes H_2CO_3 a stronger acid. We then need to calculate the equilibrium value of $[H_2CO_3]$ from an initial value of $[CO_2]$; we are also given the K value for the hydrolysis reaction and the pH of blood in which $[HCO_3^-]$ and $[CO_2]$ are known. Carbonic acid is a weak diprotic acid; its K_{a1}, based on the total concentration of CO_2 in solution, is 4.3×10^{-7} (see Appendix 5).

Analyze (a) We learned in Section 14.7 that catalysts speed up reactions but do not alter their equilibrium constants. (b) Calculating $[H_2CO_3]$ will involve solving for the numerator of the equilibrium constant expression for the hydrolysis of CO_2, knowing the $[CO_2]$ value in the denominator. If continued exercise maintains $[CO_2]$ at a constant value, there will be no $-x$ term in the denominator. With a K value of 0.034 and $[CO_2] \approx 2 \times 10^{-3}\ M$, $[H_2CO_3]$ should be about $7 \times 10^{-5}\ M$. (c) Calculating the pH of a carbonic acid solution will require a RICE table based on K_{a1} in which $[H_3O^+] = x$ at equilibrium but in which the initial concentration of HCO_3^- is 0.028 M, not zero. The normal pH of human blood is close to 7.4, so the calculated pH should be close to that.

Solve (a) Carbonic anhydrase should not affect the value of K_{a1}, though it should produce increases in both $[H_2CO_3]$ and $[HCO_3^-]$. These increases in the numerator and denominator of the K_{a1} expression offset each other and do not affect pH.

(b) Inserting the known values of K and $[CO_2]$ in the hydrolysis equilibrium constant expression:

and solving for x:

$$x = [H_2CO_3] = 9.2 \times 10^{-5}\ M$$

(c) Setting up a RICE table based on the K_{a1}reaction, where the values in the $[H_2CO_3]$ column represent a constant total concentration of $CO_2(aq) + H_2CO_3(aq)$:

$H_2CO_3(aq) + H_2O(\ell)$			
$[H_2CO_3]$ (M)			

Initial (I)	[illegible]
Change (C)	[illegible]
Equilibrium (E)	[illegible]

In solving for x, we make the simplifying assumption that its value will be much less than 0.028 M (as it must be, if the calculated pH is close to 7.4, which means $[\mathrm{H_3O^+}] \approx 10^{-7}$), and we ignore the very small x^2 term in the numerator of the following calculation:

Therefore, the pH of the blood in the muscle tissue is

$$\mathrm{pH} = -\log[\mathrm{H_3O^+}] = -\log(4.15 \times 10^{-8}) = 7.38$$

Think About It The pH value calculated in (c) is reasonable because it matches our estimate based on the normal pH of human blood.

- Predict whether a salt is acidic, basic, or neutral, and calculate the pH of a salt solution **Return to Sample Exercises 15.16, 15.17, 15.18**

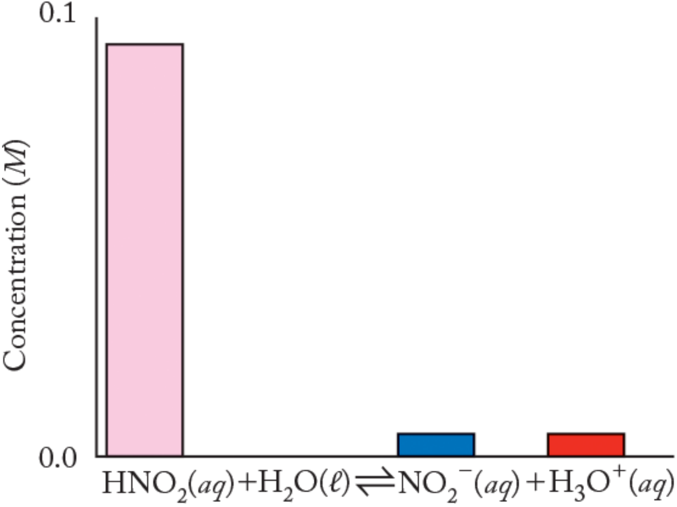
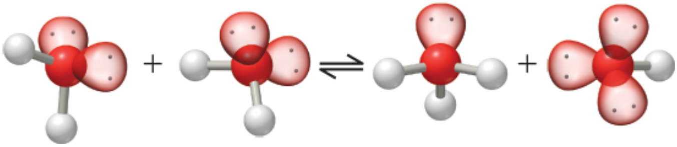
SUMMARY

- LO1 The strengths of acids and bases are related to the values of their acid and base ionization constants, K_a and K_b. Most acids are weak, which means their K_a is much less than 1 and they ionize only partially in water. (Section 15.2)



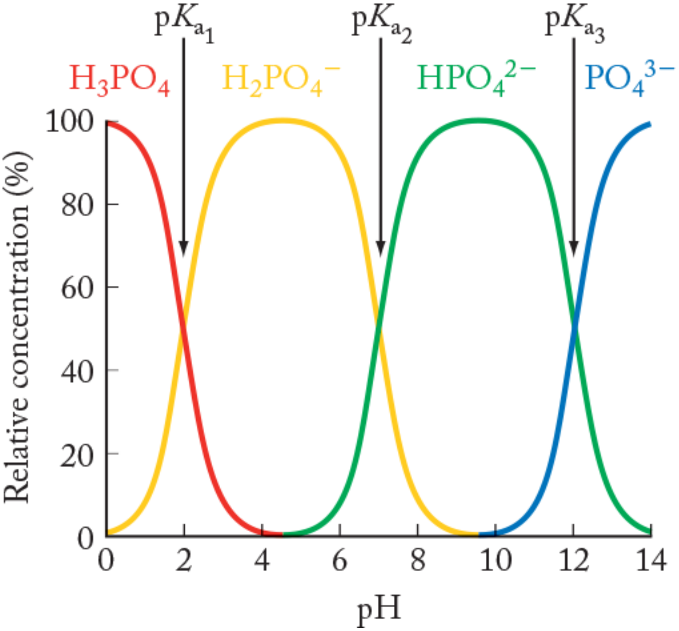
- LO2 The strengths of acids are related to both the electronegativity of the atom adjacent to the hydrogen atom and the stability of the anions they form when they release H^+ ions. The stability of oxoanions is enhanced by multiple oxygen atoms bonded to the central atom, which disperse the negative charge(s) over the anion. (Section 15.2)
- LO3 When an acid (HA) ionizes, it forms its conjugate base, A^-. When base B bonds to a H^+ ion, it forms its conjugate acid, HB^+. (Section 15.3)



- LO4 In a neutral solution at 25°C, $[H_3O^+] = [OH^-] = 1.0$

$\times 10^{-7}$. The pH scale is a logarithmic scale for expressing the acidic or basic strength of solutions. Acidic solutions have pH values less than 7, whereas basic solutions have pH values greater than 7. Because pH is the negative logarithm of H_3O^+ concentration, the higher the pH, the lower the H_3O^+ concentration. An increase in one pH unit represents a decrease in $[H_3O^+]$ to 1/10 of its initial value. Likewise, pOH is the negative logarithm of OH^- concentration. The sum of pH and pOH equals 14 in an aqueous solution at 25°C. (Section 15.4)

- LO5 The K_a and K_b values of acids and bases can be used to calculate the extent to which their solutions are ionized—that is, their degree of ionization or *percent ionization*—and vice versa. (Section 15.5)



- LO6 To calculate the pH of a weak acid or base, use a RICE table based on the acid or base ionization reaction to determine the equilibrium value of $[H_3O^+]$ or $[OH^-]$ in a solution of a weak acid or base. (Section 15.6)
- LO7 Polyprotic acids can undergo more than one acid ionization reaction, but for most, the first ionization reaction is the one that controls pH. (Section 15.7)

- LO8 A salt solution is acidic if the cation in the salt is the conjugate acid of a weak base and the anion is the conjugate base of a strong acid. A salt solution is basic if the anion in the salt is the conjugate base of a weak acid and the cation is the conjugate acid of a strong base. A salt solution is neutral if neither the cation nor the anion hydrolyzes (reacts with water) to form H_3O^+ or OH^- ions when it dissolves in water. (Section 15.8)

PARTICULATE PREVIEW WRAP-UP

All three species form covalent bonds when they accept donated protons. ClO^- becomes a neutral molecule (HClO), whereas NH_3 and H_2O become cations (NH_4^+ and H_3O^+, respectively). All three reactants contain atoms with at least one lone pair of electrons (i.e., the O atoms in ClO^- and H_2O, and the N atom in NH_3) that can bond to H^+ ions.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts	Equations	Sample Exercises
Ranking acids and bases from strongest to weakest	Acid strengths and base strengths are proportional to their concentrations and K_a and K_b values, which are related to their molecular structures.		15.1, 15.2
Identifying acid–base conjugate pairs and the complementary nature of their strengths	The conjugate base of an acid has the formula of the acid minus one H^+ ion. The stronger the acid, the weaker its conjugate base; the stronger the base, the weaker its conjugate acid.		15.3, 15.4
Interconverting $[H_3O^+]$, $[OH^-]$, pH, and pOH	Use the following:	$\text{pH} = -\log[H_3O^+]$ (15.10) $\text{pOH} = -\log[OH^-]$ (15.11) $\text{p}K_w = \text{pH} + \text{pOH} = 14.00$ (15.12)	15.5, 15.6, 15.7
Determining percent ionization and K_a given the pH of a weak acid	Use the following: $[H_3O^+] = 10^{-\text{pH}}$	$[H_3O^+] = 10^{-\text{pH}}$ $K_a = \frac{[A^-][H_3O^+]}{[HA]}$ (15.14) $\text{Percent ionization} = \frac{[A^-]_{\text{equilibrium}}}{[HA]_{\text{initial}}} \times 100\%$ (15.15)	15.8

15.10 Determining percent ionization and K_b given the pH of a weak base

Use the following:

$[OH^-] = 10^{-pOH}$

$$[OH^-] = 10^{-pOH}$$

$$K_b = \frac{[HB^+][OH^-]}{[B]} \qquad (15.16)$$

$$\text{Percent ionization} = \frac{[HB^+]_{\text{equilibrium}}}{[B]_{\text{initial}}} \times 100\% \qquad (15.17)$$

15.11 Calculating the pH of a solution of weak acid HA

Set up a RICE table based on the K_a equilibrium

$HA(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + A^-(aq)$

Let $x = [H_3O^+] = [A^-]$ at equilibrium. Calculate x by using

$$K_a = \frac{[A^-][H_3O^+]}{[HA]}$$

Then calculate $pH = -\log[H_3O^+]$.

15.12 Calculating the pH of a solution of weak base B

Set up a RICE table based on the equilibrium

$B(aq) + H_2O(\ell) \rightleftharpoons HB^+(aq) + OH^-(aq)$

Let $x = [OH^-] = [HB^+]$ at equilibrium. Calculate x by using

$$K_b = \frac{[HB^+][OH^-]}{[B]}$$

Then use

$pOH = -\log[OH^-]$

$pH = 14.00 - pOH$

15.13 Calculating the pH of a very dilute acidic (or very dilute basic) solution while considering the autoionization of water

Set up a RICE table based on the equilibrium

$H_2O(\ell) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + OH^-(aq)$

Let $x = [H_3O^+] = [OH^-]$ because of autoionization. Add x to the $[H_3O^+]$ because of the dilute acid (or to the $[OH^-]$ because of the weak base). Solve for x by using

$$K_w = [H_3O^+][OH^-] \qquad (15.8)$$

Then calculate $pH = -\log[H_3O^+]$.

15.14 Calculating the pH of a solution of a strong diprotic acid

Assume

$H_2A(aq) + H_2O(\ell) \rightarrow H_3O^+(aq) + HA^-(aq)$

is complete.

Set up a RICE table based on the K_{a1}equilibrium

$HA^-(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + A^{2-}(aq)$

Let x = additional $[H^+]$ from second ionization step; $[HA^-]_{\text{initial (2nd step)}} = [H_2A]_{\text{initial}}$. Calculate x by using

$$K_{a_2} = \frac{[H_3O^+][A^{2-}]}{[HA^-]}$$

Then calculate $pH = -\log[H_3O^+]$.

15.15 Calculating the pH of a solution of a weak diprotic acid

Set up a RICE table based on the K_{a1} equilibrium

$H_2A(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + HA^-(aq)$

Let $x = [H_3O^+] = [HA^-]$ at equilibrium. Calculate x by using

$$K_{a_1} = \frac{x^2}{[H_2A] - x}$$

Then calculate $pH = -\log[H_3O^+]$.

P15.16 Predicting whether a salt is acidic, basic, or neutral

The cations in acidic salts are the conjugate acids of weak bases. The anions in basic salts are the conjugate bases of weak acids. The cations and anions in most neutral salts do not hydrolyze.

C15.17 Calculating the pH of a solution of a basic salt

Assume the salt (MX) completely dissociates into M^+ and X^-. Set up a RICE table for the equilibrium

$X^-(aq) + H_2O(\ell) \rightleftharpoons HX(aq) + OH^-(aq)$

Let $x = [HX] = [OH^-] =$ at equilibrium.

Calculate x by using

$$K_w = K_a \times K_b$$

$$K_b = \frac{K_w}{K_{a\text{ (of conjugate acid, HA)}}}$$

$$K_b = \frac{K_w}{K_a} = \frac{x^2}{[X^-] - x}$$

Convert $[OH^-]$ to pOH, and then pH.

C15.18 Calculating the pH of a solution of an acidic salt

Assume the salt (HBX) completely dissociates into HB^+ and X^-. Set up a RICE table for the equilibrium

$HB^+(aq) + H_2O(\ell) \rightleftharpoons B(aq) + H_3O^+(aq)$

Let $x = [H_3O^+] = [B]$ at equilibrium.

Calculate x by using

$$K_a = \frac{K_w}{K_{b\text{ (of conjugate base, B)}}}$$

$$K_a = \frac{K_w}{K_b} = \frac{x^2}{[HB^+] - x}$$

Then calculate pH.

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

Which of the lines in Figure P15.1 best represents the dependence of the degree of ionization of acetic acid on its concentration in aqueous solution?

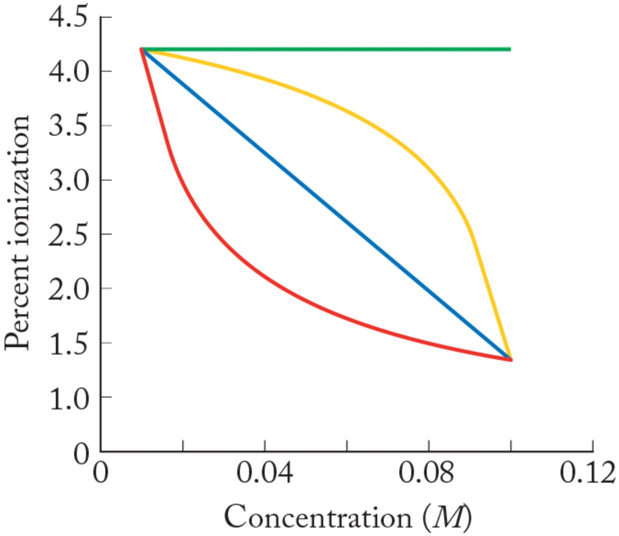


FIGURE P15.1

The graph in Figure P15.2 shows the percent ionization of two acids as a function of concentration in water. Which line describes the behavior of HNO_3, and which line describes the behavior of acetic acid (CH_3COOH)?

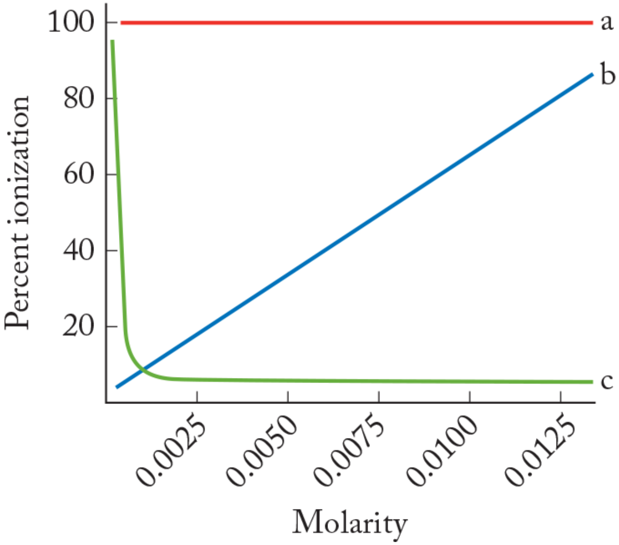

FIGURE P15.2

The bar graph in Figure P15.3 shows the degree of ionization of 1 × $10^{-3} M$ solutions of HClO, HBrO, and HIO. Which bar corresponds to HIO?

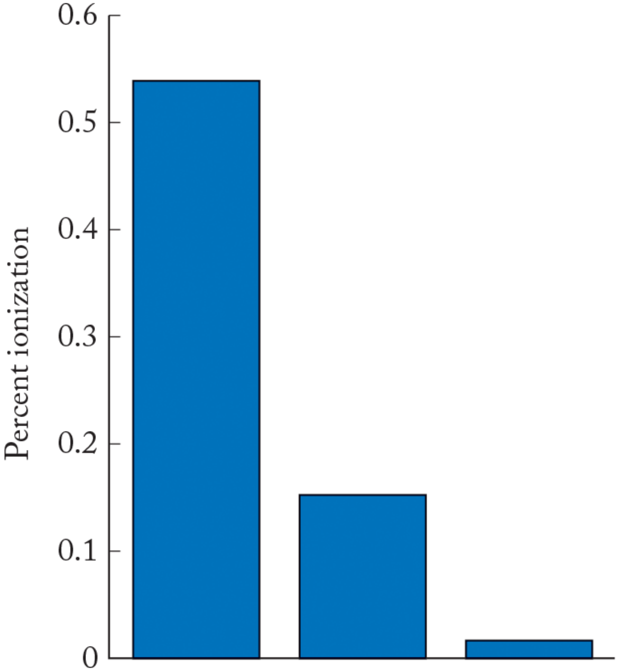

FIGURE P15.3

The bar graph in Figure P15.4 shows the degree of ionization of 1 *M* solutions of HClO, $HClO_2$, and $HClO_3$. Which bar corresponds to HClO?

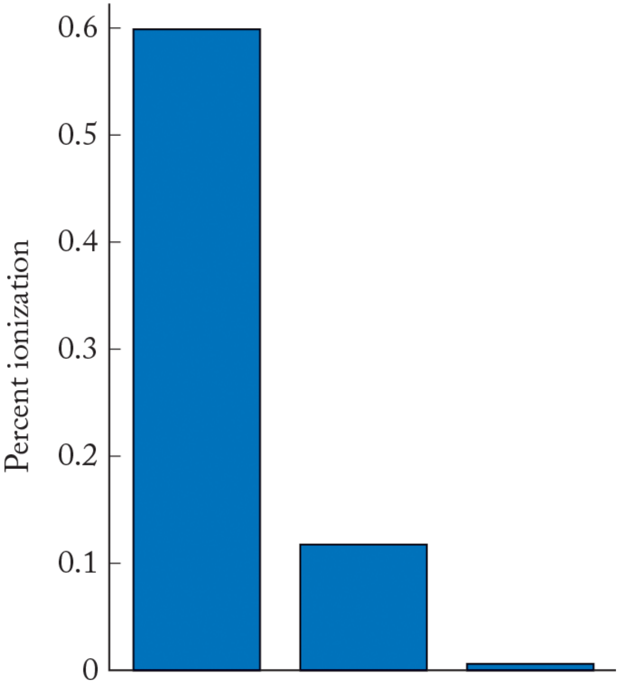

FIGURE P15.4

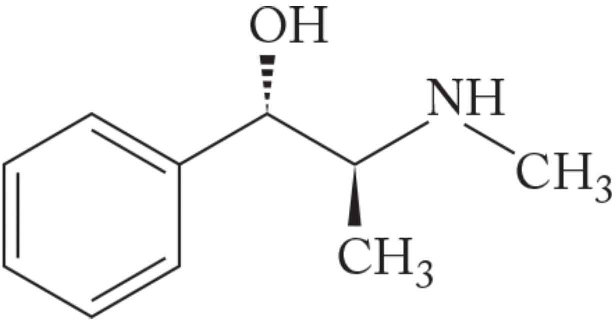
Figure P15.5 shows a condensed molecular structure of pseudoephedrine, a widely used decongestant and stimulant.

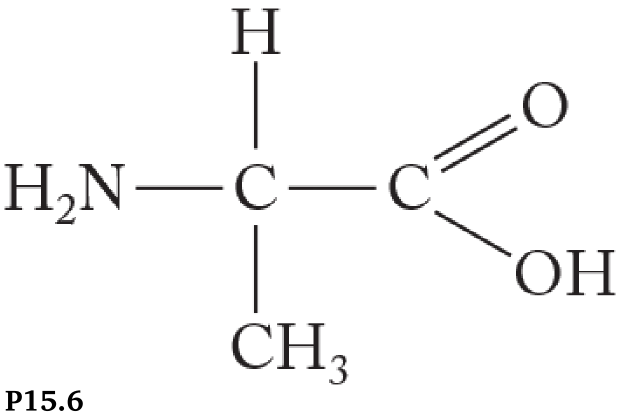
1. Is pseudoephedrine an acidic, basic, or neutral compound?
2. Which functional group in its structure gives it the property you selected in part (a)?



FIGURE

P15.5

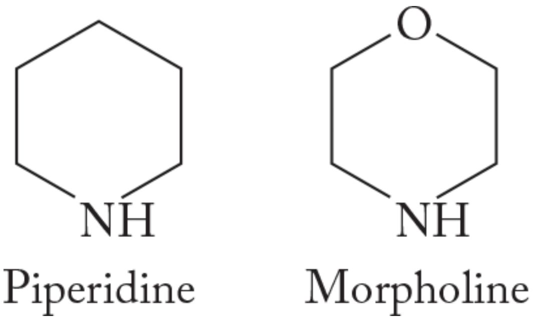
Figure P15.6 shows the molecular structure of alanine. Is an aqueous solution of alanine acidic, basic, or neutral? Explain your selection, or explain what additional information you need to make a more informed selection.



FIGURE

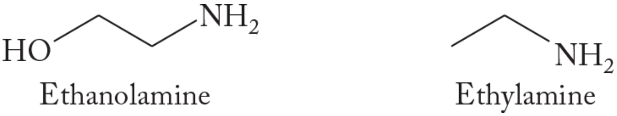
P15.6

Figure P15.7 shows the skeletal structures of piperidine and morpholine. Which is the stronger base? Explain your selection.



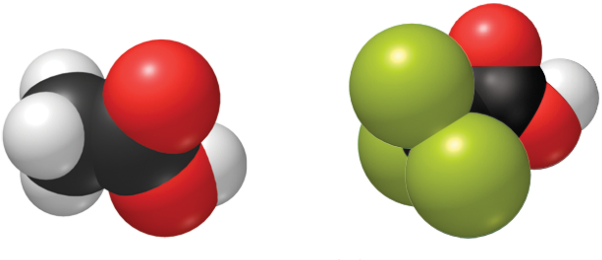
Piperidine Morpholine **FIGURE P15.7**

Based on the skeletal structures shown in Figure P15.8, is ethanolamine or ethylamine the stronger base? Explain why you think so.



Ethanolamine Ethylamine **FIGURE P15.8**

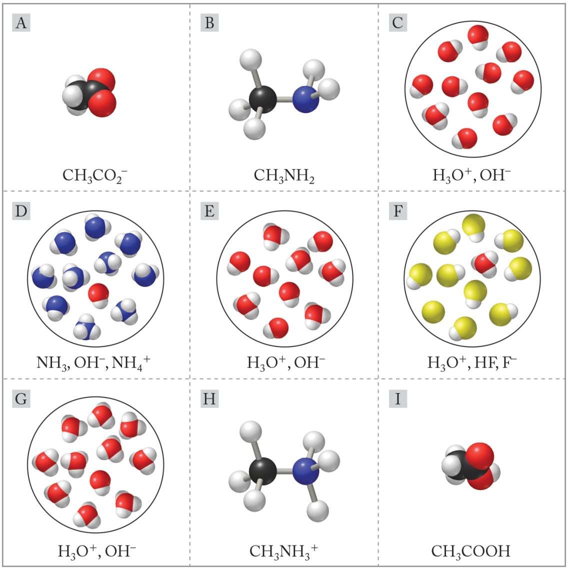
Figure P15.9 shows molecular models of acetic acid and trichloroacetic acid. Use these two models to explain why the K_a of trichloroacetic acid is about 10^4 times that of acetic acid.



Acetic acid Trichloroacetic acid **FIGURE P15.9**

Use representations [A] through [I] in Figure P15.10 to answer questions (a)–(f). Note that water has been omitted from the solutions in [D], [E], [F], and [G] for ease of viewing.

1. Which molecules are weak acids? Which are weak bases?
2. Which pairs of molecules represent conjugate acid–base pairs? (Give the letter of the acid first.)
3. Write net ionic equations describing the equilibria involving the conjugate pairs identified in part (b).
4. Which images represent acidic solutions?
5. Which images represent basic solutions?
6. Which image represents a neutral solution?



A
$CH_3CO_2^-$
B
CH_3NH_2
C
H_3O^+, OH^-
D
NH_3, OH^-, NH_4^+
E
H_3O^+, OH^-
F
H_3O^+, HF, F^-
G
H_3O^+, OH^-
H
$CH_3NH_3^+$
I
CH_3COOH

FIGURE P15.10

QUESTIONS AND PROBLEMS

The Molecular Structures and Strengths of Acids and Bases

Concept Review

In an aqueous solution of LiOH, which compound acts as a Brønsted–Lowry acid and which is the Brønsted–Lowry base?

In an aqueous solution of H_2SO_3, which compound acts as a Brønsted–Lowry acid and which is the Brønsted–Lowry base?

In an aqueous solution of methylamine, which species acts as a Brønsted–Lowry acid and which is the Brønsted–Lowry base?

Both NaOH and $Ba(OH)_2$ are strong bases. Does this mean that solutions of the two compounds with the same molarity have the same capacity to accept hydrogen ions? Why or why not?

Identify the acids and bases in the following reactions:

1. $HCl(aq) + NaOH(aq) \rightarrow NaCl(aq) + H_2O(\ell)$
2. $MgCO_3(s) + 2\ HCl(aq) \rightarrow$

   $MgCl_2(aq) + CO_2(g) + H_2O(\ell)$

3. $2\ NH_3(aq) + H_2SO_4(aq) \rightarrow (NH_4)_2SO_4(aq)$

Identify the acids and bases in the following reactions:

1. $(CH_3)_3N(aq) + H_2O(\ell) \rightleftharpoons (CH_3)_3NH^+(aq) + OH^-(aq)$
2. $CO_2(aq) + 2\ H_2O(\ell) \rightleftharpoons HCO_3^-(aq) + H_3O^+(aq)$
3. $(CH_3)_3COH(aq) + H_3O^+(aq) \rightleftharpoons$

   $(CH_3)_3COH_2^+(aq) + H_2O(\ell)$

Why is the K_{a2} of H_2SO_4 greater than the K_{a1} of H_2SeO_4?

Why is the K_{a2} of H_2SO_4 greater than the K_{a1} of H_2SO_3?

Why is the K_b of CH_3NH_2 greater than the K_b of NH_3?

Trifluoroacetic acid (CF_3COOH) is more than 10^4 times as strong as acetic acid (CH_3COOH). Explain why.

Problems

What is the concentration of H_3O^+ ions in a 0.65 *M* solution of HNO_3?

What is the concentration of H_3O^+ ions in a solution of hydrochloric acid that was prepared by diluting 7.5 mL of concentrated (11.6 *M*) HCl to a final volume of 100.0 L?

What is the value of $[OH^-]$ in a 0.0205 *M* solution of $Ba(OH)_2$?

Calcium hydroxide, also known as slaked lime, is used in industrial processes in which low concentrations of base are required. Only 0.16 g of $Ca(OH)_2$ dissolves in 100 mL of water at 25°C. What is the concentration of hydroxide ions in 250 mL of a solution containing the maximum amount of dissolved calcium hydroxide?

Conjugate Pairs

Concept Review

Identify the conjugate base of each of the following compounds: HF, $HBrO_2$, H_2SO_4, and $HClO_4$.

Identify the conjugate acid of each of the following species: $(CH_3)_2NH$, CH_3COO^-, ClO^-, and OH^-.

What is the conjugate acid of the dihydrogen phosphate ion ($H_2PO_4^-$), and what is its conjugate base?

Why is it unnecessary to publish tables of K_b values of the conjugate bases of weak acids whose K_a values are known?

pH and the Autoionization of Water

Concept Review

Explain why high pH values correspond to low acidities.

Solution A is 1000 times more acidic than solution B. What is the difference in the pH values of solution A and solution B?

Describe a solution (solute and concentration) that has a negative pH value.

Describe a solution (solute and concentration) that has a negative pOH value.

Draw the Lewis structures of the ions that would be produced if pure methanol autoionizes.

Liquid ammonia autoionizes at a temperature of 223 K. The value of the equilibrium constant for the autoionization of ammonia is considerably less than that of water. Write an equation for the autoionization of ammonia and suggest a reason why the value of *K* for the process is less than that of water.

Problems

Calculate the pH and pOH of solutions with the following $[H_3O^+]$ or $[OH^-]$ values. Indicate which solutions are acidic, basic, or neutral.

$[H_3O^+]$1.= $2.4 \times 10^{-4}\ M$
$[H_3O^+]$2.= $5.5 \times 10^{-8}\ M$
$[OH^-]$ 3.= $2.6 \times 10^{-2}\ M$
$[OH^-]$ 4.= $1.0 \times 10^{-14}\ M$

Calculate the pH and pOH of the solutions with the following hydrogen ion or hydroxide ion concentrations. Indicate which solutions are acidic, basic, or neutral.

1. $[OH^-] = 1.0 \times 10^{-7}\ M$
2. $[OH^-] = 3.9 \times 10^{-2}\ M$
3. $[H_3O^+] = 8.8 \times 10^{-4}\ M$
4. $[H_3O^+] = 5.9 \times 10^{-8}\ M$

Calculate the concentration of the following ions in the solution described:

1. $[OH^-]$ in $7.7 \times 10^{-4}\ M$ NaOH
2. $[OH^-]$ in $6.2 \times 10^{-3}\ M$ $Ca(OH)_2$
3. $[H_3O^+]$ in $1.9 \times 10^{-2}\ M$ HCl
4. $[H_3O^+]$ in $4.4 \times 10^{-4}\ M$ HCl

Determine the indicated pH or pOH values:

1. pH of a solution whose pOH = 5.5
2. pH of a solution whose pOH = 6.8
3. pOH of a solution whose pH = 9.7
4. pOH of a solution whose pH = 4.4

Calculate the pH and pOH of the following solutions:

1. stomach acid in which [HCl] = 0.155 *M*
2. 0.00500 *M* HNO_3
3. a 2:1 mixture of 0.0125 *M* HCl and 0.0125 *M* NaOH
4. a 3:1 mixture of 0.0125 *M* H_2SO_4 and 0.0125 *M* KOH

Calculate the pH and pOH of the following solutions:

1. 0.0450 *M* NaOH
2. 0.160 *M* $Ca(OH)_2$
3. a 1:1 mixture of 0.0125 *M* HCl and 0.0125 *M* $Ca(OH)_2$
4. a 2:3 mixture of 0.0125 *M* HNO_3 and 0.0125 *M* KOH

Calculate the pH of a $1.33 \times 10^{-9} M$ solution of LiOH.

Calculate the pH of a $6.9 \times 10^{-8} M$ solution of HBr.

Calculations Involving pH, K_a, and K_b

Concept Review

One-molar solutions of the following acids are prepared: CH_3COOH, HNO_2, HClO, and HCl.

1. Rank them in order of decreasing $[H_3O^+]$.
2. Rank them in order of increasing strength as acids (weakest to strongest).

On the basis of the following degree-of-ionization data for 0.100 *M* solutions, select which acid has the largest K_a.

Acid	Degree of Ionization (%)
C_6H_5COOH	2.5
HF	8.5
HN_3	1.4
CH_3COOH	1.3

A 1.0 *M* aqueous solution of HCl conducts electricity better than a 1.0 *M* solution of HF. Explain why.

Hydrogen chloride and water are molecular compounds, yet a solution of HCl dissolved in H_2O is an excellent conductor of electricity. Explain why.

When 1,2-diaminoethane ($H_2NCH_2CH_2NH_2$) dissolves in water, the resulting solution is basic. Write the formula of the ionic compound that is formed when hydrochloric acid is added to a solution of 1,2-diaminoethane.

Early Antiseptic The use of phenol, also known as carbolic acid, was pioneered in the 19th century by Sir Joseph Lister (after whom Listerine was named) as an antiseptic in surgery. Its formula is $C_6H_5\mathbf{OH}$; the red hydrogen atom is ionizable. Write the mass action expression for the acid ionization equilibrium of phenol.

The K_a values of weak acids depend on the solvent in which they dissolve. For example, the K_a of alanine in aqueous ethanol is less than its K_a in water.

1. In which solvent does alanine ionize more?
2. Which is the stronger Brønsted–Lowry base: water or ethanol?

The K_a of proline is 2.5×10^{-11} in water, 2.8×10^{-11} in an aqueous solution that is 28% ethanol, and 1.66×10^{-8} in aqueous formaldehyde at 25°C.

1. In which solvent is proline the strongest acid?
2. Rank water, ethanol, and formaldehyde based on their strengths as Brønsted–Lowry bases.

Problems

Muscle Physiology During strenuous exercise, lactic acid builds up in muscle tissues. In a 1.00 *M* aqueous solution, 2.94% of lactic acid is ionized. What is the value of its K_a?

Rancid Butter The odor of spoiled butter is caused in part by butanoic acid, which results from the chemical breakdown of butterfat. A 0.100 *M* solution of butanoic acid is 1.23% ionized. Calculate the value of K_a for butanoic acid.

At equilibrium, the value of $[H_3O^+]$ in a 0.250 *M* solution of an unknown acid is $3.36 \times 10^{-3} M$. Determine the degree of ionization of the acid and its K_a value.

Poisonous Plant Gifblaar is a small South African shrub and one of the most poisonous plants known because it contains fluoroacetic acid. If a 0.480 *M* solution of fluoroacetic acid has a pH of 1.44, what is the K_a of the acid?

Acid Rain I A weather system moving through the American Midwest produced rain with an average pH of 5.02. By the time the system reached New England, the rain it produced had an average pH of 4.66. How much more acidic was the rain falling in New England?

Acid Rain II A newspaper reported that the “level of acidity” in a sample taken from an extensively studied watershed in New Hampshire in 1998 was “an astounding 200 times lower than the worst measurement” taken in the preceding 23 years. What is this difference expressed in units of pH?

The K_b of aminoethanol ($HOCH_2CH_2NH_2$) is 3.1×10^{-5}.

1. Is aminoethanol a stronger or weaker base than ethylamine, $pK_b = 3.36$?
2. Calculate the pH of a $1.67 \times 10^{-2} M$ solution of aminoethanol.
3. Calculate the $[OH^-]$ concentration of a $4.25 \times 10^{-4} M$ solution of aminoethanol.

Food Dye Quinoline is a weakly basic liquid used in the manufacture of quinoline yellow, a greenish-yellow dye for foods, and in the production of niacin. Its pK_b is 9.15.

1. What is the pH of a 0.0752 M solution of quinoline?
2. What is the hydroxide ion concentration of the solution in part (a)?

Painkillers Morphine is an effective painkiller but is also highly addictive. Codeine is a popular prescription painkiller because it is much less addictive than morphine. Codeine contains a basic nitrogen atom that can be protonated to give the conjugate acid of codeine.

1. Calculate the pH of a $1.8 \times 10^{-3} M$ solution of morphine if its $pK_b = 5.79$.
2. Calculate the pH of a $2.7 \times 10^{-4} M$ solution of codeine if the pK_a of the conjugate acid is 8.21.

The awful odor of dead fish is caused mostly by trimethylamine

$[(CH_3)_3N]$, one of three compounds related to ammonia in which methyl groups replace one, two, or all three of the H atoms in ammonia.

1. The K_b of trimethylamine $[(CH_3)_3N]$ is 6.5×10^{-5} at 25°C. Calculate the pH of a $3.00 \times 10^{-4} M$ solution of trimethylamine.
2. The K_b of methylamine $[(CH_3)NH_2]$ is 4.4×10^{-4} at 25°C. Calculate the pH of a $2.88 \times 10^{-3} M$ solution of methylamine.
3. The K_b of dimethylamine $[(CH_3)_2NH]$ is 5.9×10^{-4} at 25°C. What concentration of dimethylamine is needed for the solution to have the same pH as the solution in part (b)?

Nicotine Addiction Nicotine is responsible for the addictive properties of tobacco. What is the pH of a $1.00 \times 10^{-3} M$ solution of nicotine?

Pseudoephedrine hydrochloride (Figure P15.62) is a common ingredient in cough syrups and decongestants. Its pK_a = 9.22. What is the pH of a solution that is 0.0295 *M* in pseudoephedrine hydrochloride?

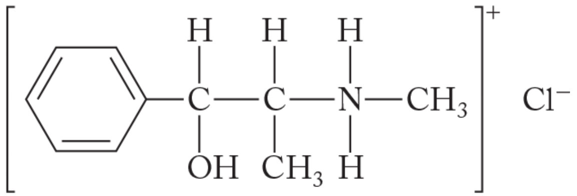


FIGURE P15.62

Polyprotic Acids

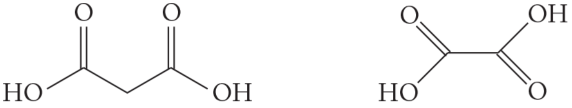
Concept Review

Why is the K_{a2} value of phosphoric acid less than its K_{a1} value but greater than its K_{a3} value?

In calculating the pH of a 1.0 *M* solution of H_2SO_3, we can ignore the H^+ ions produced by the ionization of the bisulfate (HSO_3^-) ion; however, in calculating the pH of a 1.0 *M* solution of sulfuric acid, we cannot ignore the H^+ ions produced by the ionization of the bisulfate ion. Why?

Carbonic acid (H_2CO_3) is a very weak diprotic acid ($K_{a1} = 4.3 \times 10^{-7}$), but germanic acid ($H_2GeO_3$) is even weaker ($K_{a1} = 9.8 \times 10^{-10}$). Suggest a reason why.

Figure P15.66 contains skeletal structures of the dicarboxylic acids malonic acid and oxalic acid. The K_{a1} of malonic acid is about 10^4 times larger than its K_{a2}, whereas the K_{a1} of oxalic acid is about 10^3 times larger than its K_{a2}. Suggest a reason why the separation in K_a values is greater for malonic acid.



Malonic acid

Oxalic acid

FIGURE P15.66

Problems

What is the pH of a 2.00 *M* solution of H_2SO_4?

What is the pH of a 2.00 *M* solution of H_2SO_3?

Ascorbic acid (vitamin C) is a weak diprotic acid. What is the pH of a 0.250 *M* solution of ascorbic acid?

Rhubarb Pie The leaves of the rhubarb plant contain high concentrations of diprotic oxalic acid (HOOCCOOH) and must be removed before the stems are used to make rhubarb pie. What is the pH of a 0.0288 *M* solution of oxalic acid?

Malaria Treatment Quinine occurs naturally in the bark of the cinchona tree. For centuries it was the only treatment for malaria. Calculate the pH of a 0.01050 *M* solution of quinine in water.

Dozens of pharmaceuticals, ranging from cyclizine for motion sickness to Viagra for impotence, are derived from the organic compound piperazine (Figure P15.72).

1. Solutions of piperazine are basic $K_{b1} = 5.28 \times 10^{-5}$; $K_{b2} = 2.15 \times 10^{-9}$. What is the pH of a 0.0125 *M* solution of piperazine?
2. Draw the structure of the ionic form of piperazine that would be present in stomach acid (about 0.16 *M* HCl).

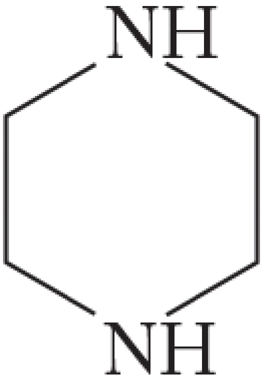


FIGURE P15.72

Acidic and Basic Salts

Concept Review

Which of the following salts produces an acidic solution in water:

ammonium acetate, ammonium nitrate, or sodium formate?

Which of the following salts produces a basic solution in water: NaF, KCl, NH_4Cl?

Neutralizing the Smell of Fish Trimethylamine $[(CH_3)_3N]$, $K_b = 6.5 \times 10^{-5}$ at 25°C, is a contributor to the "fishy" odor of not-so-fresh seafood. Some people squeeze fresh lemon juice (which contains a high concentration of citric acid) on cooked fish to reduce the fishy odor. Why is this practice effective?

Nutritional Value of Beets Beets contain high concentrations of the calcium salt of malonic acid (see Figure P15.66). Could the presence of the calcium salt of malonic acid affect the pH balance of beets? If so, in which direction? Explain.

Problems

The K_a of the conjugate acid of the artificial sweetener saccharin is 5.9×10^{-11}. What is the pK_b for saccharin?

The K_{a1} value for oxalic acid (HOOCCOOH) is 5.9×10^{-2}, and the K_{a2} value is 6.4×10^{-5}. What are the values of K_{b1} and K_{b2} of the oxalate anion ($^{-}OOCCOO^{-}$)?

Dental Health Sodium fluoride is added to many municipal water supplies to reduce tooth decay. Calculate the pH of a 0.00339 *M* solution of NaF at 25°C.

Calculate the pH of a $1.25 \times 10^{-2} M$ solution of the decongestant ephedrine hydrochloride if the pK_b of ephedrine (its conjugate base) is 3.86.

Additional Problems

Consider the following compounds: CH_3NH_2, CH_3COOH, $Ca(OH)_2$, and $HClO_4$.

1. Identify the Arrhenius acid(s).
2. Identify the Arrhenius base(s).
3. Identify the Brønsted–Lowry acid(s).
4. Identify the Brønsted–Lowry base(s).

Are all Arrhenius acids also Brønsted–Lowry acids? Are all Brønsted–Lowry acids also Arrhenius acids? If yes, explain why. If not, give a specific example to demonstrate the difference.

Are all Arrhenius bases also Brønsted–Lowry bases? Are all Brønsted–Lowry bases also Arrhenius bases? If yes, explain why. If not, give a specific example to demonstrate the difference.

Describe the intermolecular forces and changes in bonding that lead to the formation of a basic solution when methylamine (CH_3NH_2) dissolves in water.

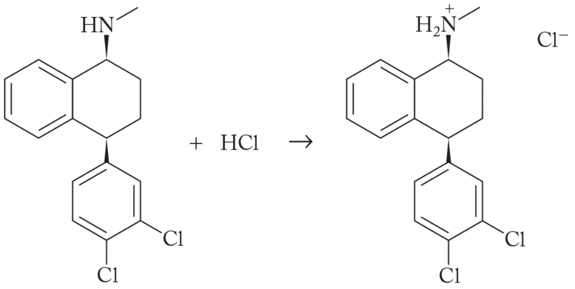
Describe the chemical reactions of sulfur that begin with the burning of high-sulfur fossil fuel and that end with the reaction between acid rain and building exteriors made of marble ($CaCO_3$).

The K_{a1} of phosphorous acid (H_3PO_3) is nearly the same as the K_{a1} of phosphoric acid (H_3PO_4).

1. Draw the Lewis structure of phosphorous acid.
2. Identify the ionizable hydrogen atoms in the structure.
3. Explain why the K_{a1} values of phosphoric and phosphorous acid are similar.

pH of Natural Waters In a 1985 study of Little Rock Lake in Wisconsin, 400 gallons of 18 *M* sulfuric acid were added to the lake over six years. The initial pH of the lake was 6.1 and the final pH was 4.7. If none of the acid was consumed in chemical reactions, estimate the volume of the lake.

Acid–Base Properties of Pharmaceuticals I Sertraline (also known by the trade name Zoloft) is a prescription drug for the treatment of depression. It is sold as its hydrochloride salt, which has the structure shown in Figure P15.88. When the hydrochloride dissolves in water, will the resulting solution be acidic or basic?

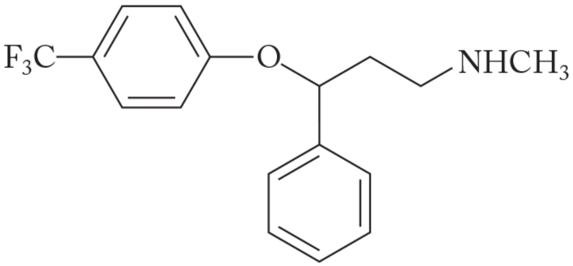


Zoloft

FIGURE P15.88

Acid–Base Properties of Pharmaceuticals II Fluoxetine (also known by the trade name Prozac; Figure P15.89) is a popular antidepressant drug.

1. Is a solution of fluoxetine in water likely to be acidic or basic? Explain your answer.
2. Fluoxetine is also sold as a hydrochloride salt. Which functional group is most likely to react with HCl?
3. Fluoxetine is sold as its hydrochloride because the solubility of the salt in water is higher than that of unreacted fluoxetine. Why is the salt more soluble?



Prozac

FIGURE P15.89

Naproxen (also known as Aleve; Figure P15.90) is an anti-inflammatory drug used to reduce pain, fever, inflammation, and stiffness caused by conditions such as osteoarthritis and rheumatoid arthritis. Naproxen is an organic acid that has limited solubility in water, so it is sold as its sodium salt.

1. Draw the molecular structure of the sodium salt.
2. Is an aqueous solution of the salt acidic or basic? Explain why.
3. Explain why the salt is more soluble in water than naproxen itself.

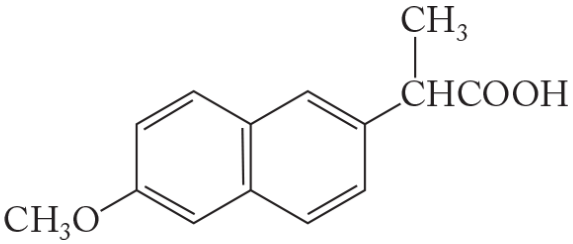


FIGURE P15.90

Pentafluorocyclopentadiene (Figure P15.91) is a strong acid.

1. Draw the conjugate base of C_5F_5H.

2. Pentafluorocyclopentadiene is very acidic, whereas most organic acids are weak. Why?

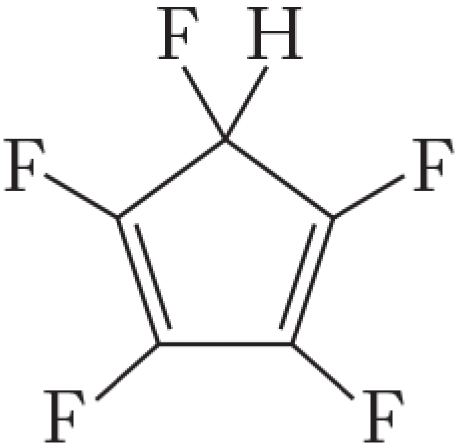

FIGURE P15.91

Ocean Acidification Some climate models predict a decrease in the pH of the oceans of 0.3 to 0.5 pH units by 2100 because of increases in atmospheric carbon dioxide.

1. Explain, by using the appropriate chemical reactions and equilibria, how an increase in atmospheric CO_2 could produce a decrease in oceanic pH.
2. How much more acidic would the oceans be if their pH dropped this much?
3. Oceanographers are concerned about how a drop in oceanic pH could affect the survival of coral reefs. Why?

Sulfuric acid reacts with nitric acid as follows:

$$HNO_3\,(aq) + 2\,H_2SO_4(aq) \rightarrow NO_2^+(aq) + H_3O^+(aq)\ 2\,HSO_4^-(aq)$$

1. Is the reaction a redox process?
2. Identify the acid, base, conjugate acid, and conjugate base in the reaction. (*Hint*: Draw the Lewis structures for each.)

Thiosulfuric acid ($H_2S_2O_3$) can be prepared by the reaction of H_2S with HSO_3Cl:

$HSO_3Cl(\ell) + H_2S(g) \rightarrow HCl(g) + H_2S_2O_3(\ell)$

1. Draw a Lewis structure for $H_2S_2O_3$, given that it is isostructural with H_2SO_4.
2. Do you expect $H_2S_2O_3$ to be a stronger or weaker acid than H_2SO_4? Explain your answer.

The pK_a values of the conjugate acids of pyridine derivatives shown in Figure P15.95 increase as more methyl groups are added. Do more methyl groups increase or decrease the strength of the parent pyridine bases?

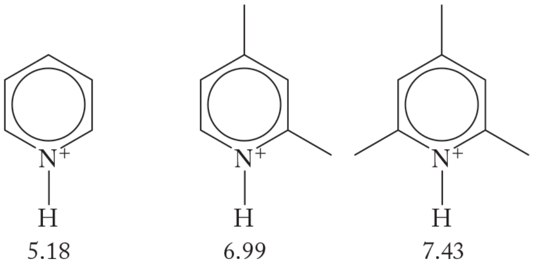

FIGURE P15.95

Compounds that do not ionize in water have been known to ionize in nonaqueous solvents. In such a solvent, what would be the conjugate acid and conjugate base of ethanol (CH_3CH_2OH)?

Glossary

conjugate base

the base formed when a Brønsted–Lowry acid donates a H 1 ion.

conjugate acid

the acid formed when a Brønsted–Lowry base accepts a H

1 ion.

pH

the negative logarithm of the hydronium ion concentration in an aqueous solution.

pOH

the negative logarithm of the hydroxide ion concentration in an aqueous solution.

degree of ionization

the ratio of the quantity of a substance that is ionized to the concentration of the substance before ionization; when expressed as a percentage, it is often called *percent ionization*.

polyprotic acid

an acid that has two or more ionizable hydrogen atoms per molecule.

CORAL REEF Increasing concentrations of CO_2 in the atmosphere are making seawater more acidic, which threatens corals and other marine life that form exoskeletons made of calcium carbonate.

Additional Aqueous Equilibria Chemistry and the Oceans

PARTICULATE REVIEW

Soluble or Insoluble?

In Chapter 16 we revisit the limited solubility of some ionic compounds in aqueous solutions. Here we see images representing aqueous solutions of four ionic compounds: calcium fluoride, potassium fluoride, lithium sulfide, and lead(II) sulfide. (To simplify the images, solvent water molecules are not shown.)

What is the chemical formula of each compound?

- Which two of these compounds are much less soluble in water than the other two?
- Match each particulate representation to one of the four compounds.

(Review Section 4.7 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

pH: To Change or Not to Change

Here are two representations of solutions that contain (a) hydrofluoric acid and (b) equal concentrations of both hydrofluoric acid and sodium fluoride. As you read Chapter 16, look for ideas that will help you answer these questions:

- Write a chemical equation describing the proton transfer equilibrium that occurs in each solution.
- Which solution(s) would resist a sharp rise in pH if some strong base were added?
- Which solution(s) would resist a sharp drop in pH if some strong acid were added?

Learning Outcomes

- LO1 Use Le Châtelier’s principle to explain the common-ion effect, and calculate the pH of a solution containing a weak acid or base and its conjugate base or acid

  Sample Exercises 16.1, 16.2

- LO2 Describe pH buffering and prepare a buffer with a desired pH and buffer capacity

  Sample Exercises 16.3, 16.4, 16.5

- LO3 Evaluate the capacity of a buffer to resist changes in its pH

  Sample Exercises 16.6, 16.7, 16.8

- LO4 Predict and interpret the results of an acid–base titration and describe how color indicators can be used to detect the equivalence points in these titrations

  Sample Exercises 16.9, 16.10, 16.11, 16.12

- LO5 Identify a compound as a Lewis acid or Lewis base in a reaction

  Sample Exercise 16.13

- LO6 Describe the bonding in complex ions and use their formation constants to calculate the concentrations of free and complexed metal ions in solution

  Sample Exercise 16.14

- LO7 Relate the acid strength of hydrated metal ions and their limited solubility in basic solutions to the charges on their ions
- LO8 Relate the solubility of an ionic compound to its solubility product constant and to solution pH

  Sample Exercises 16.15, 16.16, 16.17, 16.18

- LO9 Determine which mixtures of ionic compounds can be separated by selective precipitation reactions

  Sample Exercise 16.19

$$CO_2(g) + H_2O(\ell) \rightleftharpoons H_2CO_3(aq) \qquad (16.1)$$

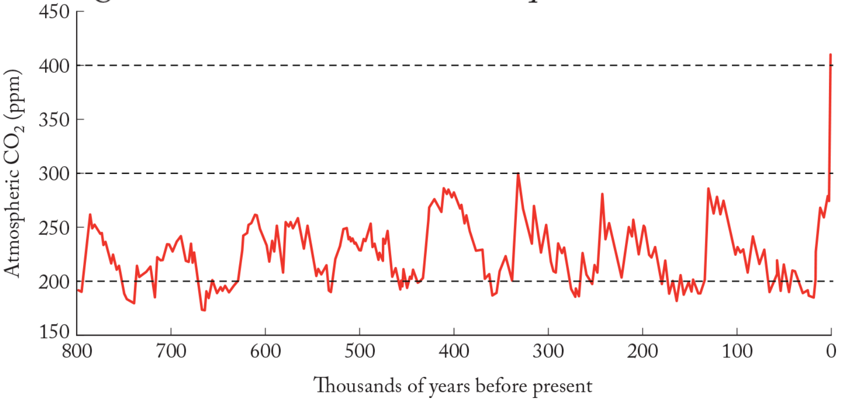

FIGURE 16.1 Analyses of bubbles of air trapped in Antarctic glaciers have enabled scientists to create a history of atmospheric CO_2 levels over the past 800,000 years, showing that atmospheric concentrations of CO_2 have generally oscillated between about 175 and 300 ppm. In recent years, however, CO_2 concentrations have sharply increased.

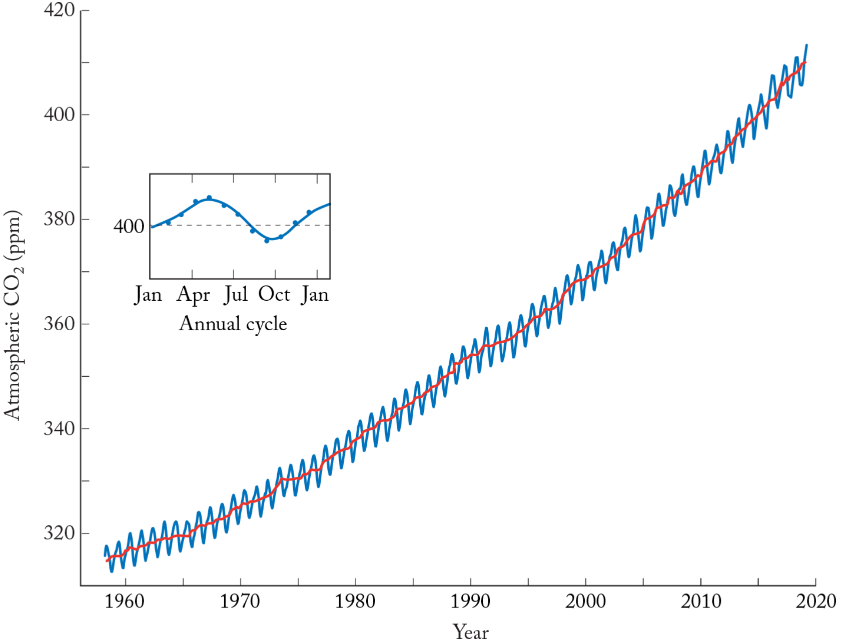

FIGURE 16.2 This graph of CO_2 concentrations in the atmosphere is based on analyses done since 1958 at the Mauna Loa Observatory in Hawaii—work begun by Charles David Keeling (1928–2005). The

annual cycle in the data is caused by seasonally changing rates of photosynthesis by trees and other vegetation in the Northern Hemisphere.

$$H_2CO_3(aq) + H_2O(\ell) \rightleftharpoons HCO_3^-(aq) + H_3O^+(aq) \quad K_{a_1} = 4.3 \times 10^{-7} \quad (16.2)$$

$$HCO_3^-(aq) + H_2O(\ell) \rightleftharpoons CO_3^{2-}(aq) + H_3O^+(aq) \quad K_{a_2} = 4.7 \times 10^{-11} \quad (16.3)$$

$$Ca^{2+}(aq) + CO_3^{2-}(aq) \rightleftharpoons CaCO_3(s)$$

16.1 Ocean Acidification: Equilibrium under Stress

Fossil fuel combustion is increasing the concentration of carbon dioxide in the atmosphere. We know this from historical records of atmospheric CO_2 concentrations. Part of this record is based on analyzing bubbles of air trapped in layers of glacial ice, which show that atmospheric CO_2 concentrations cycled between about 175 and 300 parts per million (ppm) by volume for at least 800,000 years (**Figure 16.1**). About 250 years ago, however, when CO_2 levels were already at the top of one of these cycles, they began to rise even more. Since the late 1950s, CO_2 concentrations have increased from 330 to over 410 ppm with no sign of slowing down (**Figure 16.2**).

In Chapter 8 we discussed the impact of increasing concentrations of CO_2 in the atmosphere on climate. It turns out that elevated atmospheric CO_2 concentration poses another environmental problem: ocean acidification. As we saw in Chapter 15, CO_2 gas dissolves in water, where it can form carbonic acid:

CONNECTION As discussed in Section 8.3, atmospheric CO_2 is a greenhouse gas because asymmetric stretching of the bonds in its molecules absorbs infrared radiation emitted by Earth’s surface.

Although H_2CO_3 is unstable in aqueous solutions, we write $[H_2CO_3]$ in this chapter to represent the total concentration of $CO_2(g)$ dissolved in water and to remind us that when $CO_2(g)$

dissolves in water, it forms an acidic solution:

We also saw in Chapter 15 that bicarbonate ions can donate a second H^+ ion in aqueous solution:

The value of K_{a2} is much smaller than K_{a1}, so the concentration of $CO_3{}^{2-}$ ions in slightly basic seawater is much smaller than the concentration of $HCO_3{}^-$ ions.

CONNECTION Henry's law (Section 10.8) states that the solubility of a gas (C_{gas}) is proportional to its partial pressure: $C_{gas} = k_H P_{gas}$.

The solubility of atmospheric CO_2 increases as its partial pressure increases, so higher concentrations of CO_2 in the atmosphere mean higher concentrations of dissolved CO_2 in the sea. Scientists estimate that about 30% of the "fossil" CO_2 added to the atmosphere dissolves in the sea. Increasing concentrations of dissolved CO_2 have shifted the equilibrium in Equation 16.1 to the right. This, in turn, has shifted the equilibrium in Equation 16.2 to the right resulting in an increase in the acidity of the sea. As a result, the average pH of seawater has dropped by about 0.11 pH units since the 18th century.

CONNECTION Le Châtelier's principle (Section 14.7) predicts how a system at equilibrium responds to stress.

Are oceans with lower pH a problem? They are—especially if the pH continues to drop—because many marine organisms such as plankton, shellfish, and corals have exoskeletons made of $CaCO_3$. To make $CaCO_3$, these organisms need a supply of dissolved Ca^{2+} and $CO_3{}^{2-}$ ions so that the following precipitation reaction can take place:

Unfortunately, increasing concentrations of H_3O^+ ions in the sea drive down already small concentrations of $CO_3{}^{2-}$ ions by shifting the equilibrium in Equation 16.3 to the left. There is a growing concern that the oceanic $[CO_3{}^{2-}]$ may become too low for marine organisms to form their $CaCO_3$ skeletons and that they—and the aquatic systems that rely on them, such as tropical coral reefs—will not survive.

In Chapter 16 we explore the equilibria that control the pH of the sea and of other environmental and biological systems and explain how to measure the capacity of environmental waters and biological fluids to control pH. We also examine how changes in pH can affect other equilibria, such as those that control the formation of sparingly soluble substances such as $CaCO_3$.

$$K_{a_1} = \frac{[HCO_3^-][H_3O^+]}{[H_2CO_3]} = \frac{x \cdot x}{(2.7 \times 10^{-3}) - x} \approx \frac{x^2}{2.7 \times 10^{-3}} = 4.3 \times 10^{-7}$$

$$x = [H_3O^+] = 3.4 \times 10^{-5}\ M$$

$$K_a = \frac{[H_3O^+][A^-]_{\text{initial}}}{[HA]_{\text{initial}}}$$

$$pK_a = pH - \log\frac{[A^-]}{[HA]} \qquad \text{or} \qquad pH = pK_a + \log\frac{[A^-]}{[HA]}$$

$$pH = pK_a + \log\frac{[\text{base}]}{[\text{acid}]} \tag{16.4}$$

$$pH = pK_a + \log\frac{10[\text{acid}]}{[\text{acid}]}$$

$$= pK_a + \log 10 = pK_a + 1$$

$$pH = pK_a + \log\frac{[\text{base}]}{[\text{acid}]}$$

$$pH = pK_{a_1} + \log\frac{[\text{base}]}{[\text{acid}]} = 6.37 + \log\frac{1.0 \times 10^{-4}}{1.4 \times 10^{-5}}$$

$$= 6.37 + 0.85 = 7.22$$

$$pK_a + pK_b = 14.00 \tag{16.5}$$

$$\mathrm{pH} = \mathrm{p}K_a + \log\frac{[\text{base}]}{[\text{acid}]}$$

$$= 9.25 + \log\frac{0.200}{0.300} = 9.07$$

16.2 The Common-Ion Effect

The chemical equilibria that control acid–base balance in natural systems—from seawater to the fluids in all living cells—depend on the presence of both acidic and basic compounds. We encountered one example in Sample Exercise 15.19, where we calculated the pH of blood plasma from the concentrations of CO_2 (2.7×10^{-3} *M*) and HCO_3^- (0.028 *M*) dissolved in it. These values gave us a [H_3O^+] value of 4.15×10^{-8} *M* and a pH of 7.38, which is in the normal range for human blood.

Now let's calculate the pH of a solution having the same concentration of dissolved CO_2 as in the blood plasma calculation (2.7×10^{-3} *M*), but initially containing no bicarbonate ions. We set up the appropriate RICE table with molar concentrations of the reactants and products, using [H_2CO_3] to represent the total amount of dissolved $CO_2(g)$ in solution:

Reaction (R)	$H_2CO_3(aq) + H_2O(\ell)$						
	[H_2CO_3] (*M*)						
Initial (I)	2.7×10^{-3}						
Change (C)	$-x$						
Equilibrium (E)	$(2.7 \times 10^{-3}) - x$						

Taking the K_{a1} value for carbonic acid (4.3×10^{-7}) from Equation 16.2, and solving for *x*:

Calculating pH:

$$pH = -\log[H_3O^+] = -\log(3.4 \times 10^{-5}) = 4.47$$

Thus, the new solution has a pH value nearly 3 units lower than the blood plasma sample (7.38), corresponding to a $[H_3O^+]$ value *nearly 10^3larger*. This difference makes sense because the presence of bicarbonate ions in the plasma sample inhibited the forward reaction in Equation 16.2, as predicted by Le Châtelier's principle. In this new solution, which lacks a second source of bicarbonate ions, the result is higher $[H_3O^+]$ and lower pH values.

The difference in pH between these two solutions illustrates a principle known as the common-ion effect: in any ionic equilibrium, a reaction produces less of an ion when that ion is already in the system or if more of it is added to the system. One result of this suppression of the ionization reaction is that the initial concentrations of the conjugate acid–base pair change very little before equilibrium is achieved. Therefore, we can use their initial concentrations to calculate the pH of their solution, as illustrated for this generic acid ionization equilibrium involving a solution of acid, HA, and its conjugate base, A^-:

If we take the negative logarithm of both sides of the K_a expression, we transform $[H_3O^+]$ into pH and K_a into pK_a:

Generalizing this equation by replacing [HA] and $[A^-]$ with [acid] and [base], respectively:

CONNECTION The pH of a solution is the negative logarithm of its hydronium ion concentration (see Equation 15.10 in Section 15.4).

Equation 16.4 is used to calculate the pH of solutions in which there are comparable concentrations of both an acid and its conjugate base (or both a base and its conjugate acid). It is called the Henderson–Hasselbalch equation. The presence of the conjugate base (or conjugate acid) suppresses the ionization reaction because of the common-ion effect. As a result, the equilibrium concentrations of the conjugate pairs are not significantly different from their initial concentrations.

What happens to the logarithm term in the Henderson–Hasselbalch equation when the concentrations of acid and base are equal? The numerator and denominator are the same, so the value of the fraction in Equation 16.4 is 1. The log of 1 is 0, so $\mathrm{pH} = \mathrm{p}K_a$. This equality serves as a handy reference point in working with solutions of conjugate acid–base pairs. If the concentration of the basic component is greater than that of the acid, then the logarithmic term is positive and $\mathrm{pH} > \mathrm{p}K_a$. If [base] < [acid], on the other hand, then the logarithmic term is negative, and $\mathrm{pH} < \mathrm{p}K_a$.

CONNECTION The $\mathrm{p}K_a$ notation (Section 15.4) is an equivalent expression of K_a values but without using scientific notation and negative exponents.

Suppose the concentration of the base is 10 times the concentration of the acid; that is, [base] = 10[acid]. Substituting this equality into Equation 16.4, we have

Thus, a 10-fold higher concentration of base produces a pH that is 1 unit above the $\mathrm{p}K_a$ value. Similarly, if the concentration of the acid component is 10 times that of the base, then $\mathrm{pH} = \mathrm{p}K_a - 1$. Sample Exercises 16.1 and 16.2 further illustrate how the Henderson–Hasselbalch equation simplifies pH calculations when we know the concentrations of both components of conjugate pairs.

SAMPLE EXERCISE 16.1 Calculating the pH of a Solution of a Weak Acid and Its Conjugate Base LO1

What is the pH of a sample of river water in which $[HCO_3^-] = 1.0 \times 10^{-4} M$ and the concentration of dissolved CO_2 in equilibrium with atmospheric CO_2 is $1.4 \times 10^{-5} M$?

Collect and Organize We are given the concentration of $CO_2(aq)$, which we will represent as $[H_2CO_3]$. We also know the concentration of the conjugate base of H_2CO_3—namely, HCO_3^-. The pH of a solution of a weak acid and its conjugate base can be calculated using the Henderson–Hasselbalch equation:

Analyze The conjugate acid–base pair relationship in this reaction is described by Equation 16.2:

$$H_2CO_3(aq) + H_2O(\ell) \rightleftharpoons HCO_3^-(aq) + H_3O^+(aq)$$

This reaction has a pK_{a1} value (Table A5.1) of 6.37. The concentration of the base is nearly 10 times the concentration of the acid, so the log term in the Henderson–Hasselbalch equation should be almost 1, and the calculated pH should be about 7.

Solve Inserting the concentration and pK_{a1} values into the Henderson–Hasselbalch equation:

Think About It This result is near the pH value we expected. Remember that a pH value of 7.22 contains only two significant figures (the 2 and the 2) because there were two significant figures in all three of the values used to calculate it. The 7 in pH 7.22 is not significant because its function is to tell us that the corresponding $[H_3O^+]$ value is between 10^{-7} and $10^{-8} M$.

Practice Exercise What is the pH of a solution in which $[HCOOH] = 2.5 \times 10^{-2} M$ and $[HCOO^-] = 7.8 \times 10^{-3} M$?

(Answers to Practice Exercises are in the back of the book.)

We can also use the Henderson–Hasselbalch equation to calculate the pH of a solution of a weak base and its conjugate acid. An extra step is usually involved because we may know the pK_b value of the base but not the pK_a value of its conjugate acid, and only pK_a values are used in the Henderson–Hasselbalch equation. However, we learned in Section 15.8 that the equilibrium constants for conjugate acid–base pairs are related by Equation 15.18 ($K_a \times K_b = K_w$). To recast this as an equation with pK terms, we insert the numerical value of K_w at 25°C (1.0×10^{-14}):

$$K_a \times K_b = K_w = 1.0 \times 10^{-14}$$

and take the –log values of all three terms:

Thus, converting the pK_b of a base into the pK_a of its conjugate acid is simply a matter of subtracting the pK_b value from 14.00.

SAMPLE EXERCISE 16.2 Calculating the pH of a Solution of a Weak Base and Its Conjugate Acid LO1

What is the pH of a solution that is 0.200 *M* in NH_3 and 0.300 *M* in NH_4Cl?

Collect and Organize We are asked to calculate the pH of a solution containing known concentrations of a weak base (NH_3) and a salt of its conjugate acid (NH_4^+). We can use the Henderson–Hasselbalch equation to calculate the pH of such a solution from the concentrations of the two components and the pK_a of the acid. Table A5.3 contains K_b and pK_b values of common bases. The pK_a and pK_b values of a conjugate acid–base pair are related by Equation 16.5:

$$pK_a + pK_b = 14.00$$

Analyze Our approach involves converting the pK_b value for NH_3 from Table A5.3 (4.75) into a pK_a value. Addition of ammonium ion to a solution of ammonia should produce a solution that is still basic, but not as basic as a solution that contains only ammonia.

Solve Inserting the pK_b value into Equation 16.5, and solving for pK_a:

$$pK_a = 14.00 - pK_b = 14.00 - 4.75 = 9.25$$

We can then use this value and the given concentrations of NH_3 and NH_4^+ in Equation 16.4:

Think About It We predicted the solution would be basic, but not as basic as a solution of ammonia alone. To check whether this prediction was true, we can calculate the pH of 0.200 *M* NH_3 by using the approach we followed in Sample Exercise 15.12. The result is a pH of 11.27—more than 2 pH units higher (more basic) than the solution of ammonia and ammonium chloride in this exercise.

Practice Exercise Calculate the pH of a solution that is 0.100 *M* in methylamine and 0.150 *M* in methylammonium chloride.

Glossary

common-ion effect

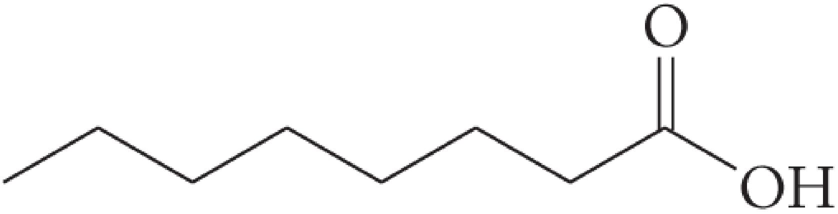
a shift in the position of an equilibrium caused by an ion taking part in the reaction.

Henderson–Hasselbalch equation

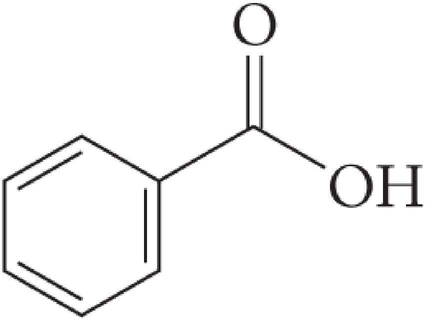
an equation used to calculate the pH of solutions containing comparable concentrations of acid and conjugate base.

Learning Objectives

- Use Le Châtelier's principle to explain the common-ion effect, and calculate the pH of a solution containing a weak acid or base and its conjugate base or acid **Return to Sample Exercises 16.1, 16.2**
- Use Le Châtelier's principle to explain the common-ion effect, and calculate the pH of a solution containing a weak acid or base and its conjugate base or acid **Return to Sample Exercises 16.1, 16.2**



Octanoic acid



Benzoic acid

FIGURE 16.3 Octanoic acid and benzoic acid are organic acids that are only slightly water soluble.

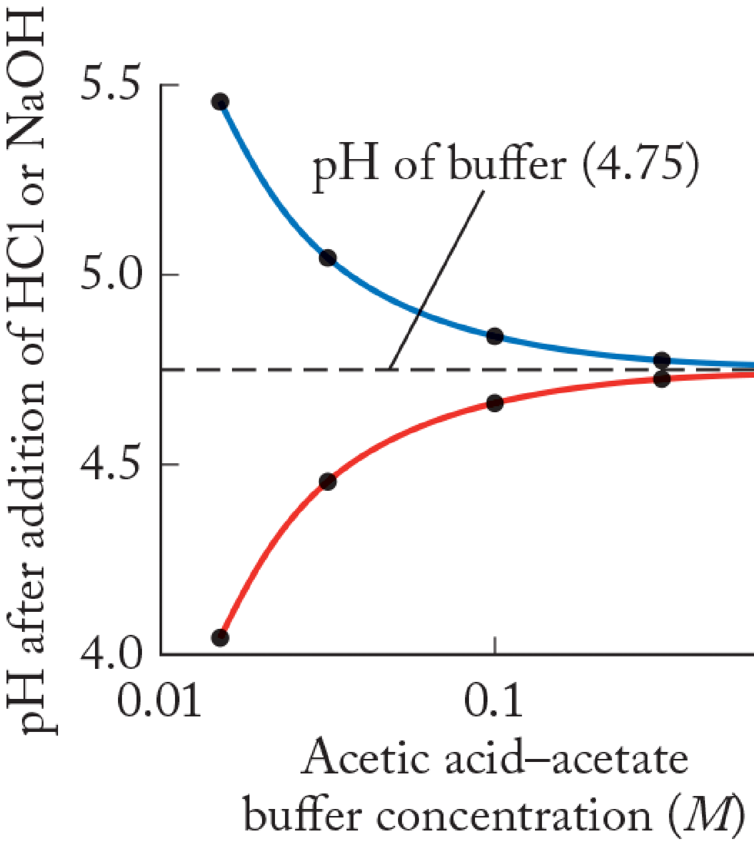


FIGURE 16.4 When strong acid (red line) or strong base (blue line) is added to a buffer solution, the extent to which the pH changes is inversely proportional to buffer concentration: the higher the concentrations of the buffer components, the smaller the change in pH. In this illustration, 100 mL samples of five solutions that are 0.015, 0.030, 0.100, 0.300, and 1.000 *M* acetic acid and sodium acetate all have an initial pH of 4.75 (dashed line). The graph shows the pH values of these solutions after 1.00 mL of 1.00 *M* HCl or 1.00 *M* NaOH has been added.

$$\text{pH} = \text{p}K_a + \log\frac{[\text{base}]}{[\text{acid}]} = 7.19 + \log\frac{[\text{HPO}_4{}^{2-}]}{[\text{H}_2\text{PO}_4{}^{-}]}$$

Buffer A: $\text{pH} = \text{p}K_a + \log\frac{n_{\text{CH}_3\text{COO}^-}}{n_{\text{CH}_3\text{COOH}}} = 4.75 + \log\frac{0.090\ \cancel{\text{mol}}}{0.110\ \cancel{\text{mol}}} = 4.66$

Buffer B: $\text{pH} = \text{p}K_a + \log\frac{n_{\text{CH}_3\text{COO}^-}}{n_{\text{CH}_3\text{COOH}}} = 4.75 + \log\frac{0.0050\ \cancel{\text{mol}}}{0.0250\ \cancel{\text{mol}}} = 4.05$

Buffer A, 0.25 mol NaOH added: $\mathrm{pH} = \mathrm{p}K_\mathrm{a} + \log \frac{n_\mathrm{base}}{n_\mathrm{acid}} = 3.75 + \log \frac{(1.00 + 0.25)}{(1.00 - 0.25)} = 3.97$

0.50 mol NaOH added: $\mathrm{pH} = \mathrm{p}K_\mathrm{a} + \log \frac{n_\mathrm{base}}{n_\mathrm{acid}} = 3.75 + \log \frac{(1.00 + 0.50)}{(1.00 - 0.50)} = 4.23$

0.75 mol NaOH added: $\mathrm{pH} = \mathrm{p}K_\mathrm{a} + \log \frac{n_\mathrm{base}}{n_\mathrm{acid}} = 3.75 + \log \frac{(1.00 + 0.75)}{(1.00 - 0.75)} = 4.60$

Buffer B, 0.25 mol NaOH added: $\mathrm{pH} = \mathrm{p}K_\mathrm{a} + \log \frac{n_\mathrm{base}}{n_\mathrm{acid}} = 4.23 + \log \frac{(0.50 + 0.25)}{(1.50 - 0.25)} = 4.01$

0.50 mol NaOH added: $\mathrm{pH} = \mathrm{p}K_\mathrm{a} + \log \frac{n_\mathrm{base}}{n_\mathrm{acid}} = 4.23 + \log \frac{(0.50 + 0.50)}{(1.50 - 0.50)} = 4.23$

0.75 mol NaOH added: $\mathrm{pH} = \mathrm{p}K_\mathrm{a} + \log \frac{n_\mathrm{base}}{n_\mathrm{acid}} = 4.23 + \log \frac{(0.50 + 0.75)}{(1.50 - 0.75)} = 4.45$

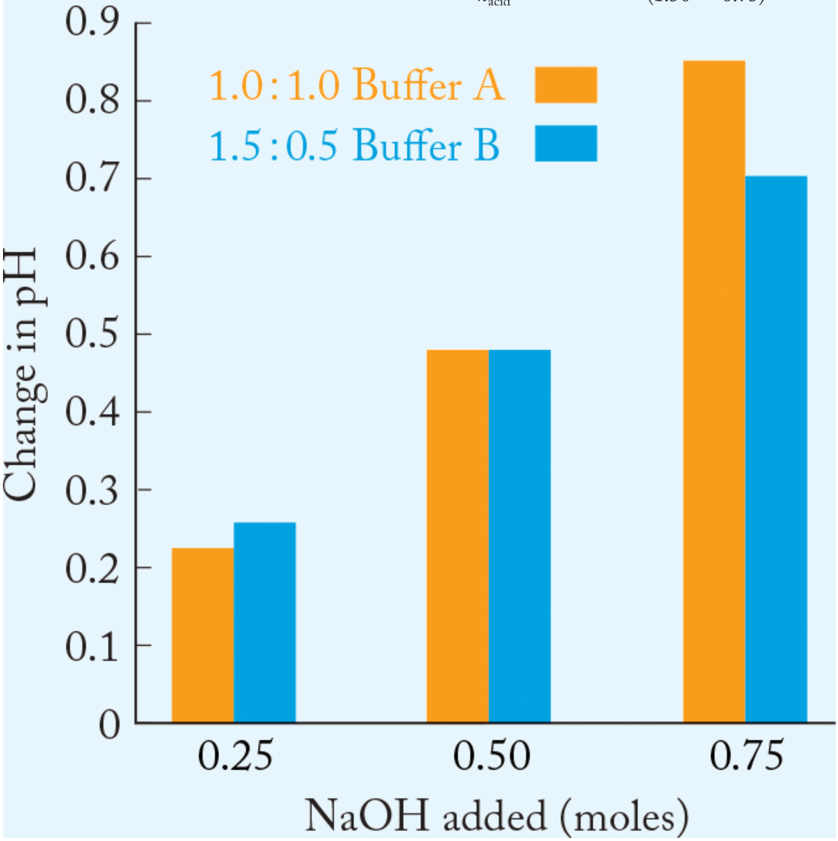

FIGURE 16.5 Changes in pH produced by additions of NaOH to two buffers. Buffer A contains equal molar concentration of a weak acid and its conjugate base; buffer B contains the same total concentration of acid and conjugate base as in A, but the mole ratio of acid to conjugate base is 3 to 1.

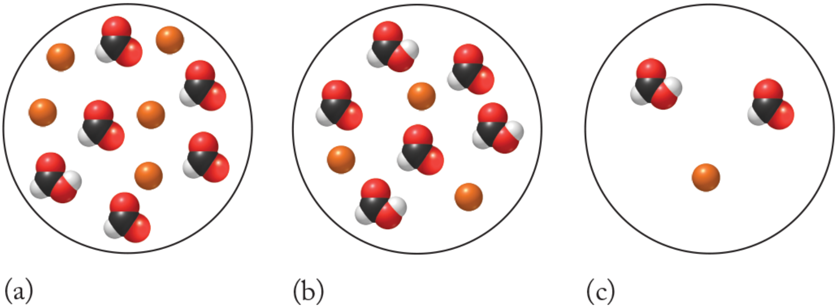

FIGURE 16.6 Possible representations of buffers.

16.3 pH Buffers

The common-ion effect plays a key role in controlling the pH of solutions that contain relatively high concentrations of both a weak acid and its conjugate base. These solutions have the capacity to withstand additions of acidic or basic substances with little or no measurable change in their pH, and they are known as pH buffers. A buffer solution maintains a constant pH because the weak acid component of the buffer gives it the capacity to neutralize additions of basic substances, whereas the conjugate base component gives it the capacity to neutralize acids. Ideally, a buffer has similar concentrations of both components of its conjugate pairs so that it can neutralize additions of acids or bases equally well. When the ratio of the conjugate pair is close to 1, the log term in the Henderson–Hasselbalch equation is close to 0, and the pH of the buffer is close to the pK_a of the weak acid in it. Actually, a buffer with different concentrations of its conjugate acid–base pair can still be effective at controlling pH over a range of pH values up to about 1 unit above or below its acid's pK_a value.

SAMPLE EXERCISE 16.3 Building an Acidic Buffer LO2

Select a weak acid in Table A5.1 of Appendix 5 that, when mixed with the sodium salt of its conjugate base in approximately equimolar proportions, produces a buffer with a pH of 2.80. Will the buffer contain *the same* concentrations of acid and conjugate base, or slightly more acid or base?

Collect, Organize, and Analyze The weak acid we seek is one whose $\mathrm{p}K_\mathrm{a}$ is close to the target pH, 2.80.

Solve Among the acids in Table A5.1 with $\mathrm{p}K_\mathrm{a}$ values near 2.80 are bromoacetic acid ($\mathrm{p}K_\mathrm{a} = 2.70$) and chloroacetic acid ($\mathrm{p}K_\mathrm{a} = 2.85$). Either could be used to prepare a buffer at pH 2.80, though neither would contain the same concentration of the acid and its conjugate base: the bromoacetic acid buffer would require a slightly higher concentration of the conjugate base, and the chloroacetic acid buffer would contain a little more of the acid.

Think About It A key factor in preparing an effective buffer is to select an acid with a $\mathrm{p}K_\mathrm{a}$ that is close (within 1 pH unit) to the target pH of the buffer. In this range the concentrations of the acid and its conjugate base, though perhaps not equal, are at least comparable, which means the buffer has the capacity to withstand additions of acidic or basic substances with only minor changes in pH. Another criterion for selecting weak acids for aqueous buffers is that they are soluble in water. Both acids selected in this sample exercise are carboxylic acids with relatively small molar masses and are quite soluble in water. However, organic acids with large hydrocarbon (hydrophobic) regions in their molecular structures, such as octanoic acid and benzoic acid (**Figure 16.3**), are only slightly soluble in water.

Practice Exercise Select a weak acid in Table A5.1 that, when mixed with the sodium salt of its conjugate base in approximately equimolar proportions, produces a buffer with a pH of 1.77.

CONNECTION The limited solubility of hydrophobic compounds in water is explained in Section 10.7.

SAMPLE EXERCISE 16.4 Building a Basic Buffer LO2

Select a weak base in Table A5.3 that, when mixed with the chloride salt of its conjugate acid in approximately equimolar proportions, produces a buffer with a pH of 9.25. Indicate whether the buffer will contain *the same* concentrations of base and conjugate acid, or slightly more base or acid.

Collect, Organize, and Analyze We can follow a strategy like that used in Sample Exercise 16.3, but we need to search the table for a weak base *that has a conjugate acid whose* $\mathrm{p}K_\mathrm{a}$ is close to the target pH of 9.25. This means we are looking for a base with a $\mathrm{p}K_\mathrm{b}$ value of $14.00 - 9.25 = 4.75$.

Solve According to Table A5.3, NH_3 has a $\mathrm{p}K_\mathrm{b}$ of 4.75, which exactly matches the target pH. This match means that the buffer should contain equimolar proportions of aqueous ammonia (NH_3) and ammonium chloride (NH_4Cl).

Think About It A buffer with equal concentrations of an acid–base conjugate pair can withstand additions of acid or base with equally small changes in pH.

Practice Exercise Select a weak base in Table A5.3 that, when mixed with the chloride salt of its conjugate acid in approximately equimolar proportions, produces a buffer with a pH of 10.93.

Having gained experience in selecting the components that are needed to prepare pH buffers, let’s now calculate the quantities of these components that are needed to prepare a volume of a buffer with a desired pH.

SAMPLE EXERCISE 16.5 Preparing a Buffer Solution with a Desired pH LO2

A buffer system containing dihydrogen phosphate ($H_2PO_4^-$) and hydrogen phosphate (HPO_4^{2-}) helps regulate the pH of cytoplasm in living cells.

1. What is the mole ratio of HPO_4^{2-} ions to $H_2PO_4^-$ ions in a buffer with a pH of 6.75?
2. If the combined concentration of $H_2PO_4^-$ and HPO_4^{2-} ions in the buffer is to be 0.200 *M*, how many grams of NaH_2PO_4 ($\mathscr{M}$ = 120.0 g/mol) and of Na_2HPO_4 ($\mathscr{M}$ = 142.0 g/mol) are needed to prepare 20.0 L of the buffer?

Collect and Organize We need to determine the mole ratio of HPO_4^{2-} ions to $H_2PO_4^-$ ions in a pH 6.75 buffer and to calculate the masses of the sodium salts of these ions that are needed to make 20.0 L of 0.200 *M* buffer. According to Table A5.1, the pK_a of $H_2PO_4^-$ (the pK_{a2} of H_3PO_4) is 7.19. The Henderson–Hasselbalch equation relates the pH of a buffer to the pK_a of its acid component and to the concentrations of that acid and its conjugate base.

Analyze The pH of this buffer is controlled by the acid ionization equilibrium of dihydrogen phosphate ions:

$$H_2PO_4^-(aq) + H_2O(\ell) \rightleftharpoons HPO_4^{2-}(aq) + H_3O^+(aq)$$

The target pH (6.75) is less than the pK_a (7.19), so the buffer must contain a higher concentration of $H_2PO_4^-$ ions (the acid) than HPO_4^{2-} ions (the base).

Solve

1. Let's rearrange the Henderson–Hasselbalch equation to solve for the ratio of base to acid.

$$\log \frac{[\text{base}]}{[\text{acid}]} = \text{pH} - pK_a$$

Substituting the values for pH and pK_a gives us:

$$\log \frac{[HPO_4^{2-}]}{[H_2PO_4^-]} = \text{pH} - pK_a = 6.75 - 7.19 = -0.44$$

Then the ratio of $[HPO_4^{2-}]$ to $[H_2PO_4^-]$ is

$$\frac{[HPO_4^{2-}]}{[H_2PO_4^-]} = 10^{-0.44} = 0.36$$

2. The sum of $[H_2PO_4^-]$ and $[HPO_4^{2-}]$ is 0.200 M, so if we let $x = [HPO_4^{2-}]$, then $[H_2PO_4^-] = (0.200 - x)\ M$. Calculating the dissolved concentrations of HPO_4^{2-} and $H_2PO_4^-$:

$$\frac{x}{0.200 - x} = 0.36$$

$$x = 0.36(0.200 - x)$$

$$1.36x = 0.072$$

$$x = [HPO_4^{2-}] = 0.053\ M$$

$$(0.200 - x) = [H_2PO_4^-] = 0.147\ M$$

The masses of their sodium salts in 20.0 L of buffer are

$$Na_2HPO_4\text{:}\quad 20.0\ \cancel{L} \times 0.053\ \frac{\cancel{mol}}{\cancel{L}} \times 142.0\ \frac{g}{\cancel{mol}} = 150\ g$$

$$NaH_2PO_4\text{:}\quad 20.0\ \cancel{L} \times 0.147\ \frac{\cancel{mol}}{\cancel{L}} \times 120.0\ \frac{g}{\cancel{mol}} = 353\ g$$

Think About It The buffer contains a higher concentration of $H_2PO_4^-$ ions than HPO_4^{2-} ions, which is consistent with our prediction and with the ratio of acid to conjugate base of any buffer that has a pH below the pK_a of the acid used to make it.

Practice Exercise How many grams of sodium ascorbate and ascorbic acid are needed to make 10.0 L of pH 5.25

buffer if the total concentration of the two buffer components is 0.500 *M*?

Buffer Capacity

In addition to selecting the appropriate conjugate acid–base pair to prepare a buffer, chemists also need to decide how concentrated the buffer should be. The greater the concentrations of the conjugate pair components, the greater is its buffer capacity—the ability of the buffer to withstand additions of acid or base without a significant change in pH (**Figure 16.4**).

SAMPLE EXERCISE 16.6 Calculating Buffer Response to Additions of Acid or Base LO3

1. What is the change in pH of the buffer prepared in Sample Exercise 16.5 if 1.00 mL of 0.200 *M* HNO_3 is added to 100.0 mL of the buffer?
2. Compare the pH change in part (a) to the pH change when the same quantity of acid is added to 100.0 mL pure water (pH = 7.00).

Collect and Organize We know the volume and composition of a pH buffer, and we are asked to determine how much the pH of the buffer changes when a known volume and concentration of acid is added. The buffer in Sample Exercise 16.5 contains 0.147 *M* $H_2PO_4^-$ ions and 0.053 *M* HPO_4^{2-} ions. Its pH is controlled by the acid ionization of $H_2PO_4^-$ ions

$$H_2PO_4^-(aq) + H_2O(\ell) \rightleftharpoons HPO_4^{2-}(aq) + H_3O^+(aq)$$

and can be calculated using the Henderson–Hasselbalch equation in which $H_2PO_4^-$ ions are the acid and HPO_4^{2-} ions are the base:

Analyze

1. When strong acid is added to a pH buffer, the acid is

neutralized by the base component of the buffer. In this exercise, HPO_4^{2-} ions neutralize added H_3O^+ ions as the acid ionization reaction runs in reverse:

$$HPO_4^{2-}(aq) + H_3O^+(aq) \rightarrow H_2PO_4^-(aq) + H_2O(\ell)$$

The single reaction arrow is used to indicate that the added acid is completely neutralized. Therefore, x mol H_3O^+ ions are completely consumed by x mol HPO_4^{2-} ions, producing x mol $H_2PO_4^-$ ions. To calculate the effect of these changes on buffer pH, we need to calculate the initial numbers of moles of $H_2PO_4^-$ and HPO_4^{2-} ions in 100.0 mL of buffer and then add or subtract the moles of H_3O^+ ions from these initial values as described above. The resulting mole ratio of HPO_4^{2-} ions to $H_2PO_4^-$ ions can be used in the above Henderson–Hasselbalch equation. The ratio will be less after some of the HPO_4^{2-} ions are consumed and $H_2PO_4^-$ ions are produced. Therefore, the final pH of the buffer should be less than its initial value of 6.75.

2. Adding a strong acid to pure water is an exercise in dilution, a concept introduced in Section 4.3 and for which we can use Equation 4.4:

$$V_{\text{initial}} \times M_{\text{initial}} = V_{\text{diluted}} \times M_{\text{diluted}}$$

Solve

1. A table that resembles a RICE table but that is based on neutralization of the added acid provides guidance in solving buffer capacity problems such as this one. It is sometimes called a ICA table because its rows contain the **I**nitial quantities of the reactants and product, the **C**hanges in those quantities during the reaction, and the quantities in solution **A**fter the reaction is complete. Using the given volume and concentration values and the strategy described in the Analyze section above:

$HPO_4^{2-}(aq)$ **$H_2PO_4^-(aq)$**						
Initial						

$$100 \times 0.0 = 5.3$$

$$1.0 \times 0.2 = 0.2$$

$$100.0\ \cancel{\text{mL}} \times 0.147\ \text{mol}/\cancel{\text{L}} = 14.7\ \text{mmol}$$

[illegible]

The mole ratio of HPO_4^{2-} and HPO_4^{2-} in the bottom row, 5.1 mmol/14.9 mmol, can be inserted directly in the log term of the Henderson–Hasselbalch equation to calculate pH because these two mole (*n*) quantities are dissolved in the same volume of solution. Therefore, the mole ratio has the same value as the concentration ratio (because the identical volume terms in the numerator and denominator cancel out).

$$\text{pH} = 7.19 + \log\frac{[\text{HPO}_4^{\ 2-}]}{[\text{H}_2\text{PO}_4^{\ -}]} = 7.19 + \log\frac{n_{\text{HPO}_4^{\ 2-}}}{n_{\text{H}_2\text{PO}_4^{\ -}}}$$

$$= 7.19 + \log\frac{5.1\ \cancel{\text{mol}}}{14.9\ \cancel{\text{mol}}} = 7.19 - 0.47 = 6.72$$

Thus, the addition of acid changes the pH of the buffer by $(6.72 - 6.75) = -0.03$ pH units.

2. Solving for M_{diluted} in Equation 4.4:

$$M_{\text{diluted}} = [\text{H}_3\text{O}^+] = \frac{V_{\text{initial}} \times M_{\text{initial}}}{V_{\text{diluted}}}$$

$$= \frac{1.00\ \text{mL} \times (0.200\ M)}{(100.0\ \text{mL} + 1.00\ \text{mL})} = 0.00198\ M$$

$$\text{pH} = -\log[\text{H}_3\text{O}^+] = -\log 0.00198 = 2.70$$

Thus, the change in pH of pure water is $(2.70 - 7.00) = -4.30$ pH units.

Think About It Addition of a strong acid lowered the pH of the buffer by only 0.03 pH units because it consumed only 0.2 mmol/5.3 mmol = 0.038 or 3.8% of the basic component of the buffer system. This decrease in pH is a tiny fraction of the change in pH that happened when the same quantity of acid was added to unbuffered pure water.

Practice Exercise What is the pH of a buffer that contains 0.225 *M* acetic acid and 0.375 *M* sodium acetate? What is the pH of 100.0 mL of the buffer after 1.00 mL of 0.318 *M* NaOH is added to it?

SAMPLE EXERCISE 16.7 Effect of Concentration on Buffer Capacity LO3

Calculate the buffer pH after 0.0100 moles of H_3O^+ ions are added to (a) 0.100 L of buffer A, containing 1.00 *M* acetic acid and 1.00 *M* sodium acetate, and (b) 0.100 L of buffer B, containing 0.150 *M* acetic acid and 0.150 *M* sodium acetate.

Collect and Organize We are asked to calculate the pH of equal volumes of two buffer solutions after the same quantity of acid (0.0100 mol H_3O^+) is added to both. According to Table A5.1, the pK_a of CH_3COOH is 4.75. The pH of a buffer with known concentrations of a conjugate acid–base pair can be calculated using the Henderson–Hasselbalch equation.

Analyze When strong acid is added to a pH buffer, the acid is neutralized by the base component of the buffer. In this example, the conjugate base of acetic acid, acetate (CH_3COO^-) ions, neutralizes the added H_3O^+ ions as the acid ionization reaction

$$CH_3COOH(aq) + H_2O(\ell) \rightleftharpoons CH_3COO^-(aq) + H_3O^+(aq)$$

runs in reverse

$$CH_3COO^-(aq) + H_3O^+(aq) \rightarrow CH_3COOH(aq) + H_2O(\ell)$$

The stoichiometry of the second equation tells us that adding (and reacting) 0.0100 mol H_3O^+ to either of two buffers consumes 0.0100 mol CH_3COO^- and produces 0.0100 mol CH_3COOH. To calculate the effect of these changes on buffer pH, we need to calculate the initial numbers of moles of CH_3COOH and CH_3COO^- ions in both buffers and then add or subtract 0.100 mol from these values as described above. As we saw in Sample Exercise 16.6, the mole ratio of CH_3COO^- to CH_3COOH after the neutralization reaction is complete can be used in the Henderson–Hasselbalch equation to calculate the final pH. The trends shown in Figure 16.4 suggest that the more concentrated buffer will experience a smaller change in pH upon the addition of acid.

Solve Set up ICA tables for buffers A and B like that used in Sample Exercise 16.6.

Buffer A

	$H_3O^+(aq)$ / $CH_3COOH(aq)$
Initial	0.0100 mol
Change	−0.0100 mol
After	0.000 mol

Buffer B

	$H_3O^+(aq)$ / $CH_3COOH(aq)$
Initial	0.0100 mol
Change	−0.0100 mol
After	[illegible]50 mol

The mole ratio of CH_3COO^- to CH_3COOH in each buffer can be substituted for the $[CH_3COO^-]/[CH_3COOH]$ ratio in the Henderson–Hasselbalch equation because both components are dissolved in the same volume of buffer. Using these substitutions and solving for pH:

Think About It Adding the same quantity of acid produced pH changes of 0.09 units in buffer A and 0.70 units in an equal volume of buffer B. As predicted, the buffer with a higher concentration was better able to resist pH change because the relative changes in the concentrations of its components were smaller.

Practice Exercise Calculate the change in pH when 0.145 mol OH^- is added to 1.00 L of two buffers: (a) a solution containing 1.16 *M* NaH_2PO_4 and 1.16 *M* Na_2HPO_4 and (b) a solution containing 0.58 *M* NaH_2PO_4 and 0.58 *M* Na_2HPO_4.

Does the mole ratio of acid to conjugate base make a difference in how well a buffer controls pH? Suppose, for example, you want to prepare an acidic buffer and you know that contamination by basic substances is more likely than contamination by acids. You might use a 1:1 mixture if you could find a weak acid with a pK_a that exactly matched the target pH—but what if there was another conjugate acid–base pair available that required the acid component to be three times as concentrated as the base to achieve the desired pH? Would the second buffer, with the greater proportion of acid in it, do a better job of controlling pH against additions of base than the 1:1 buffer? Sample Exercise 16.8 helps answer this question.

SAMPLE EXERCISE 16.8 Effect of Base/Acid Ratio on Buffer Capacity LO3

Equal volumes of two pH 3.75 buffers are prepared. Buffer A contains 1.00 mol formic acid (pK_a = 3.75) and 1.00 mol sodium formate. Buffer B is prepared using the same overall concentration of conjugate pair components, but the pK_a of the weak acid in this buffer is 4.23, so it contains 1.5 mol acid and 0.5 mol conjugate base to achieve the target pH of 3.75. What are the changes in pH of the two buffers if 0.25 mol, 0.50 mol, and 0.75 mol NaOH are added to both? Assume the NaOH additions do not significantly increase the volumes of the buffers.

Collect, Organize, and Analyze The composition of the buffer A changes due to this neutralization reaction:

$$HCOOH(aq) + OH^-(aq) \rightarrow HCOO^-(aq) + H_2O(\ell)$$

A similar equation could be written for buffer B based on its acid and conjugate base. The three additions of NaOH will reduce the moles of the acid components in both buffers by 0.25, 0.50, and 0.75 moles and increase the moles of the base components by the same amounts. The Henderson–Hasselbalch equation can be used to calculate the pH values of the two buffers, but the [base]/[acid] term in the equation will be replaced with the mole ratio of base/acid because the volumes of the buffers are unknown. We know, however, that they are the same. Therefore, the ratio of the concentration values of base to acid in each of the solutions is equal to the mole ratio of base to acid.

Solve Setting up Henderson–Hasselbalch equations with the initial moles of acid and base values in the two buffers and the changes in these initial values from the additions of NaOH:

The changes in buffer pH from the target pH of 3.75 are shown in **Figure 16.5**.

Think About It The greater capacity of buffer B to neutralize additions of base is evident when 0.75 moles of NaOH are added to both: neutralizing the base consumes 75% of the formic acid in buffer A, but only 50% of the acid in buffer B. Therefore, the pH change experienced by buffer B is less than that of buffer A. However, Figure 16.5 also shows that buffer A does a better job of controlling pH when small quantities of base are added. From this exercise we can conclude that the most effective buffers for most applications are those with nearly equal concentrations of their acidic and basic components.

Practice Exercise Small volumes of strong acid, each containing 0.025 mol H_3O^+ ions, are added to 1.00 L samples of two basic buffers. Buffer A contains 0.150 mol diethylamine and

0.150 mol diethylammonium chloride. Buffer B contains 0.200 mol methylamine and 0.100 mol methylammonium chloride. Calculate the changes in pH in the two buffers because of adding the strong acid.

CONCEPT TEST

Which representation in **Figure 16.6** depicts the formic acid–sodium formate buffer that will have the smallest change in pH upon the addition of a strong acid or strong base? Solvent molecules have been omitted for clarity.

(Answers to Concept Tests are in the back of the book.)

Glossary

pH buffer	a solution that resists changes in pH when acids or bases are added to it; typically a solution of a weak acid and its conjugate base or a weak base and its conjugate acid.
buffer capacity	the quantity of acid or base that a pH buffer can neutralize while keeping its pH within a desired range.

$$= 6.03 \times 10^{-3}\ M$$

16.4 Indicators and Acid–Base Titrations

Swimming pool operators routinely check the pH of pool water to make sure it is close to 7.3, which is the average pH of our eyes. They often add sodium carbonate to raise the water's pH after acidic summertime precipitation sends it below 7.3. To determine how much sodium carbonate to add, they test the pH of the water by using a kit that includes a pH indicator (**Figure 16.7**), which is a substance that changes color as its pH changes.

Phenol red is a pH indicator. It is a weak acid ($pK_a = 7.6$) that is yellow in its un-ionized form (which, for convenience, we assign the generic formula HIn) and violet in its ionized (In^-) form. At a pH that is 1 unit above the pK_a (i.e., at pH 8.6), the ratio $[In^-]/[HIn]$ is 10:1 and a phenol red solution is violet. At a pH less than 6.6, phenol red is largely un-ionized, and a solution of it is yellow. In the pH range from about 6.8 to 8.6, the color changes from yellow to orange to red to violet with increasing pH (**Figure 16.8**). These color changes allow pH to be determined to within about ±0.2 unit.

CONNECTION In Section 4.6 we learned that when the number of moles of titrant is stoichiometrically equal to the number of moles of the analyte, the titration is at its equivalence point. When the indicator begins to change color, the titration is at its (observable) end point.

As with buffers, a pH indicator is useful over a pH range from about 1 pH unit below to 1 pH unit above the indicator's pK_a value. In addition to their role in determining pH values, indicators are also used to detect the large changes in pH that occur at the equivalence points in acid–base titrations. The ideal indicator for a titration has a pK_a value that is near the pH of the titration reaction mixture at the equivalence point.

Acid–Base Titrations

We introduced acid–base titration methods in Section 4.6. Here we summarize the principal steps involved:

1. Assemble a titration apparatus (such as the one shown in **Figure 16.9**).
2. Accurately transfer a known volume of sample to the beaker.
3. Either add a few drops of an indicator solution to the sample

or insert the probe of a pH meter.

4. Fill the buret with a solution (the *titrant*) of known concentration of a substance that reacts with a solute (the *analyte*) in the sample.
5. Slowly add titrant to the sample and monitor the change in pH. When the volume of titrant needed to completely consume the analyte has been added, the equivalence point has been reached, as indicated by either a change in indicator color or a large change in pH as sensed by a pH electrode. This volume of titrant is a measure of the concentration of analyte in the sample.

The neutralization titrations in Chapter 4 involved titrating strong acids with strong bases and vice versa. In this section we begin with titrations of aqueous samples containing weak as well as strong monoprotic acids or *monobasic* bases. (A monobasic base accepts one hydrogen ion per molecule.) In the examples that follow, we monitor changes in pH during the titration by using a pH electrode, and we plot the pH of the titration reaction mixture against the volume of titrant added.

First, let's compare the titration curves of two 20.0 mL samples: one contains 0.100 *M* HCl and the other contains 0.100 *M* acetic acid (CH_3COOH). Both are titrated with 0.100 *M* NaOH. The two graphs of pH versus titrant volume are shown in **Figure 16.10**. The initial pH of the HCl solution is lower than that of the acetic acid solution because HCl is a stronger acid, and the HCl titration curve stays below the acetic acid curve until they reach their equivalence points, where both acids have been completely neutralized.

As NaOH titrant is first added to the HCl sample, the pH of the sample (the red curve in Figure 16.10) does not change much. This makes sense for two reasons: first, each drop of NaOH titrant neutralizes only a tiny fraction of the H_3O^+ ions present in the sample during the early stages of the titration. Second, pH is a log scale. Therefore, small changes in $[H_3O^+]$ translate into even smaller changes in pH.

Not until the red curve approaches the equivalence point do small additions of titrant begin to produce sizable increases in pH. This make sense because sample pH is determined by the $[H_3O^+]$ remaining in it, and this concentration becomes very small as most of the H_3O^+ ions have been neutralized. Near the equivalence point each additional drop of NaOH titrant consumes a larger fraction of the H_3O^+ ions that remain and produces a larger increase in pH until the sample is completely neutralized.

At the equivalence point, the sample consists of Na^+ and Cl^- ions dissolved in water. All the H_3O^+ ions in the original sample and all the OH^- ions in the added titrant have reacted to form molecules of H_2O. Sodium and chloride ions do not hydrolyze and do not influence pH; therefore, the pH of the sample at the equivalence point is 7.00.

SAMPLE EXERCISE 16.9 Calculating pH during Titration of a Strong Acid with a Strong Base LO4

What is the pH of the solution being titrated in Figure 16.10 just before the equivalence point when 19.0 mL of 0.100 *M* NaOH has been added to 20.0 mL of 0.100 *M* HCl?

Collect and Organize We are asked to calculate the pH in the titration of a sample of a strong acid, HCl, with a strong base, NaOH, at a point before the equivalence point, which means that some of the acid remains unreacted. HCl is completely ionized in water

$$HCl(aq) + H_2O(\ell) \rightarrow H_3O^+(aq) + Cl^-(aq)$$

and NaOH completely dissociates into its ions in water

$$NaOH(aq) \rightarrow Na^+(aq) + OH^-(aq)$$

Combining these equations and eliminating spectator ions yields this net ionic equation for the titration reaction:

$$H_3O^+(aq) + OH^-(aq) \rightarrow 2\ H_2O(\ell)$$

Analyze To solve the problem, we will need to calculate the concentration of H_3O^+ ions remaining in the reaction mixture, which means calculating how many moles of H_3O^+ ions were in the original 20.0 mL sample and how many of those moles were neutralized by the OH^- ions in 19.0 mL of titrant. Taking the difference between these values will determine the remaining moles of H_3O^+ ions and dividing by the total volume of the reaction mixture will gives us $[H_3O^+]$. Taking the $-\log$ of this value will give us pH.

Solve The amount of acid initially in the sample is

The amount of base added is

Each H_3O^+ ion reacts with one OH^- ion, so there is an excess of H_3O^+ ions:

excess H_3O^+ ions $= 2.00 \times 10^{-3}$ mol H_3O^+ ions $-$ 1.90×10^{-3} mol H_3O^+ ions reacted

$= 1.0 \times 10^{-4}$ mol H_3O^+ remain in solution

These H_3O^+ ions are dissolved in (20.0 mL + 19.0 mL) = 39.0 mL solution.

Therefore, the molarity of the unreacted ions is

and

$\text{pH} = -\log(2.6 \times 10^{-3}) = 2.59$

Think About It The pH of the solution before the equivalence point in a strong acid–strong base titration is determined by the concentration of H_3O^+ ions not yet neutralized. In this exercise, $[H_3O^+]$ remaining in the sample was enough to produce a pH of 2.59: well below the equivalence point pH of 7.00. This difference reflects the rapid pH change that occurs near the equivalence points in titrations of strongly acidic solutions.

Practice Exercise What is the pH of the solution in Figure 16.10 just after the equivalence point when 21.0 mL of 0.100 *M* NaOH has been added to 20.0 mL of 0.100 *M* HCl?

CONCEPT TEST

The representations in **Figure 16.11** depict the particles present during the titration of LiOH with HI. Which representation depicts the starting solution? The equivalence point? Put the representations in order from the beginning to the end of the titration. The solvent has been omitted for clarity.

The pH of the acetic acid sample (the blue curve in Figure 16.10) changes abruptly with the first few drops of added base, but then the changes become smaller and the titration curve levels out. In the nearly flat region, the sample acts like a pH buffer as additions of NaOH titrant neutralize acetic acid, forming the sodium salt of its conjugate base:

$$CH_3COOH(aq) + NaOH(aq) \rightarrow CH_3COONa(aq) + H_2O(\ell)$$

As long as there are significant concentrations of both acetic acid and acetate ions in the sample, the changes in pH with added titrant are small.

Titrations of Weak Acids

When enough titrant has been added to consume nearly all the acid in the CH_3COOH sample, its pH rises sharply, much like the red curve and for the same reason: small additions of titrant consume proportionately more of the remaining acid in the sample as the blue curve approaches the equivalence point. At their equivalence points, the same volume of NaOH titrant has been added to both acid solutions because the initial concentrations of the two acids and their sample volumes were the same. Therefore, the number of moles of acid in each sample was the same, and that is the quantity that defines the number of moles of base needed to reach the equivalence point. It does not matter whether the acids were initially completely ionized, because even a weak acid such as acetic acid is completely neutralized at its equivalence point. Why is that? Adding NaOH to a solution of acetic acid (or any weak acid) consumes H_3O^+ ions, which, in accordance with Le Châtelier's principle, shifts the position of the acid ionization equilibrium to the right:

$$CH_3COOH(aq) + H_2O(\ell) \rightleftharpoons CH_3COO^-(aq) + H_3O^+(aq)$$

Even though the volumes of titrant needed to reach the equivalence points of the red and blue curves in Figure 16.10 are the same, the pH values at the two equivalence points are not. The pH values of the equivalence points are 7.00 (neutral) in the HCl titration, but 8.73 (weakly basic) in the acetic acid titration, because the product of this titration reaction is a solution of sodium acetate (CH_3COONa). Acetate ions react with water, forming molecules of acetic acid and OH^- ions:

$$CH_3COO^-(aq) + H_2O(\ell) \rightleftharpoons CH_3COOH(aq) + OH^-(aq)$$

In general, the pH at the equivalence point in the titration of any weak acid (HA) with a strong base is greater than 7.00 because hydrolysis of the anion (A^-) of the salt formed by the neutralization reaction produces OH^- ions.

Beyond their equivalence points, the red and blue curves overlap because the pH values of the solutions in this region are controlled only by the increasing concentration of OH^- ions as excess NaOH beyond that needed to neutralize the acids is added to the reaction mixtures.

An important reference point in the acetic acid titration in Figure 16.10 is the *midpoint*, which is located at the point where half the volume needed to reach the equivalence point has been added. At the midpoint, half of the acetic acid initially in the sample has been converted into its acetate ions. As a result, the concentration of acetate ions produced by the neutralization reaction and the concentration of acetic acid remaining from the original sample *are the same*. If we insert this equality ([base] = [acid]) into the log term of the Henderson–Hasselbalch equation, the value of the term is zero, and the equation reduces to $\mathrm{pH} = \mathrm{p}K_a$. In an acetic acid titration, this pH value is 4.75.

CONCEPT TEST

The representations in **Figure 16.12** depict the particles present during a titration of HClO with KOH. Which represents the weak acid at the start of the titration? At the midpoint? At the equivalence point? The solvent has been omitted for clarity.

SAMPLE EXERCISE 16.10 Calculating pH during the Titration of a Weak Acid with a Strong Base LO4

What is the pH of the acetic acid sample in Figure 16.10 after (a) 5.0 mL and (b) 15.0 mL of 0.100 *M* NaOH titrant have been added to a 20.0 mL sample in which $[CH_3COOH]$ is initially 0.100 *M*?

Collect, Organize, and Analyze We are asked to calculate the pH at the points along the blue titration curve in Figure 16.10 at which 5.0 mL and 15.0 mL of titrant have been added. These volumes are less than that needed to reach the equivalence point, meaning that all the OH^- ions added to the sample will react with CH_3COOH and convert the acid into CH_3COO^- ions as described by this net ionic equation:

$$CH_3COOH(aq) + OH^-(aq) \rightarrow CH_3COO^-(aq) + H_2O(\ell)$$

We can use the 1:1 stoichiometry of the reaction along with the volume and concentration of the original sample and the volumes and concentration of the titrant added to calculate how many moles of CH_3COOH were in the original sample, how many moles of OH^- ions have been added (which is equal to the moles of CH_3COO^- ions produced), and how many moles of CH_3COOH remain in the sample. These last two quantities can be used with the Henderson–

Hasselbalch equation to determine the two pH values. The two volumes are 5.0 mL less than and 5.0 mL greater than the midpoint titration volume of 10.0 mL. It is likely that the calculated pH values will also be equally less than and greater than the midpoint pH (4.75 = the pK_a of acetic acid).

Solve The following ICA tables (introduced in Sample Exercise 16.6) provide a guide in determining how many moles of CH_3COOH remain after each addition of titrant, how many moles of CH_3COO^- are produced, and sample pH.

1. 5.0 mL of titrant:

$CH_3COOH(aq)$
Initial
Change 0.50 mmol
After 1.50 mmol

The total sample volume is (20.0 mL + 5.0 mL) = 25.0 mL. We could divide the moles of CH_3COOH and CH_3COO^- ions in the **A**fter row by 25.0 mL to calculate $[CH_3COOH]$ and $[CH_3COO^-]$ values to use in the Henderson–Hasselbalch equation. However, we can skip this step and use the moles of CH_3COO^- ions and moles of CH_3COOH in the **A**fter row, as we did in Sample Exercise 16.7 and for the same reason: the two mole quantities are dissolved in the same volume of solution, so their mole ratio has the same value as their concentration ratio:

Therefore:

1. 15.0 mL of titrant:

$CH_3COOH(aq)$
Initial
Change 1.50 mmol
After 0.50 mmol

Using the mole values in the **A**fter row in the Henderson–

Hasselbalch equation:

Think About It As predicted, the pH values are spaced equally below and above the midpoint pH: $4.75 - 4.27 = 0.48$ and $5.23 - 4.75 = 0.48$. The procedure used in this sample exercise worked because the reaction mixture acted like a pH buffer. Letting the initial quantity of acetate ions be zero meant ignoring the small concentration of them present in a 0.100 *M* solution of acetic acid due to ionization of the acid. This is reasonable because the initial pH of the solution is about 3, which means the initial concentrations of $[H_3O^+]$ and $[CH_3COO^-]$ are about $1 \times 10^{-3} M$ and the initial quantity of CH_3COO^- ions in 20.0 mL is about 0.02 mmol. This value is less than 5% of the quantities of the ion we used to calculate pH.

Practice Exercise If 30.0 mL of titrant is required to reach the equivalence point in the titration with a strong base of an aqueous sample of formic acid, what is the pH of the titration mixture after (a) 10.0 mL, (b) 15.0 mL, and (c) 20.0 mL of titrant have been added?

CONCEPT TEST

Why is it better to titrate a weak acid with a strong base instead of titrating a weak acid with a weak base?

Titration curves of weak or strong base analytes with strong acid titrants resemble the curves in Figure 16.10 but are inverted, starting with high initial pH values and ending with low ones. **Figure 16.13** illustrates two such titrations. One sample contains a strong base, 0.100 *M* NaOH; the other contains a weak base, 0.100 *M* NH_3. Both are titrated with 0.100 *M* HCl. The initial pH of the NaOH titration curve is higher than that of the NH_3 sample because

NaOH is a stronger base. The pH of the NaOH sample does not change much as acid is added until near the equivalence point. As the equivalence point is approached, the principal ions present in the reaction mixture are Na^+, Cl^-, and decreasing concentrations of OH^-. The sample pH, which is determined only by the $[OH^-]$ still present, starts to fall steeply. When enough acid has been added to consume all the OH^- ions in the sample, the equivalence point is reached. The solution now consists of water and NaCl, which is neutral, so pH = 7.00 at the equivalence point.

The pH of the NH_3 solution changes abruptly with the first few drops of added acid, but then the changes become smaller and the titration curve levels out. In this nearly flat region, additions of acidic titrant are consumed as NH_3 reacts with H_3O^+ ions to form NH_4^+ ions. In this region of the titration curve, the sample acts like a pH buffer, just as the mixture of acetic acid and acetate ions did in the titration in Figure 16.10. The pH value at the equivalence point in the ammonia titration is 5.27 (slightly acidic) because the product of the titration reaction is NH_4Cl, an acidic salt, which reacts with water, forming ammonia molecules and H_3O^+ ions. Beyond their equivalence points, the NaOH and NH_3 curves are identical because the pH is determined only by the moles of HCl added after the equivalence point and the total volume of the titration reaction mixtures.

As in the acetic acid titration, the midpoint in the NH_3 titration curve is significant because it is the point at which half of the NH_3 initially in the sample has been converted into NH_4^+ ions. As a result, $[NH_3] = [NH_4^+]$. This concentration equality can be used in the Henderson–Hasselbalch equation based on the hydrolysis of ammonium ions:

This pK_a value can be calculated from the pK_b value for ammonia, which is 4.75 (see Table A5.3), using Equation 16.5: $pK_a = 14.00 - 4.75 = 9.25$. Because the value of the log term in the Henderson–Hasselbalch equation is zero, $pH = pK_a = 9.25$ at the midpoint of this titration.

CONCEPT TEST

What is the pH at the midpoint of the titration of an aqueous sample of methylamine with a standard solution of hydrochloric acid?

CONCEPT TEST

The representations in **Figure 16.14** depict the particles present during a titration of NH_3 with HCl. Which represents the start of the titration? The region where the solution best functions as a buffer? The equivalence point? The solvent has been omitted for clarity.

Titrations with Multiple Equivalence Points

So far, the titration curves discussed in this chapter have each had only one equivalence point. An alkalinity titration (**Figure 16.15**), on the other hand, has two equivalence points. In environmental science, the alkalinity of a water sample refers to the capacity of the water to neutralize additions of acid. Titration of the sample with strong acid provides a way to determine that capacity.

If carbonate is present in the sample, the first additions of titrant convert carbonate into bicarbonate:

$$CO_3^{2-}(aq) + H_3O^+(aq) \rightarrow HCO_3^-(aq) + H_2O(\ell)$$

This reaction continues until all the carbonate initially in the sample has been converted into bicarbonate. This represents the first equivalence point in the titration and is marked by a sharp drop in pH. In the second stage of the titration, the bicarbonate ions formed in the first stage plus any bicarbonate present in the original sample react with additional acidic titrant, forming carbonic acid, most of which decomposes into carbon dioxide and water:

$HCO_3^-(aq) + H_3O^+(aq) \rightarrow CO_2(aq) + 2\ H_2O(\ell)$

The solubility of CO_2 in water is limited, so its production in the second step of an alkalinity titration often results in formation of bubbles of carbon dioxide as it comes out of solution:

$CO_2(aq) \rightarrow CO_2(g)$

In the first stage of the alkalinity titration, the titration curve has a region in which added acid has little effect on pH. This is a buffering region where HCO_3^- and CO_3^{2-} function as a weak acid–conjugate base pair. At the first equivalence point, the dominant carbon-containing species is HCO_3^- and the sample is still slightly basic ($pH > 8$). This basic pH tells us that the bicarbonate is more effective as a base (Equation 16.6) than as an acid (Equation 16.7):

We can confirm the dominance of the reaction in Equation 16.6 by considering the two-step acid ionization equilibria of carbonic acid. Equation 16.7 represents the second step and its equilibrium constant is $K_{a2} = 4.7 \times 10^{-11}$. The K_b of the base ionization described in Equation 16.6 is linked to the first ionization of carbonic acid:

Convert K_{a1} into K_b using Equation 15.18:

This K_b value is much greater than the value of K_{a2}:

Thus, bicarbonate is nearly 500 times stronger a base than it is an acid.

During the second stage of the titration, conversion of HCO_3^- ions to H_2CO_3 produces a second pH buffer and another plateau of slowly changing pH. When the HCO_3^- ions are completely consumed, pH drops sharply for a second time at the second equivalence point. Its pH is below 7, reflecting the acidic character and pK_{a1} value of carbonic acid.

The initial pH of the sample in Figure 16.15 is slightly above 10, which is quite basic and above the pH range tolerated by many species of aquatic life. Such highly basic water may be found in arid regions such as the U.S. Southwest, where rocks containing $CaCO_3$ and other basic compounds are in contact with water. The pH of most freshwater is lower than 8, which means that the dominant carbonate species is bicarbonate. The alkalinity titration curves of these waters have only one equivalence point, coinciding with the pH of the second equivalence point in Figure 16.15.

SAMPLE EXERCISE 16.11 Interpreting the Results of a Titration with Multiple Equivalence Points I LO4

If the volume of titrant needed to reach the first equivalence point in the titration shown in Figure 16.15 is 9.00 mL, and *a total of* 27.00 mL is required to reach the second equivalence point, what was the ratio of carbonate to bicarbonate in the original sample?

Collect, Organize, and Analyze Carbonate (CO_3^{2-}) ions in the sample combine with H_3O^+ ions from the titrant and are converted to bicarbonate (HCO_3^-) ions in the first stage of the titration. Bicarbonate ions—including any in the original sample plus all those produced in the first-stage reaction—are converted to carbonic acid (H_2CO_3) in the second stage.

Solve The volume of titrant needed to titrate the CO_3^{2-} in the sample (9.00 mL) is exactly half the additional volume ($27.00 - 9.00 = 18.00$ mL) needed to titrate the HCO_3^- in the reaction mixture. However, 9.00 mL of the titrant consumed in the second stage was needed just to titrate the HCO_3^- produced in the first stage. This means the volume of titrant needed to titrate the HCO_3^- that was in the original sample was only $(18.00 - 9.00) = 9.00$ mL. Therefore, the original sample contained equal concentrations of CO_3^{2-} and HCO_3^- ions.

Think About It It would be tempting to interpret the volumes of titrant consumed in the two stages to mean that there was twice as much bicarbonate as carbonate in the original sample. It's important to remember that the HCO_3^- ions titrated in the second stage come from the original sample *and* from HCO_3^- ions produced from CO_3^{2-} ions during the first stage of the titration.

Practice Exercise Is the midpoint pH in the first stage of an alkalinity titration always the same as the pK_{a2} of carbonic acid? Explain why or why not.

We can detect both equivalence points in an alkalinity titration by using a pH electrode, or we can use appropriate indicators. Phenol red would *not* be a good choice for the titration in Figure 16.15 because it changes color between pH 6.8 and 8.4. This range is just below the pH of the first equivalence point and well above the pH of the second equivalence point. To detect the first equivalence point, we need an indicator with a pK_a near the pH of the solution at the first equivalence point, which is about 8.5. One candidate in Figure 16.8 is phenolphthalein (pK_a = 9.7), which is pink in its basic form and colorless at low pH.

To detect the second equivalence point, we could add bromcresol green (pK_a = 4.6) after the first equivalence point has been reached. We would not add it earlier because its blue-green color in basic solutions would obscure the pink-to-colorless transition of phenolphthalein. We do not need to be concerned about the phenolphthalein obscuring the bromcresol green color change because phenolphthalein is colorless in acidic solutions.

SAMPLE EXERCISE 16.12 Interpreting the Results of a Titration with Multiple Equivalence Points II LO4

A 100.0 mL sample of water from the Sapphire Pool in Yellowstone National Park (**Figure 16.16**) is titrated with 0.0300 *M* HCl. A few drops of phenolphthalein are added at the beginning of the titration, and the solution turns pink. It takes 5.91 mL of titrant to reach the pink-to-clear equivalence point. Then a few drops of bromcresol green are added, and it takes an additional 26.02 mL of titrant before the blue-green color changes to yellow. What were the initial concentrations of carbonate and bicarbonate in the sample?

Collect and Organize We are asked to determine the concentrations of CO_3^{2-} and HCO_3^- ions in a water sample from the results of a titration. These determinations are based on the volumes of titrant needed to reach two equivalence points. In the first stage, CO_3^{2-} ions in the sample are converted to HCO_3^- ions:

In the second stage, HCO_3^- ions are converted to H_2CO_3:

Analyze According to the stoichiometries of the reactions, it takes 1 mole of HCl to titrate 1 mole of carbonate to bicarbonate in the first stage, and it takes 1 mole of HCl to titrate 1 mole of bicarbonate to carbonic acid in the second stage. The HCO_3^- ions titrated in stage 2 include any in the original sample plus all the HCO_3^- ions produced by reaction 1. The difference between the titrant volumes needed to reach the two equivalence points, $(26.02 - 5.91) = 20.11$ mL, is the volume of acid required to react with the HCO_3^- that was present in the original sample. This difference is between 3 and 4 times the volume of titrant consumed in stage 1, so we can predict that there was 3 to 4 times as much HCO_3^- in the original sample as CO_3^{2-}.

Solve Calculating the concentrations of CO_3^{2-} and HCO_3^- in the original sample from the volumes and molarity of the HCl titrant consumed in stages 1 and 2:

Think About It The titration results confirm that the bicarbonate concentration in the original sample was just over 3 times the carbonate concentration.

Practice Exercise Suppose you titrate a 100.0 mL sample of water from another pool in Yellowstone National Park with a ratio of carbonate to bicarbonate of 3:1. If the total volume of titrant used was 24.04 mL, approximately what volume of titrant was used to reach the first equivalence point? What additional volume of titrant was used to reach the second equivalence point?

CONCEPT TEST

In a titration that initially contains both CO_3^{2-} and HCO_3^-, the volume of titrant required to reach the first equivalence point is less than that required to titrate from the first equivalence point to the second. Why?

Glossary

pH indicator

a water-soluble weak organic acid that changes color as it ionizes.

(a) $NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^-$

NH_3: Acts as a Brønsted–Lowry base by accepting a H^+ ion from H_2O

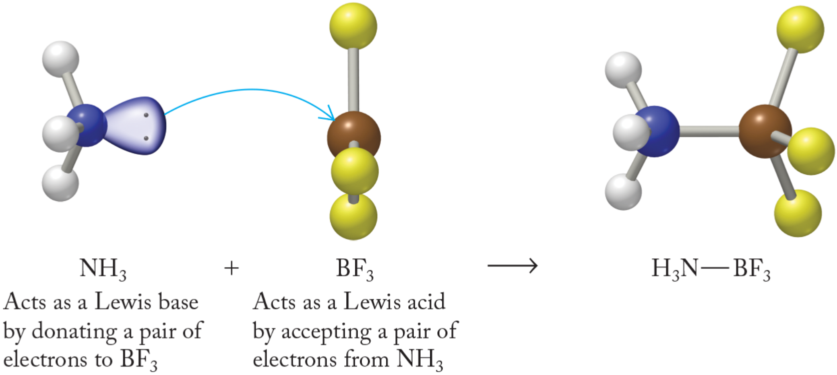
H_2O: Acts as a Brønsted–Lowry acid by donating a H^+ ion from NH_3

(b) $NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^-$

NH_3: Acts as a Lewis base by donating its lone pair of electrons to form a N—H bond

H_2O: Acts as a Lewis acid by accepting a pair of electrons as an O—H bond breaks

FIGURE 16.17 (a) Brønsted–Lowry view of the reaction between H_2O (proton donor) and NH_3 (proton acceptor). (b) Lewis view of the reaction: H_2O acts as a Lewis acid (electron-pair acceptor) and NH_3 acts as a Lewis base (electron-pair donor).

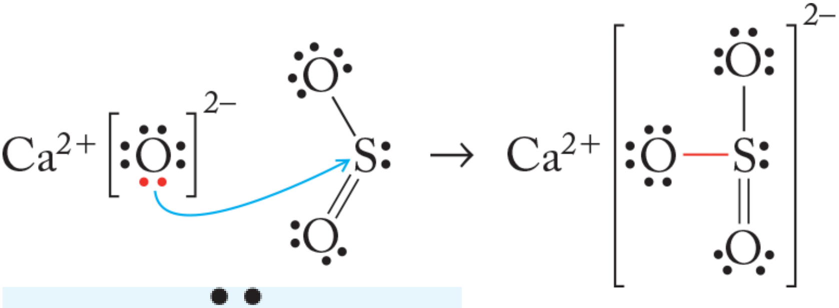


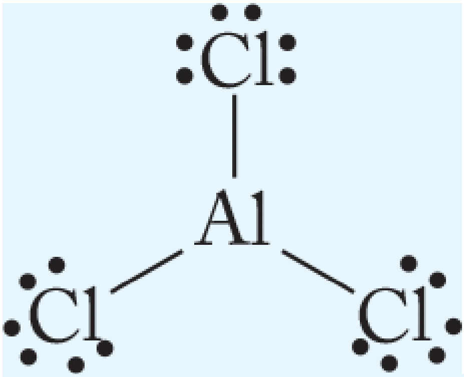
$NH_3 + BF_3 \longrightarrow H_3N—BF_3$

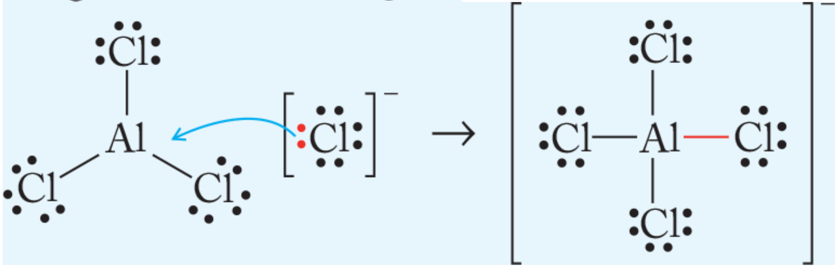
NH_3: Acts as a Lewis base by donating a pair of electrons to BF_3

BF_3: Acts as a Lewis acid by accepting a pair of electrons from NH_3

FIGURE 16.18 In the reaction between NH_3 and BF_3, NH_3 acts as a Lewis base and BF_3 acts as a Lewis acid. This is an acid–base reaction in the Lewis sense because we focus on the acceptance and donation of an electron pair, not the transfer of a proton, as in the Brønsted–Lowry system.







16.5 Lewis Acids and Bases

Until now we have used the Brønsted–Lowry definitions of acids (H^+ ion donors) and bases (H^+ ion acceptors). However, the time has come to expand our concept of acids and bases to include acid–base interactions that may or may not involve the transfer of H^+ ions. Let's begin by revisiting what happens when ammonia gas dissolves in water:

$$NH_3(g) + H_2O(\ell) \rightleftharpoons NH_4^+(aq) + OH^-(aq)$$

Figure 16.17a shows a Brønsted–Lowry interpretation of this reaction: in donating H^+ ions to ammonia, H_2O acts as a Brønsted–Lowry acid. In accepting H^+ ions, NH_3 acts as a Brønsted–Lowry base.

Another way to view this reaction is illustrated in **Figure 16.17b**. Instead of focusing on the transfer of hydrogen ions, consider the two reactants as a donor and an acceptor of a *pair of electrons*. In this view, the N atom in NH_3 donates its lone pair of electrons to one of the H atoms in H_2O. In the process, one of the H□O bonds in H_2O is broken in such a way that the bonding pair of electrons remains with the O atom. The donated lone pair from the N atom forms a fourth N□H covalent bond. The result is the same as in the Brønsted–Lowry model of acid–base behavior: a molecule of NH_3 bonds to a H^+ ion, forming an $NH_4{}^+$ ion, and a molecule of H_2O loses a H^+ ion, becoming a OH^- ion.

CONNECTION Lewis’s pioneering theories of the nature of covalent bonding were described in Section 8.2.

Viewing this process as the donation and acceptance of an electron pair provides the following basis for defining acids and bases:

- A Lewis base is a substance that *donates* a lone pair of electrons in a chemical reaction.
- A Lewis acid is a substance that *accepts* a lone pair of electrons in a chemical reaction.

These definitions are named after their developer, Gilbert N. Lewis, who also pioneered research into the nature of chemical bonds. The Lewis definition of a base is consistent with the Brønsted–Lowry model we have used because a substance must be able to donate a pair of electrons if it is to bond with a H^+ ion. However, the same parallelism is not true for acids. The Brønsted–Lowry model defines an acid as a hydrogen-ion donor, but the Lewis definition includes species that have no hydrogen ions to donate, but that can still accept electrons.

One such compound is boron trifluoride (BF_3). With only six valence electrons, the boron atom in BF_3 can accept another pair to complete its octet. NH_3 is a suitable electron-pair donor, as shown in **Figure 16.18**. There is no transfer of H^+ ions in this reaction, so it is not an acid–base reaction according to the Brønsted–Lowry model. However, NH_3 donates a lone pair of electrons and BF_3 accepts them, so it is an acid–base reaction according to the broader Lewis model.

Many important Lewis bases are anions, including the halide ions (i.e., F^-, Cl^-, Br^-, and I^-), OH^-, and O^{2-}. To see how O^{2-} functions as a Lewis base, let's revisit the reaction described in Section 14.6 between SO_2 and CaO that is used to reduce SO_2 emissions from coal-burning power stations:

$$CaO(s) + SO_2(g) \rightleftharpoons CaSO_3(s)$$

The oxide ion in CaO is the electron-pair donor, so O^{2-} is a Lewis base. Sulfur dioxide is the electron-pair acceptor and is therefore a Lewis acid. As an SO_2 molecule is adsorbed onto the surface of solid CaO, the oxide ion donates an electron pair to the sulfur atom, resulting in an additional S□O covalent bond and the formation of a sulfite anion, SO_3^{2-}. The formal charges on the S atom and the double-bonded O atom in SO_3^{2-} are both zero; the formal charges on the two single-bonded O atoms are -1, giving an ion with an overall charge of $2-$.

CONNECTION Formal charge and how to calculate it are described in Section 8.5.

SAMPLE EXERCISE 16.13 Identifying Lewis Acids and Bases LO5

In the following reaction, which species is a Lewis acid and which is a Lewis base?

$$AlCl_3 + Cl^- \rightarrow AlCl_4^-$$

Collect and Organize We are given a chemical reaction and asked to identify the Lewis acid (i.e., the reactant that accepts a pair of electrons) and the Lewis base (i.e., the reactant that donates that pair of electrons).

Analyze A Cl^- ion has four lone pairs of electrons in its valence shell, so it has the capacity to *donate* one of them to form a covalent bond to aluminum. To analyze the capacity of $AlCl_3$ to act as a Lewis acid, we need to draw its Lewis structure, which includes a total of (3×7) electrons from 3 Cl atoms, plus 3 from 1 Al atom, or 24 electrons in all. Using 6 electrons to draw three Al□Cl bonds leaves 18 with which to complete the octets around each of the three Cl atoms:

This structure accounts for all the valence electrons, but it leaves Al with only 6 valence electrons and the capacity to accept one more pair—that is, to act as a Lewis acid.

Solve In this reaction, $AlCl_3$ is a Lewis acid and the Cl^- ion is a Lewis base as shown in these Lewis structures:

Think About It Drawing the Lewis structure of $AlCl_3$ and determining that the central Al atom has an incomplete octet is the key to identifying its capacity to accept another pair of electrons and to act as a Lewis acid.

Practice Exercise In the following reaction, which reactant is the Lewis acid, and which is the Lewis base?

$CO_2(g) + CaO(s) \rightarrow CaCO_3(s)$

Glossary

Lewis base

a substance that *donates* a lone pair of electrons in a chemical reaction.

Lewis acid

a substance that *accepts* a lone pair of electrons in a chemical reaction.

$$K_c = \frac{1}{K_f} = \frac{[Cu^{2+}][NH_3]^4}{[Cu(NH_3)_4{}^{2+}]}$$

$$K_f = \frac{[Cu(NH_3)_4{}^{2+}]}{[Cu^{2+}][NH_3]^4} = 5.0 \times 10^{13}$$

$$K_c = \frac{1}{K_f} = \frac{[Cu^{2+}][NH_3]^4}{[Cu(NH_3)_4{}^{2+}]} = \frac{1}{5.0 \times 10^{13}} = 2.0 \times 10^{-14}$$

$$K_c = \frac{[Cu^{2+}][NH_3]^4}{[Cu(NH_3)_4{}^{2+}]} = \frac{(x)(1.60 \times 10^{-3})^4}{(1.0 \times 10^{-4})} = 2.0 \times 10^{-14}$$

$$x = 3.1 \times 10^{-7} = [Cu^{2+}]$$

$$Ag^+(aq) + 2\ NH_3(aq) \rightleftharpoons Ag(NH_3)_2{}^+(aq) \qquad K_f = 1.7 \times 10^7$$

16.6 Formation of Complex Ions

In Chapter 10 we described how ions dissolved in water are *hydrated*; that is, they are surrounded by water molecules oriented with the positive ends of their dipoles directed toward anions and their negative ends directed toward cations (**Figure 16.19**). In some hydrated cations, ion–dipole interactions lead to the sharing of lone-pair electrons on the oxygen atoms of H_2O with empty valence-shell orbitals on the cations. This interaction between a lone pair and an empty orbital is yet another example of Lewis acid–base behavior. These shared electron pairs meet our definition of covalent bonds, but these bonds are called *coordinate covalent bonds*, or simply coordinate bonds. They are also called *dative covalent bonds.*

Coordinate bonds form when either a molecule or an anion donates a lone pair of electrons to an empty valence-shell orbital of an atom, cation, or molecule. Once formed, a coordinate bond is indistinguishable from any other kind of covalent bond. When a cation forms coordinate bonds with one or more molecular or ionic electron-pair donors, the resulting structure is called a complex ion. The electron-pair donors in complex ions are called ligands. For example, when six molecules of water form coordinate bonds to a Ni^{2+} cation in an aqueous solution, they form a complex ion with the formula $Ni(H_2O)_6{}^{2+}$ to show that there are six ligands (six water molecules bonded to the metal) in this complex ion.

We can investigate the formation of complex ions with the mathematical tools we have used in examining acid–base equilibria. These tools are appropriate because complex formation processes are reversible, and many of them reach chemical equilibrium rapidly. **Figure 16.20** shows two aqueous solutions: one contains copper(II) sulfate ($CuSO_4$), and the other contains NH_3. The $CuSO_4$ solution is robin's-egg blue, the color characteristic of $Cu^{2+}(aq)$ ions dissolved in water, whereas the ammonia solution is colorless. When the solutions are mixed, the robin's-egg blue turns a dark navy blue, as shown on the right in Figure 16.20. This is the color of $Cu(NH_3)_4{}^{2+}$ complex ions. The change in color provides visual evidence that the following equilibrium lies far to the right, favoring complex ion formation:

$$Cu^{2+}(aq) + 4\ NH_3(aq) \rightleftharpoons Cu(NH_3)_4{}^{2+}(aq)$$

CONNECTION Spheres of hydration around cations and anions were introduced in Section 10.3.

This conclusion is supported by the large equilibrium constant for the reaction:

The equilibrium constant $\boldsymbol{K_f}$ is called a formation constant because it describes the formation of a complex ion. For the general case in which 1 mole of metal ions (M^{m+}) combines with n moles of ligand (X^{x-}) to form the complex ion $MX_n{}^{(m-nx)+}$, the formation constant expression is

Formation constants can be used to calculate the concentration of free (uncomplexed) metal ions, $M^{m+}(aq)$, in equilibrium with a given (usually larger) concentration of a ligand. Because K_f values are usually very large (see Table A5.5), equilibrium concentrations of uncomplexed metal ions are usually very small. One approach to calculating the concentration of an uncomplexed metal ion is to consider the reverse of the formation reaction and calculate how much of the complex ion, in this case $Cu(NH_3)_4{}^{2+}(aq)$, dissociates. In Section 14.4 we learned that the equilibrium constant for the reverse reaction is the reciprocal of the original equilibrium constant.

The calculation of concentration of uncomplexed copper ion, $[Cu^{2+}]$, is illustrated in Sample Exercise 16.14.

SAMPLE EXERCISE 16.14 Calculating the Concentration of Free Metal Ions in Equilibrium with a Complex Ion LO6

Ammonia gas is dissolved in a $1.00 \times 10^{-4} M$ solution of $CuSO_4$ to give an equilibrium concentration of $[NH_3] = 1.60 \times 10^{-3} M$. Calculate the concentration of $Cu^{2+}(aq)$ ions in the solution.

Collect and Organize The concentration of $CuSO_4$ means that $[Cu^{2+}]$ before complex formation is $1.00 \times 10^{-4} M$. The equilibrium concentration of the ligand (NH_3) is $1.60 \times 10^{-3}\ M$. The values of $[NH_3]$, $[Cu^{2+}]$, and $[Cu(NH_3)_4{}^{2+}]$ at equilibrium are related by the formation constant expression:

Analyze Because K_f is large, we can assume that essentially all the Cu^{2+} ions are converted to complex ions and $[Cu(NH_3)_4^{2+}] = 1.00 \times 10^{-4}\ M$. Only a tiny concentration of free Cu^{2+} ions, x, remains at equilibrium. We can calculate the $[Cu^{2+}]$ by considering how much $Cu(NH_3)_4^{2+}$ dissociates:

$$Cu(NH_3)_4^{2+}(aq) \rightleftharpoons Cu^{2+}(aq) + 4\ NH_3(aq)$$

The equilibrium constant, K_c, for this equilibrium is the reciprocal of K_f:

We can construct a RICE table incorporating the concentrations and concentration changes of the products and reactants. Given the small value of K_c, we should obtain a $[Cu^{2+}]$ value at equilibrium that is much less than $1.00 \times 10^{-4}\ M$.

Solve First, we complete the row of equilibrium concentrations of Cu^{2+}, NH_3, and $Cu(NH_3)_4^{2+}$ in the following RICE table:

Reaction (R) $Cu(NH_3)_4^{2+}(aq)$			
$[Cu(NH_3)_4^{2+}]$ (M) $[Cu^{2+}]$ (M) $[NH_3]$ (M)			
Initial (I) 1.00×10^{-4} 0			
Change (C) $-x$			
Equilibrium (E) 1.00×10^{-4} x			

Next, we make the simplifying assumption that x is much smaller than $1.00 \times 10^{-4}\ M$. Therefore, we can ignore the x terms in the equilibrium value of $[Cu(NH_3)_4^{2+}]$ and use the simplified values in the K_c expression:

Think About It This result validates our simplifying assumption and confirms our prediction that $[Cu^{2+}]$ at equilibrium is much less than $[Cu^{2+}]$ initially. In fact, the ratio of the free to complexed copper(II) ions is only $(3.1 \times 10^{-7})/(1.00 \times 10^{-4}) = 0.0031$ or 0.31%.

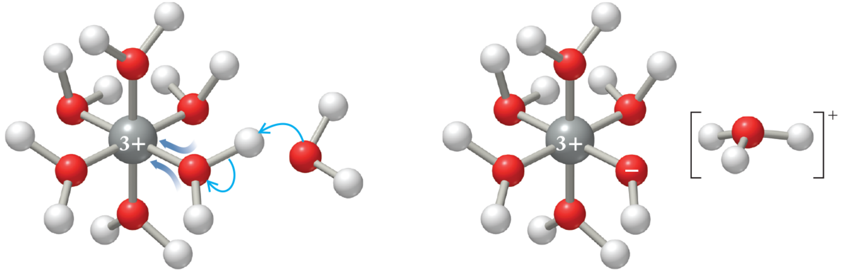
Practice Exercise Calculate the equilibrium concentration of $Ag^+(aq)$ in a solution that is initially 0.100 *M* $AgNO_3$ and 0.800 *M* NH_3 after the following reaction takes place:

Glossary

coordinate bond	a covalent bond formed when one anion or molecule donates a pair of electrons to another ion or molecule.
complex ion	an ionic species consisting of a metal ion bonded to one or more Lewis bases.
ligand	a Lewis base bonded to the central metal ion of a complex ion.
formation constant (K_f)	an equilibrium constant describing the formation of a metal complex from a free metal ion and its ligands.

Learning Objectives

- Describe the bonding in complex ions and use their formation constants to calculate the concentrations of free and complexed metal ions in solution **Return to Sample Exercise 16.14**



$$Fe(H_2O)_6^{3+}(aq) \quad + \quad H_2O(\ell) \rightleftharpoons Fe(H_2O)_5(OH)^{2+}(aq) \quad + \quad H_3O^+(aq)$$

FIGURE 16.21 A hydrated Fe^{3+} cation draws electron density away from the water molecules of its inner coordination sphere, which makes it possible for one or more of these molecules to donate a H^+ ion to a water molecule outside the sphere. The hydrated Fe^{3+} ion has one less H_2O ligand with an electrostatic attraction between the complex ion and the OH^- ion.

16.7 Hydrated Metal Ions as Acids

CONNECTION Electronegativity (Section 8.3) increases as you go left-to-right across a row of the periodic table, and it decreases as you go down a column (see Figure 8.9).

In Chapter 15 we saw that the strength of an oxoacid depends on the electronegativity of its central atom. For example, the relative strengths of the three hypohalous acids, HOCl > HOBr > HOI, align with the relative electronegativities of their halogen atoms: Cl > Br > I. This order makes sense because the more electronegative the halogen, the more it draws electron density away from the oxygen in the polar –OH bond (see Figure 15.5). These shifts make the negative ion formed by dissociation better able to bear a negative charge because of increased delocalization.

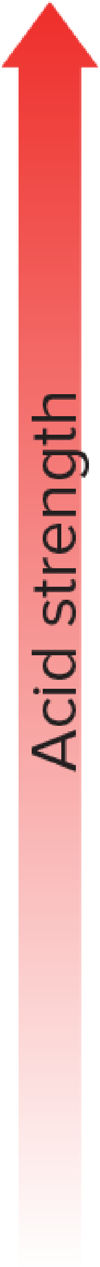
A similar shift in electron density occurs in hydrated metal ions having the generic formula $M(H_2O)_6^{n+}$ when $n > 2$. The electrons in the O–H bonds of the water molecules surrounding the metal ions are attracted to the positively charged ions. The resulting distortion in electron density increases the likelihood of one of these O□H bonds ionizing and donating a H^+ ion to a neighboring molecule of water:

$$M(H_2O)_6{}^{n+}(aq) + H_2O(l) \rightleftharpoons M(H_2O)_5(OH)^{(n-1)+}(aq) + H_3O^+(aq)$$

Figure 16.21 provides a molecular view of this reaction, using $Fe^{3+}(aq)$ as the central ion. Similar reactions allow other hydrated metal ions, particularly those with charges of 3+, to function as Brønsted–Lowry acids. The K_a values of several metal ions are listed in **Table 16.1**. Note how much stronger the 3+ ions are than the 2+ ions, as we would expect given the greater electron-withdrawing power of the more highly charged central ions.

TABLE 16.1 K_a Values of Hydrated Metal Ions

Ion	K_a
$Be^{3+}(aq)$	3×10^{-3}



Acid strength

$Cr^{3+}(aq)$ 1×10^{4}		
$Al^{3+}(aq)$ 1×10^{5}		
$Cu^{2+}(aq)$ 3×10^{5}		

$Pb^{2+}(aq)$	3×10^{5}
$Zn^{2+}(aq)$	1×10^{9}
$Co^{2+}(aq)$	2×10^{10}
$Ni^{2+}(aq)$	1×10^{10}

Figure 16.21 shows how one of the six water molecules of hydration surrounding a Fe^{3+} ion is converted into a hydroxide ion because of the acid ionization reaction. This reduces the charge of the complex ion from 3+ to 2+. If the pH of a solution of $Fe(H_2O)_5(OH)^{2+}$ ions is raised by adding a small quantity of a strong base such as NaOH, the ions undergo additional acid ionization reactions to form $Fe(H_2O)_4(OH)_2{}^{+}$:

$$Fe(H_2O)_5(OH)^{2+}(aq) + H_2O^{-}(aq) \rightleftharpoons Fe(H_2O)_4(OH)_2{}^{+}(aq) + H_2O(\ell)$$

and, at still higher pH, solid iron(III) hydroxide:

$$Fe(H_2O)_4(OH)_2{}^{+}(aq) + H_2O^{-}(aq) \rightleftharpoons Fe(H_2O)_3(OH)_3(s) + H_2O(\ell)$$

For simplicity, we usually write the formula of iron(III) hydroxide as $Fe(OH)_3(s)$, even though each formula unit also contains three water molecules of hydration.

CONCEPT TEST

Would $Fe^{2+}(aq)$ be a stronger or weaker Lewis acid than $Fe^{3+}(aq)$? Where should the K_a of $Fe^{2+}(aq)$ be listed in Table 16.1 relative to that of $Fe^{3+}(aq)$?

Two other 3+ cations, Cr^{3+} and Al^{3+}, display similar behavior, but they differ from Fe^{3+} in that they are more soluble in strongly basic solutions than in weakly basic solutions. Why? Because solid $Cr(OH)_3$ and $Al(OH)_3$ may accept additional OH^{-} ions at high pH, forming soluble anionic complex ions:

$$Cr(OH)_3(s) + OH^{-}(aq) \rightleftharpoons Cr(OH)_4{}^{-}(aq) = Cr(H_2O)_2(OH)_4{}^{-}(aq)$$

$$Al(OH)_3(s) + OH^{-}(aq) \rightleftharpoons Al(OH)_4{}^{-}(aq) = Al(H_2O)_2(OH)_4{}^{-}(aq)$$

Zinc hydroxide, $Zn(OH)_2$, is the only other transition metal hydroxide that is soluble at high pH, because it forms $Zn(OH)_4^{2-}$ ions.

Nearly all transition metals exist as $M^{n+}(aq)$ ions only in strongly acidic solutions. They exist as complex ions, such as $M(H_2O)_5(OH)^{(n-1)+}$, in aqueous solutions that range from slightly acidic to slightly basic ($3 < pH < 9$). This pH range includes most environmental waters and biological fluids.

$$\frac{1.1 \times 10^{-4}\ \cancel{\text{mol}}}{\cancel{\text{L}}} \times \frac{58.32\ \text{g}}{1\ \cancel{\text{mol}}} \times \frac{1\ \cancel{\text{L}}}{1000\ \cancel{\text{mL}}} \times 100\ \cancel{\text{mL}} = 6.4 \times 10^{-4}\ \text{g}$$

$$[\text{SO}_4{}^{2-}]_{\text{initial}} = \frac{2.8\ \cancel{\text{g}}}{\text{L}} \times \frac{1\ \text{mol}}{96.06\ \cancel{\text{g}}} = \frac{0.029\ \text{mol}}{\text{L}}$$

$$(1) \qquad \text{CaF}_2(s) \rightleftharpoons \text{Ca}^{2+}(aq) + 2\ \text{F}^-(aq) \qquad K_{\text{sp}} = 5.3 \times 10^{-9}$$

$$(2) \qquad \text{H}_3\text{O}^+(aq) + \text{F}^-(aq) \rightleftharpoons \text{HF}(aq) + \text{H}_2\text{O}(\ell)$$

$$K_2 = \frac{[\text{HF}]}{[\text{H}_3\text{O}^+][\text{F}^-]} = \frac{1}{6.8 \times 10^{-4}} = 1.47 \times 10^3$$

$$\frac{[\text{F}^-]}{[\text{F}^-] + [\text{HF}]} = \frac{[\text{F}^-]}{[\text{F}^-] + 73.5[\text{F}^-]} = \frac{[\text{F}^-]}{74.5[\text{F}^-]} = 0.0134$$

$$[\text{Al}^{3+}] = \frac{K_{\text{sp}}}{[\text{OH}^-]^3} = \frac{1.3 \times 10^{-33}}{(1.0 \times 10^{-7})^3} = 1.3 \times 10^{-12}\ M \qquad (16.8)$$

$$[\text{Al}^{3+}] = \frac{K_{\text{sp}}}{[\text{OH}^-]^3} = \frac{1.3 \times 10^{-33}}{(1.0 \times 10^{-11})^3} = 1.3\ M$$

$$\text{Pb}^{2+}(aq): \qquad 0.134\ \frac{\text{mol}}{\cancel{\text{L}}} \times 0.275\ \cancel{\text{L}} = 0.03685\ \text{mol}$$

$$[\text{Pb}^{2+}] = \frac{0.03685}{0.400\ \text{L}} = 0.0921\ M$$

$$\text{Cl}^-(aq): \qquad 0.0339\ \frac{\text{mol}}{\cancel{\text{L}}} \times 0.125\ \cancel{\text{L}} = 0.004238\ \text{mol}$$

$$[\text{Cl}^-] = \frac{0.004238}{0.400\ \text{L}} = 0.0106\ M$$

$$K_{\text{sp}} = 5.5 \times 10^{-6} = [\text{Ca}^{2+}][\text{OH}^-]^2 = (0.10)(x)^2$$

$$x = \sqrt{\frac{5.5 \times 10^{-6}}{0.10}} = 7.4 \times 10^{-3}\ M$$

$$K_{\text{sp}} = 5.6 \times 10^{-12} = [\text{Mg}^{2+}][\text{OH}^-]^2 = (x)(7.4 \times 10^{-3})^2$$

$$x = \frac{5.6 \times 10^{-12}}{(7.4 \times 10^{-3})^2} = 1.0 \times 10^{-7}\ M$$

$$K_{sp} = 1.7 \times 10^{-5} = [Pb^{2+}][Cl^-]^2 = (x)(0.275)^2$$

$$x = \frac{1.7 \times 10^{-5}}{(0.275)^2} = 2.25 \times 10^{-4}\ M$$

$$K_{sp} = 3.3 \times 10^{-8} = (2.25 \times 10^{-4})(x)^2$$

$$x = \sqrt{\frac{3.3 \times 10^{-8}}{2.25 \times 10^{-4}}} = 0.0121\ M$$

$$(1) \qquad H_2CO_3(aq) + H_2O(\ell) \rightleftharpoons HCO_3^-(aq) + H_3O^+(aq) \qquad pK'_{a_1} = 5.85$$

$$(2) \qquad HCO_3^-(aq) + H_2O(\ell) \rightleftharpoons CO_3^{2-}(aq) + H_3O^+(aq) \qquad pK'_{a_2} = 9.00$$

$$pH = pK_a + \log\frac{[\text{base}]}{[\text{acid}]} = 9.00 + \log\frac{[CO_3^{2-}]}{[HCO_3^-]}$$

16.8 Solubility Equilibria

In Section 15.2 we noted that the common strong bases include the hydroxides of alkaline earth elements. One exception is $Mg(OH)_2$, which is a weak base because it has limited solubility in water. Magnesium hydroxide is the active ingredient in a product found in many medicine cabinets: the antacid called *milk of magnesia*. This liquid appears “milky” because it is an aqueous *suspension* (not solution) of solid, white $Mg(OH)_2$. We can express the limited solubility of solid $Mg(OH)_2$ with the following equation:

$$Mg(OH)_2(s) \rightleftharpoons Mg^{2+}(aq) + 2\ OH^-(aq)$$

Because $Mg(OH)_2$ is a solid, its effective concentration does not change as long as some of it is present in the system. Therefore, the equilibrium constant for the dissolution of $Mg(OH)_2$ is

$$K_{sp} = [Mg^{2+}][OH^-]^2$$

where $\boldsymbol{K_{sp}}$ represents an equilibrium constant called the *solubility-product constant* or simply the solubility product.

The K_{sp} values of $Mg(OH)_2$ and other slightly soluble compounds are listed in Table A5.4. We can use these values to calculate the concentrations of these compounds in aqueous solutions. Two terms are widely used to describe how much of a solid dissolves in a solvent: *solubility*, which is often expressed in grams of solute per 100 mL of solution, and *molar solubility*, which is expressed in moles of solute per liter of solution. In Sample Exercise 16.15 we use the K_{sp} of $Mg(OH)_2$ to calculate its solubility and molar solubility.

SAMPLE EXERCISE 16.15 Calculating the Solubility of an Ionic Compound from Its K_{sp}LO8

What is the molar solubility of $Mg(OH)_2$ at 25°C, and what is its solubility expressed in grams $Mg(OH)_2$ per 100 mL of solution? The K_{sp} of $Mg(OH)_2$ from Table A5.4 is 5.6×10^{-12}.

Collect, Organize, and Analyze The RICE table below is based on the dissolution of $Mg(OH)_2$ in water:

$$Mg(OH)_2(s) \rightleftharpoons Mg^{2+}(aq) + 2\ OH^-(aq)$$

Converting molar solubility (x mol/L) into (g/100 mL) requires multiplying x by the molar mass of $Mg(OH)_2$, 58.32 g/mol, and factoring in the smaller volume (100 mL versus 1 L).

Solve

Reaction	$Mg(OH)_2(s)$	$\rightleftharpoons$	$Mg^{2+}(aq)$	+	$2\ OH^-(aq)$
			$[Mg^{2+}]$ (M)		$[OH^-]$ (M)
Initial (I)			0		0
Change (C)			$+x$		$+2x$
Equilibrium (E)			x		$2x$

Inserting the equilibrium terms in the K_{sp} expression and solving for x:

$$K_{sp} = [Mg^{2+}][OH^-]^2 = (x)(2x)^2 = (x)(4x^2) = 4x^3 = 5.6 \times 10^{-12}$$

$x = 1.1 \times 10^{-4} M$

Converting this molar solubility into g/100 mL:

Think About It Note the lack of concentration terms for $Mg(OH)_2(s)$ in the RICE table and its absence from the K_{sp} expression. Like all pure solids, its concentration has no relevance in equilibrium calculations as long as it is present in the reaction mixture. Also, the entire algebraic expression for $[OH^-]$, $2x$, is squared in this calculation: $(2x)^2 = 4x^2$. Forgetting to square the coefficient is a common mistake. Finally, the calculated molar solubility is much larger than the K_{sp} value. This difference is true for all sparingly soluble ionic compounds because K_{sp} values are the products of small concentration values multiplied together, producing even smaller K_{sp} values.

Practice Exercise What is the solubility of $Ca_3(PO_4)_2$ at 25°C expressed in mol/L and in g/100 mL? See Table A5.4 for the appropriate K_{sp} value.

CONCEPT TEST

In Sample Exercise 16.15 we calculated molar solubility from K_{sp}, but the reverse calculation is also possible. If the molar solubility of BaF_2 is $1.10 \times 10^{-3} M$, what is the K_{sp} for barium fluoride?

SAMPLE EXERCISE 16.16 Evaluating the Common-Ion Effect on Solubility LO8

The mineral barite is mostly barium sulfate ($BaSO_4$) and is widely used in industry and in medical imaging. Calculate the molar solubility at 25°C of $BaSO_4$ in (a) pure water and (b) seawater in which the concentration of sulfate ions is 2.8 g/L.

Collect and Organize We want to calculate the molar solubility of

$BaSO_4$ in both pure water and in seawater that already contains sulfate ions. The K_{sp} value of $BaSO_4$ given in Table A5.4 is 1.08×10^{-10}.

Analyze As each mole of $BaSO_4$ dissolves, 1 mole of Ba^{2+} ions and 1 mole of $SO_4{}^{2-}$ ions go into solution:

$$BaSO_4(s) \rightleftharpoons Ba^{2+}(aq) + SO_4{}^{2-}(aq)$$

The presence of a background concentration of sulfate ions means that the common-ion effect will shift the above equilibrium to the left, which means the solubility of $BaSO_4$ we calculate for seawater should be less than its solubility in pure water.

Solve

1. Setting up a RICE table based on the above dissolution equilibrium in pure water:

Reaction (R)	$BaSO_4(s)$	$Ba^{2+}(aq)$	$SO_4{}^{2-}(aq)$
		$[Ba^{2+}]$ (M)	$[SO_4{}^{2-}]$ (M)
Initial (I)		0	0
Change (C)		$+x$	$+x$
Equilibrium (E)		x	x

$$K_{sp} = [Ba^{2+}][SO_4{}^{2-}] = (x)(x) = 1.08 \times 10^{-10}$$

$$x = 1.04 \times 10^{-5} M$$

1. The RICE table for seawater must include an initial concentration value for $SO_4{}^{2-}$ ions, which requires converting the given concentration in g/L into mol/L:

Reaction (R)	$BaSO_4(s)$	$Ba^{2+}(aq)$	$SO_4{}^{2-}(aq)$
		$[Ba^{2+}]$ (M)	$[SO_4{}^{2-}]$ (M)
Initial (I)		0	0.0210
Change (C)		$+x$	$+x$
Equilibrium (E)		x	$(0.0210 + x)$

Incorporating the equilibrium terms into the K_{sp} expression:

$$K_{sp} = [Ba^{2+}][SO_4{}^{2-}] = (x)(0.029 + x) = 1.08 \times 10^{-10}$$

Solving for x is simplified if we assume that the K_{sp} of $BaSO_4$ is so small that we can ignore its contribution to the total $SO_4{}^{2-}$ concentration. Therefore,

$$(x)(0.029 + x) \approx (x)(0.029) = 1.08 \times 10^{-10}$$

$$x = 3.7 \times 10^{-9} M$$

Think About It The calculated value of x is much less than 5% of the initial $[SO_4{}^{2-}]$ value: $(3.7 \times 10^{-9}/0.029 = 1.9 \times 10^{-7})$, so our simplifying assumption was justified. The solubility of $BaSO_4$ is much lower in seawater, as predicted, and is another illustration of the common-ion effect: the dissolution of $BaSO_4$ is suppressed by the $SO_4{}^{2-}$ ions already present in seawater.

CONNECTION As noted in Section 14.8, the $-x$ or $+x$ component of an equilibrium concentration or partial pressure term can be ignored if x is less than 5% of the initial concentration of partial pressure.

Practice Exercise What is the molar solubility of $MgCO_3$ in alkaline spring water at 25°C in which $[CO_3{}^{2-}] = 0.0075\ M$? See Table A5.4 for the appropriate K_{sp} value.

Sample Exercise 16.16 shows how the common-ion effect can suppress the solubility of an ionic compound. Other perturbations to solubility equilibria can promote solubility, as occurs when the anion of the compound is the conjugate base of a weak acid. The molar solubilities of such compounds increase in acidic solutions, as shown in Sample Exercise 16.17.

SAMPLE EXERCISE 16.17 Calculating the Effect of pH on Solubility LO8

What is the molar solubility of CaF_2 at 25°C in (a) pure water and (b) an acidic buffer in which $[H_3O^+]$ is a constant 0.050 *M*?

Collect and Organize We are asked to calculate the solubility of CaF_2 in both pure water and in an acidic buffer. The dissolution process is described by the following equilibrium:

Analyze To account for the effect of acid on the solubility of a fluoride salt, we need to consider the chemical equilibrium in which the fluoride ion acts as a Brønsted–Lowry base (H^+ ion acceptor):

This reaction is the reverse of the acid ionization reaction:

$$HF(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + F^-(aq)$$

As a result, the equilibrium constant for reaction 2 is the reciprocal of the K_a (see Table A5.1) of HF:

As reaction 2 proceeds, F^- ions are consumed, which shifts the equilibrium in reaction 1 to the right, increasing CaF_2 solubility. Therefore, the solubility of CaF_2 should increase when acid is present.

Solve

1. Let x be the molar solubility of CaF_2 in pure water. According to the stoichiometry of reaction 1, $[Ca^{2+}] = x$ mol/L and $[F^-] = 2x$ mol/L. Inserting these symbols in the K_{sp} expression:

   $$K_{sp} = [Ca^{2+}][F^-]^2 = (x)(2x)^2 = 5.3 \times 10^{-9}$$

   $$4x^3 = 5.3 \times 10^{-9}$$

   $$x = 1.1 \times 10^{-3} M$$

2. In the acidic buffer, $[H_3O^+] = 0.050$ *M*. The F^- and H_3O^+ ions combine as shown in reaction 2. Assuming $[H_3O^+]$ is a constant 0.050 *M*, then:

$$K_2 = \frac{[\mathrm{HF}]}{[0.050][\mathrm{F}^-]} = 1.47 \times 10^3$$

$$\frac{[\mathrm{HF}]}{[\mathrm{F}^-]} = 73.5$$

$$(3) \qquad [\mathrm{HF}] = 73.5[\mathrm{F}^-]$$

This calculation tells us that most of the F^- produced when calcium fluoride dissolves is converted into HF. The tiny fraction that remains free F^- ions is defined by this ratio:

$$(4) \qquad \frac{[\mathrm{F}^-]}{[\mathrm{F}^-] + [\mathrm{HF}]}$$

Here the numerator is the concentration of free F^- ions at equilibrium and the denominator is the concentration of all the F^- ions produced when CaF_2 dissolved. Combining expressions 3 and 4 to calculate the fraction of dissolved fluoride ions that are free F^- ions and not molecules of HF:

If x is the molar solubility of CaF_2 in the acid, x mol/L Ca^{2+} and $2x$ mol/L F^- are produced. However, most of the fluoride ions are converted into HF, and the free F^- ion concentration is only $(0.0134 \times 2x) = 0.0268x$. Inserting this value in the K_{sp} expression:

$K_{sp} = [Ca^{2+}][F^-]^2 = (x)(0.0268\,x)^2 = 7.18 \times 10^{-4}\,x^3 = 5.3 \times 10^{-9}$

$x = 1.9 \times 10^{-2} M$

Think About It A comparison of the results from parts (a) and (b) reveals that the molar solubility of CaF_2 is $(1.9 \times 10^{-2}\ \cancel{M}/1.1 \times 10^{-3}\ \cancel{M})$ or 17 times higher in the acidic buffer, as we predicted, because most of the F^- ions produced when CaF_2 dissolves in the buffer are converted into molecules of HF. This conversion removes a product from the K_{sp} equilibrium mixture. According to Le Châtelier's principle, the result will be a shift in the position of the equilibrium to the right, in favor of forming product and increasing solubility.

Practice Exercise What is the molar solubility of $ZnCO_3$ at 25°C in pure water and in a pH 7.00 buffer solution? Assume the pH of the buffer is unaffected by the presence of $ZnCO_3$. See Table A5.4 for the appropriate K_{sp} value.

CONCEPT TEST

Would adding a solution of sodium fluoride or nitric acid increase the solubility of PbF_2? Would either solution decrease the solubility of PbF_2? Which would have little effect?

According to Table A5.4, the hydroxides of many metals, including all transition metals, have very small K_{sp} values. However, these tiny K_{sp} values apply to equilibrium concentrations of *free metal ions*. As we have seen in this chapter, many metals form stable complex ions in aqueous solution, reducing their free metal ion concentration. What, for example, is the solubility of Al^{3+} ions in pH 7.00 water? The K_{sp} of $Al(OH)_3$ is

$$K_{sp} = [Al^{3+}][OH^-]^3 = 1.3 \times 10^{-33}$$

Solving the K_{sp} expression for $[Al^{3+}]$ and inserting $[OH^-] = 1.0 \times 10^{-7}$, we get

This very small value seems to imply that no aluminum salt is soluble in water because the $Al^{3+}(aq)$ ions that it releases as it dissolves would immediately precipitate as $Al(OH)_3$. However, that conclusion is incorrect. For example, $Al(NO_3)_3$, like all nitrate salts, is quite soluble in water. This solubility can be explained by the acidic properties of hydrated Al^{3+} ions, $Al(H_2O)_6{}^{3+}$, which make $Al(NO_3)_3$ an acidic salt. The pH of 0.1 *M* $Al(NO_3)_3$ is about 3.0. At this pH, $[OH^-] = 1 \times 10^{-11}$. Inserting this value in Equation 16.8 and solving for $[Al^{3+}]$, we get:

The maximum value is more than 10 times the concentration of Al^{3+} ions in a 0.1 *M* solution of $Al(OH)_3$.

K_{sp} and Q

We can also use K_{sp} values to predict whether a concentration of an ionic compound is possible or whether a precipitate will form when the solutions of two salts are mixed. In making these predictions, it is convenient to use the concept of the reaction quotient Q that we developed in Chapter 14. When applied to the equilibrium governing a slightly soluble salt, Q is sometimes called the *ion product*, because it is the product of the concentrations of the ions in solution after each is raised to a power equal to its subscript in the formula of the compound. If the calculated Q value is greater than the K_{sp} of the compound ($Q > K_{sp}$), the reaction will favor reactant formation, and the compound will precipitate (or never dissolve in the first place). If $Q < K_{sp}$, the reaction will favor product formation, and the compound will be soluble and will not precipitate.

SAMPLE EXERCISE 16.18 Predicting Whether a Precipitate Forms When Two Solutions Are Mixed LO8

Lead(II) chloride is a white pigment used in 15th-century European painting. Will $PbCl_2$ precipitate when 275 mL of a 0.134 *M* solution of $Pb(NO_3)_2$ is added to 125 mL of a 0.0339 *M* solution of NaCl?

Collect and Organize We are asked whether $PbCl_2$ will precipitate when two solutions containing Pb^{2+} ions and Cl^- ions are mixed. The solubility product of $PbCl_2$ is

$$K_{sp} = [Pb^{2+}][Cl^-]^2 = 1.70 \times 10^{-5}$$

Analyze To determine whether a precipitate forms, we need to calculate Q and compare its value to K_{sp}. If $Q > K_{sp}$, $PbCl_2$ will precipitate; if $Q < K_{sp}$, it will not precipitate. Q has the same form as the equilibrium constant, $[Pb^{2+}][Cl^-]^2$, but the concentration values used in it are the values for a given system that may or may not be at equilibrium.

Solve First we calculate the concentrations of the lead ions and chloride ions in the two solutions immediately after they are mixed. Mixing the two solutions dilutes both, so the volumes of the solutions (275 mL and 125 mL) must be added to get the final solution volume (400 mL = 0.400 L).

The value of Q is

$$Q = [Pb^{2+}][Cl^-]^2 = (0.0921)(0.0106)^2 = 1.03 \times 10^{-5}$$

Because $Q < K_{sp}$, no precipitate forms.

Think About It Lead(II) chloride was categorized as a *slightly soluble* compound in Table 4.5. In this scenario, $PbCl_2$ does not precipitate because the solutions of Pb^{2+} and Cl^- ions are too dilute to provide the concentrations required for the precipitate to form.

Practice Exercise Will calcium fluoride precipitate when 175 mL of a $4.78 \times 10^{-3} M$ solution of $Ca(NO_3)_2$ is added to 135 mL of a $7.35 \times 10^{-3} M$ solution of KF? See Table A5.4 for the appropriate K_{sp} value.

We can use differences in the solubilities of ionic compounds to selectively separate ions, particularly cations, in solution. For example, suppose an aqueous solution contains 0.10 *M* Ca^{2+} ion and 0.020 *M* Mg^{2+} ion. Is it possible to selectively remove the Mg^{2+} ions from solution by precipitating them as $Mg(OH)_2$ while leaving the Ca^{2+} ions in solution? This approach might work because $Mg(OH)_2$ is much less soluble than $Ca(OH)_2$, as indicated by their K_{sp} values:

$$K_{sp} = [Mg^{2+}][OH^-]^2 = 5.6 \times 10^{-12}$$

$$K_{sp} = [Ca^{2+}][OH^-]^2 = 5.5 \times 10^{-6}$$

One way to answer this ion separation question involves calculating the maximum concentration of OH^- ions that will *not* cause the 0.10 *M* Ca^{2+} ion to precipitate and then determining whether that concentration is high enough to precipitate all the Mg^{2+} ions. We can calculate the target $[OH^-]$ value from the K_{sp} of calcium hydroxide:

Now we need to determine whether all the Mg^{2+} ions in solution would have precipitated as $Mg(OH)_2$ if $[OH^-]$ reached $7.4 \times 10^{-3} M$. Inserting this value in the K_{sp} expression for $Mg(OH)_2$ and solving for the $[Mg^{2+}]$ that would be in equilibrium with it:

The concentration of Mg^{2+} ions in the original solution is 0.020 *M*. If we assume that quantitative removal of the Mg^{2+} ions is achieved if their concentration drops to below 0.1% of the original value, or $2.0 \times 10^{-5} M$, then quantitative removal was achieved before $Ca(OH)_2$ precipitation began. This approach of precipitation of $Mg(OH)_2$ has been used to selectively separate these ions from seawater, where $[Ca^{2+}] = 0.0106$ *M* and $[Mg^{2+}] = 0.054$ *M*.

CONCEPT TEST

In evaluating the use of a precipitation reaction to separate magnesium ions from calcium ions in solution, we did not specify the concentration of the hydroxide ion solution used to form the precipitates. Why did we not need this value?

SAMPLE EXERCISE 16.19 Separating Anions in Solution LO9

Both lead(II) chloride and lead(II) fluoride are slightly soluble salts. A solution of lead(II) nitrate is added to a solution that is 0.275 *M* in both $Cl^-(aq)$ and $F^-(aq)$. Can we use this method to separate the two halide ions? If "complete precipitation" is defined as there being less than 0.1% of a particular ion left in solution, is the precipitation of the first salt complete before the second salt begins to precipitate?

Collect and Organize We are given a solution that contains two ions that form slightly soluble lead(II) salts, and we are asked whether one ion can be completely removed before the second one starts to precipitate when lead(II) ion is added to the solution. We have the K_{sp} values for both salts and the initial concentrations of both ions.

Analyze The equilibrium constant expressions for both ions are

$$K_{sp} = [Pb^{2+}][Cl^-]^2 = 1.7 \times 10^{-5}$$

$$K_{sp} = [Pb^{2+}][F^-]^2 = 3.3 \times 10^{-8}$$

The K_{sp} of $PbCl_2$ is $(1.7 \times 10^{-5}/3.3 \times 10^{-8}) = 500$ times the K_{sp} of PbF_2. Therefore, PbF_2 should precipitate first when Pb^{2+} ions are added to a solution containing the same concentrations of F^- and Cl^- ions. We need to determine the maximum $[Pb^{2+}]$ that could be added to precipitate PbF_2 and not cause $PbCl_2$ to precipitate. When we determine that value, we can calculate $[F^-]$ remaining in solution to determine whether the precipitation of F^- as PbF_2 was complete.

Solve The maximum concentration of Pb^{2+} in the solution that will not cause the chloride ion to precipitate is

---

The concentration of $F^-(aq)$ in the solution at this concentration of lead(II) ion is

---

The original solution was 0.275 M in F^- ions. A residual concentration of 0.0121 M F^- represents $(0.0121/0.275) \times 100\% = 4.4\%$ of the original $[F^-]$, which is greater than our 0.1% residual value that represents complete removal. Therefore, precipitation of $PbF_2(s)$ is *not* complete and we cannot use this method to separate the two ions.

Think About It This attempt at selective precipitation did not work because the ratio of the K_{sp} values was only 500 *and* because the halide concentration terms in the K_{sp} expressions were both squared. These squared concentration terms had the effect of producing a F^-/Cl^- ion ratio at equilibrium that was only the square root of their K_{sp} ratio: $(1/500)^{0.5} = 0.045$, or 4.5%.

Practice Exercise A water sample contains barium ions (0.0375 M) and calcium ions (0.0667 M). Can they be completely separated by selective precipitation of CaF_2? See Table A5.4 for the appropriate K_{sp} values.

CONNECTION Ion pair formation in 1.0 M solutions of ionic compounds significantly reduces the number of free ions in these solutions (see Section 11.5).

We end Chapter 16 with Sample Exercise 16.20, which integrates acid–base and solubility equilibria by revisiting ocean acidification from Section 16.1. In this exercise we use the ionization equilibria of carbonic acid, as we have done in several other exercises, but this time we use different $K_{a1}$and K_{a2}values. Why? Because the K values we have used until now have all been *theoretical* values, which means they apply to ideal solutions in which each solute ion behaves as freely and independently as if it were the only ion present. Theoretical K values work best for very dilute solutions, but they don't perform as well for solutions as concentrated (salty) as seawater. They do not, for example, account for ion pair formation. Therefore, we use *apparent* K'_{a1} and K'_{a2} values at 25°C in Sample Exercise 16.20 that apply to chemical equilibria in typical seawater, which contains 35 g of dissolved sea salts per kilogram of seawater. Their symbols contain a prime (′) after the K to indicate that their values apply only to that particular sample.

SAMPLE EXERCISE 16.20 Integrating Concepts: Evaluating the Impact of Ocean Acidification

As we discussed at the beginning of this chapter, increasing concentrations of atmospheric CO_2 have increased the concentration of CO_2 dissolved in the sea. As we saw in Equations 16.1–16.3, an increase in $[CO_2]$ will then shift the following equilibria to the right:

1. The average pH of the Pacific Ocean near Hawaii dropped from 8.12 to 8.07 between 1989 and 2014. By how much did the average acidity ($[H_3O^+]$) of the ocean increase? Express your answer as a percentage of the 1989 acidity.
2. Ocean pH is expected to drop by at least another 0.30 units by the end of this century. Assuming the concentrations of most other dissolved ions remain the same as today—that is, $[Ca^{2+}] = 0.0106\ M$ and $[HCO_3^-] + [CO_3^{2-}] = 0.00211\ M$—will the skeletal structures of marine organisms that are composed of $CaCO_3$ be soluble or insoluble in seawater in 2100? The K'_{sp} value for aragonite (the crystalline form of $CaCO_3$ in corals and seashells) is 6.46×10^{-7}.

Collect and Organize We are asked to convert a decrease in pH into an increase in acidity and to evaluate the impact of that increase on the solubility of $CaCO_3$. We know the concentration of Ca^{2+} ions and the total ($[CO_3^{2-}] + [HCO_3^-]$) value, as well as the appropriate K'_{sp} value. The last two ions are a conjugate acid–base pair whose concentrations are linked by reaction (2) and the Henderson–Hasselbalch equation based on it:

Analyze The ratio of the acidity of the seawater near Hawaii in 2014 compared with that in 1989 can be calculated by applying the definition $[H_3O^+] = 10^{-pH}$. To determine whether $CaCO_3$ dissolves in seawater in 2100, we need to calculate the $[CO_3^{2-}]/$

[HCO_3^-] ratio in equilibrium with seawater at pH (8.07 − 0.30 = 7.77) and then use that ratio and the total carbonate and bicarbonate value to calculate [CO_3^{2-}]. The product of that value and [Ca^{2+}] will give us a Q value that can be compared with the K'_{sp} of $CaCO_3$ to determine whether seawater will be saturated with $CaCO_3$.

Solve

1. Converting the decrease in pH values to an increase in [H_3O^+], expressed as a ratio of the 2014 value to the 1989 value:

$$\frac{[H^+]_{2014}}{[H^+]_{1989}} = \frac{10^{-8.07}\ \cancel{M}}{10^{-8.12}\ \cancel{M}} = 10^{0.05} = 1.12$$

   Therefore, the acidity of the 2014 sample is 1.12 times the acidity of the 1989 sample, which means acidity increased 12% during the 25 years before 2014.

2. The [CO_3^{2-}]/[HCO_3^-] ratio in 2100 will be

$$7.77 = 9.00 + \log\frac{[CO_3^{2-}]}{[HCO_3^-]}$$

$$\frac{[CO_3^{2-}]}{[HCO_3^-]} = 0.0589$$

   If we let x be [CO_3^{2-}], then

$$\frac{x}{(0.00211 - x)} = 0.0589$$

$$x = 1.17 \times 10^{-4}\ M$$

Calculating Q for $CaCO_3$:

$Q = [Ca^{2+}][CO_3{}^{2-}] = 0.0106 \times 1.17 \times 10^{-4} = 1.24 \times 10^{-6}$

This value of Q is $(1.24 \times 10^{-6})/(6.46 \times 10^{-7}) = 1.9$ times the value of K'_{sp}, which means seawater will still be supersaturated with respect to $CaCO_3$.

Think About It The results of the calculations suggest that coral exoskeletons and seashells should still be able to form in pH 7.77 seawater because it will be supersaturated with respect to $CaCO_3$. However, the predicted degree of supersaturation (essentially 100%) in 2100 will have decreased from 400% in 1989 [you may repeat the part (b) calculation, using pH 8.12 to confirm this value]. Moreover, some climate change models predict even greater decreases in oceanic pH by 2100. There appears to be reason for concern.

Glossary

solubility product (K_{sp}) (also called *solubility-product constant*)
an equilibrium constant that describes the formation of a saturated solution of a slightly soluble salt.

Learning Objectives

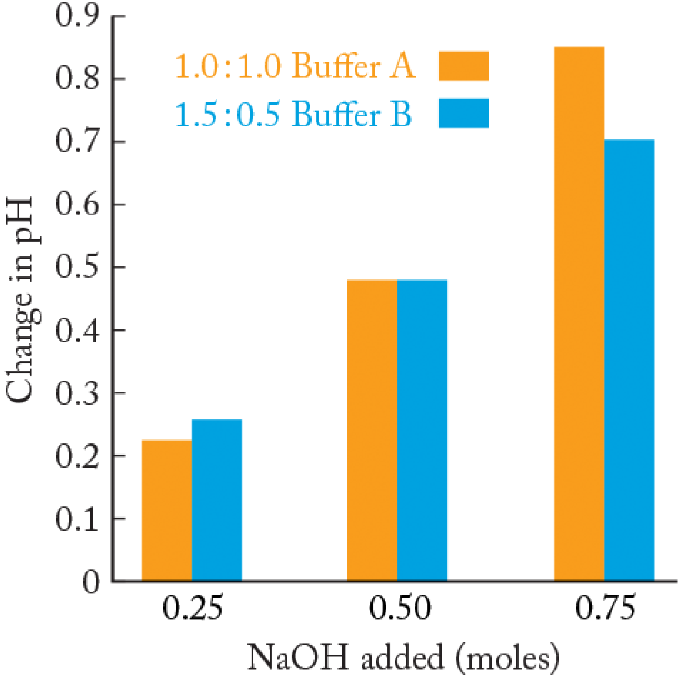
- Relate the solubility of an ionic compound to its solubility product constant and to solution pH **Return to Sample Exercises 16.15, 16.16, 16.17, 16.18**
- Relate the solubility of an ionic compound to its solubility product constant and to solution pH **Return to Sample Exercises 16.15, 16.16, 16.17, 16.18**
- Relate the solubility of an ionic compound to its solubility product constant and to solution pH **Return to Sample Exercises 16.15, 16.16, 16.17, 16.18**
- Relate the solubility of an ionic compound to its solubility

product constant and to solution pH **Return to Sample Exercises 16.15, 16.16, 16.17, 16.18**

- Determine which mixtures of ionic compounds can be separated by selective precipitation reactions **Return to Sample Exercise 16.19**

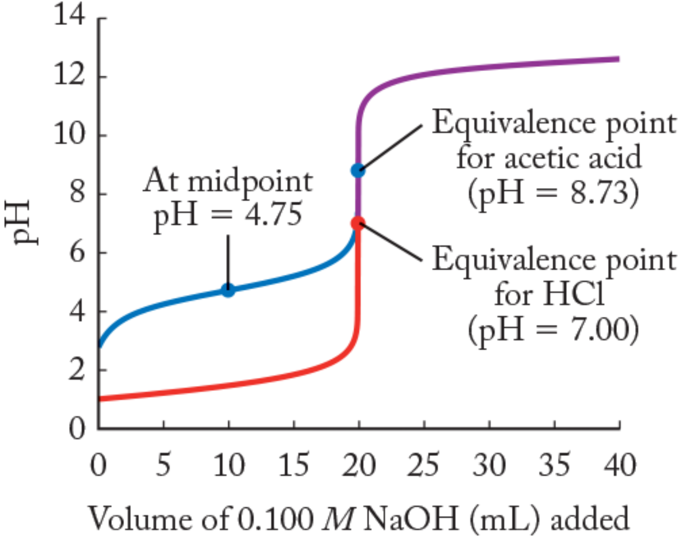
SUMMARY

- LO1 As predicted by Le Châtelier's principle, adding conjugate base to a solution of a weak acid inhibits ionization of the acid, causing the pH of the solution to be greater than in the acid alone. Adding conjugate acid to a solution of a weak base lowers the pH of the solution. These shifts are examples of the common-ion effect. (Section 16.2)

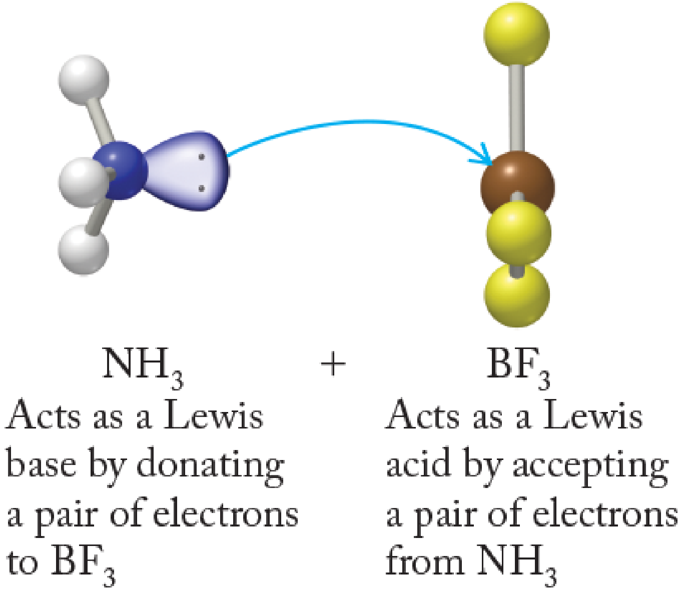


- LO2 A pH buffer is a solution that contains either a weak acid and a salt of its conjugate base or a weak base and a salt of its conjugate acid. The acidic component should have a pK_a close to the desired pH of the buffer. (Section 16.3)
- LO3 pH buffers have the capacity to resist pH change because their acid components neutralize additions of bases and their base components neutralize additions of acids. The pK_a of the buffer's acid component should be within 1 pH unit of the

buffer’s target pH. (Section 16.3)



- LO4 Color pH indicators or pH electrodes are used to detect the equivalence points in pH titrations, which are used to determine the concentrations of acids or bases in aqueous samples. (Section 16.4)



NH3
+
BF3
Acts as a Lewis base by donating a pair of electrons to BF3
Acts as a Lewis acid by accepting a pair of electrons from NH3

- LO5 A Lewis base is a substance that donates pairs of electrons to a Lewis acid, defined as an electron-pair acceptor. The donated electron pair forms a coordinate bond. In some Lewis acid–Lewis base reactions, other bonds must break to accommodate the new one. (Sections 16.5 and 16.6)

- LO6 Coordinate covalent bonds are formed by ligands sharing lone pairs of electrons with empty orbitals of metal ions. The stability of the complex ions formed in this way is expressed mathematically by their formation constant (K_f), which can be used to calculate the equilibrium concentration of free metal ions in a solution of complex ions. (Section 16.6)
- LO7 Highly charged (e.g., 3+) hydrated metal ions are weak acids because of the ionization of water molecules covalently bonded to them. (Section 16.7)
- LO8 The solubility of slightly soluble ionic compounds is described by their $\boldsymbol{K_{sp}}$, or solubility product. Their solubility can be influenced by the common-ion effect, complex ion formation, and pH, especially if the anion is the conjugate base of a weak acid. (Section 16.8)
- LO9 The relative solubilities of two slightly soluble ionic compounds can be used to selectively precipitate one from solution while the other remains soluble. (Section 16.8)

PARTICULATE PREVIEW WRAP-UP

The proton transfer reactions are described in the following reaction equation:

$$HF(aq) + H_2O(\ell) \rightleftharpoons F^-(aq) + H_3O^+(aq)$$

The only source of fluoride ions in (a) is HF molecules that ionize as the reaction proceeds more rapidly in the forward direction until equilibrium is achieved. In (b) there is a second source of fluoride ions in the reaction mixture, which gives it the capacity to act as a pH buffer: more fluoride ions give it the capacity to neutralize additions of acid, as the above reaction runs in reverse, and the HF component neutralizes additions of base, forming F^- ions and H_2O:

$$HF(aq) + OH^-(aq) \rightleftharpoons F^-(aq) + H_2O(\ell)$$

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts and Equations	Sample Exercises
Calculating pH of a solution of a weak base and its conjugate acid (or a weak acid and its conjugate base)	Insert the concentrations of the buffer components and the acid's pK_a into the Henderson–Hasselbalch equation: $\mathrm{pH} = \mathrm{p}K_a + \log \frac{[\mathrm{base}]}{[\mathrm{acid}]}$ (16.4)	16.1, 16.2
Preparing a buffer of given pH	Select a weak acid with pK_a within 1 pH unit of the target pH. Add a Na^+ salt of its conjugate base in a proportion calculated using the Henderson–Hasselbalch equation.	16.3, 16.4, 16.5
Assessing the effect of concentration and [base]:[acid] ratio on buffer capacity	Neutralize the strong acid or base completely with the base or acid components of the buffer. Calculate pH from the concentrations of the components that remain by using the Henderson–Hasselbalch equation.	16.6, 16.7, 16.8
Interpreting results of acid–base titrations	Use the volume of titrant needed to reach the equivalence point to calculate the number of moles of it consumed by the analyte, and, from the stoichiometry of the titration reaction, the number of moles of analyte in the sample.	16.9, 16.10, 16.11, 16.12
Identifying Lewis acids and bases	Lewis bases donate pairs of electrons, whereas Lewis acids accept these pairs of electrons.	16.13
Using formation constants to calculate the concentration of free or complexed ion	Set up a RICE table based on the complex formation reaction. Let x be the concentration of free (not complexed) metal ion. Solve for x, which is usually much smaller than the concentration of the complex.	16.14
Calculating the solubility of an ionic compound from its K_{sp}	Express the concentrations of the ions in the K_{sp} expression in terms of x moles of the compound that dissolve in 1 L of solution.	16.15, 16.16
Calculating the effect of pH on solubility	If A^- is the conjugate base of a weak acid HA, calculate the fraction of A^- that remains as the free ion. Use this fraction as the coefficient for molar solubility in the K_{sp} expression.	16.17
Determining whether a precipitate forms when solutions are mixed, and which precipitate forms first if more than one is possible	Compare the value of Q to K_{sp} to determine whether ions will precipitate, and use K_{sp} expressions to calculate the maximum concentrations of one ion in solution that will not cause another ion to precipitate.	16.18, 16.19

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

The graph in Figure P16.1 shows the titration curves of a 1 *M* solution of a weak acid with a strong base and a 1 *M* solution of a strong acid with the same base. Which curve is which?

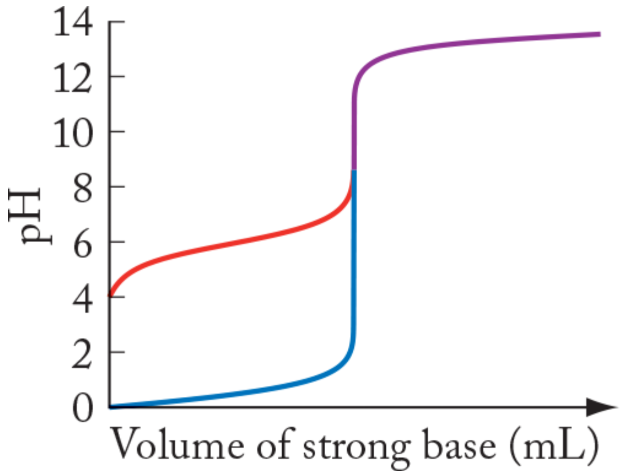


FIGURE P16.1

Estimate (to two significant figures) the pK_a of the weak acid in Problem 16.1.

Suppose you have four color indicators to choose from to detect the equivalence point of the titration reaction represented by the red curve in Figure P16.1. The pK_a values of the four indicators are 3.3, 5.0, 7.0, and 9.0. Which indicator would be the best one to choose?

Explain why the slope of the red titration curve in Figure P16.1 is nearly flat in the region extending about halfway from the start of the titration to its equivalence point.

One of the titration curves in Figure P16.5 represents the titration of an aqueous sample of Na_2CO_3 with strong acid; the other represents the titration of an aqueous sample of $NaHCO_3$ with the same acid. Which curve is which?

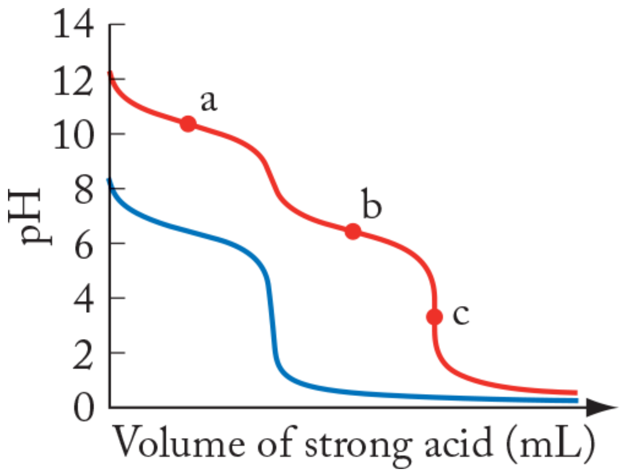

FIGURE P16.5

Identify the principal carbon-containing species in solution at points a, b, and c on the red titration curve in Figure P16.5.

Each of the three beakers in Figure P16.7 contains a few drops of the color indicator bromthymol blue, which is yellow in acidic solutions and blue in basic solutions. One beaker contains a solution of ammonium chloride, one contains ammonium acetate, and the third contains sodium acetate. Which beaker contains which salt?

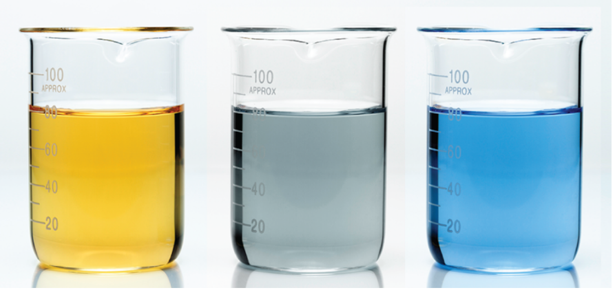

FIGURE P16.7

The graphs in Figure P16.8 show the conductivity of a solution as a function of the volume of titrant added. Which of the graphs best represents the titration of (a) a strong acid with a strong base and (b) a weak acid with a strong base?

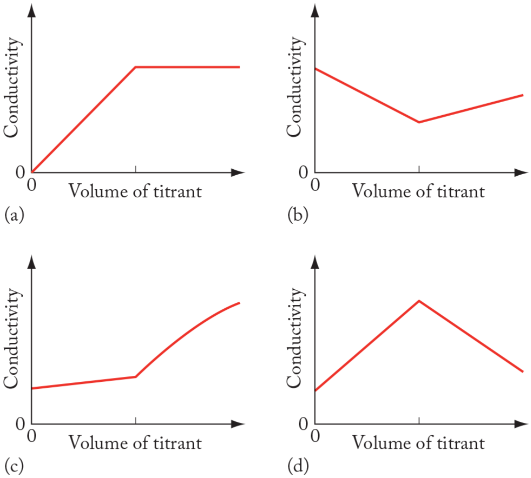

FIGURE P16.8

(a) What kind of aqueous solution is represented in Figure P16.9: a weak acid, a weak base, or a buffer? The solvent molecules and cations have been omitted for clarity. (b) What particles depicted in Figure P16.9 will change, and how will they change, upon addition of a strong base such as

NaOH?

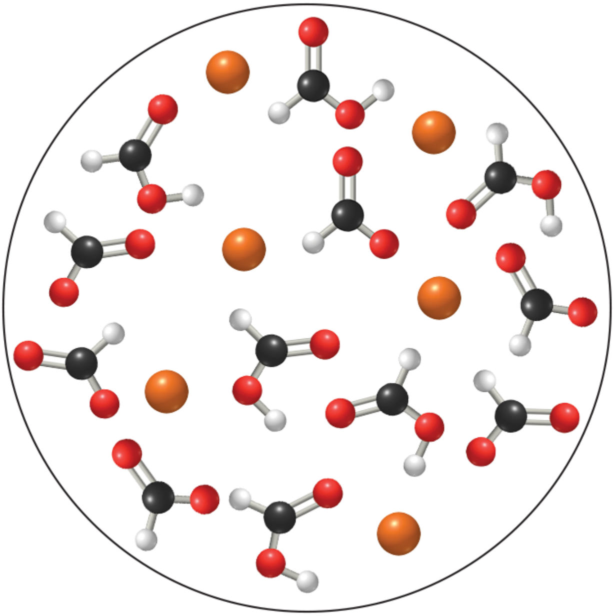

FIGURE P16.9

Use representations [A] through [I] in Figure P16.10 to answer questions (a)–(f).

1. Images [C] and [G] depict the different molecular structures of the indicator methyl red at high and low pH. Which is which?
2. If methyl red is red at low pH and yellow at higher pH, match the flasks in images [A] and [I] to the species in [C] and [G].
3. Which image represents a buffer with equal concentrations of a weak acid and its conjugate base?
4. Which image represents the buffer from your answer to part (c) after the addition of strong acid, and which represents that buffer after the addition of strong base?
5. Saturated solutions of two sparingly soluble salts, calcium

sulfide and calcium fluoride, are shown in [D] and [F]. Which is which?

6. Will acidifying the solution in [D] to pH 2.00 by adding strong acid increase the solubility of the solid? Will adding the same amount of acid to [F] increase the solubility of the solid?

QUESTIONS AND PROBLEMS

Note: Tables A5.1 and A5.3 in Appendix 5 contain K_a, K_b, pK_a, pK_b, and K_f values that may be useful in answering the questions and solving the problems in Chapter 16.

The Common-Ion Effect; pH Buffers

Concept Review

Why does a solution of a weak acid and its conjugate base control pH better than a solution of the weak acid alone?

Why does a solution of a weak base and its conjugate acid control pH better than a solution of the weak base alone?

Identify a suitable buffer system to maintain a pH of 3.00 in an aqueous solution.

Identify a suitable buffer system to maintain a pH of 9.0 in an aqueous solution.

What does “buffer capacity” mean?

Three buffers are prepared using equal concentrations of formic acid and sodium formate, hydrofluoric acid and sodium fluoride, and acetic acid and sodium acetate. Rank the three buffers from highest to lowest pH.

How does diluting a pH 9.00 buffer with an equal volume of pure water affect its pH?

Buffer A contains nearly equal concentrations of its conjugate acid–base pair. Buffer B contains the same total concentration of acidic and basic components as buffer A, but B has twice as much of its weak acid as its conjugate base. Which buffer experiences a smaller change in pH when:

1. the same small quantity of strong base is added to both?
2. the same small quantity of strong acid is added to both?

Problems

What is the pH of a buffer that is 0.250 *M* trichloroacetic acid and 0.200 *M* sodium trichloroacetate at 25°C?

What is the pH of a buffer that is 0.150 *M* dimethylamine and 0.100 *M* dimethylammonium chloride at 25°C?

What is the pH of a buffer that is 0.125 *M* H_3PO_4 and 0.250 *M* $H_2PO_4{}^-$ at 25°C?

What is the pH of a buffer that is 0.200 *M* $H_2PO_4{}^-$ and 0.250 *M* $HPO_4{}^{2-}$ at 25°C?

What is the mole ratio of sodium acetate to acetic acid in a buffer with a pH of 4.00?

What is the mole ratio of ammonia to ammonium chloride in a buffer with a pH of 9.00?

What masses of bromoacetic acid and sodium bromoacetate are needed to prepare 1.00 L of pH = 3.00 buffer if the total concentration of the two components is 1.00 *M*?

What masses of acetic acid and sodium acetate are needed to prepare 125 mL of pH = 5.00 buffer if the total concentration of the two components is 0.500 *M*?

What masses of dimethylamine and dimethylammonium chloride do you need to prepare 1.000 L of pH = 12.00 buffer if the total concentration of the two components is 0.500 *M*?

What masses of ethylamine and ethylammonium chloride do you need to prepare 1.000 L of pH = 11.00 buffer if the total concentration of the two components is 0.500 *M*?

What is the pH at 25°C of a solution that results from mixing equal volumes of a 0.050 *M* solution of ammonia and a 0.025 *M* solution of hydrochloric acid?

What is the pH at 25°C of a solution that results from mixing equal volumes of a 0.050 *M* solution of acetic acid and a 0.025 *M* solution of sodium hydroxide?

What volume of 0.422 *M* NaOH must be added to 0.500 L of 0.300 *M* acetic acid to raise its pH to 4.00 at 25°C?

What volume of 1.16 *M* HCl must be added to 0.250 L of 0.350 *M* dimethylamine to produce a buffer with a pH of 10.75 at 25°C?

A buffer consists of 0.120 *M* HNO_2 and 0.150 *M* $NaNO_2$ at 25°C.

1. What is the pH of the buffer?
2. What is the pH after the addition of 1.00 mL of 11.6 *M* HCl to 1.00 L of the buffer solution?

A buffer is prepared by mixing 50.0 mL of 0.200 *M* NaOH with 100.0 mL of 0.175 *M* acetic acid.

1. What is the pH of the buffer?
2. What is the pH of the buffer after 1.00 g of NaOH is dissolved in it?

Indicators and Acid–Base Titrations

Concept Review

Do all titrations of samples of strong monoprotic acids with solutions of strong bases have the same pH at their equivalence points? Explain why or why not.

Do all titrations of samples of weak monoprotic acids with solutions of strong bases have the same pH at their equivalence points? Explain why or why not.

Describe two properties of phenolphthalein that make it a good choice of indicator for detecting the first equivalence point in an alkalinity titration.

Phenolphthalein can be used as a color indicator to detect the equivalence points of titrations of samples containing either weak or strong acids even though the pH values of the equivalence point vary depending on the identity of the acid. Explain how this is possible.

In the titration of a solution of a weak monoprotic acid with a standard solution of NaOH, the pH halfway to the equivalence point was 4.44. In the titration of a second solution of the same acid, exactly twice as much of the standard solution of NaOH was needed to reach the equivalence point. What was the pH halfway to the equivalence point in this titration?

The pH of a solution of a strong monoprotic acid is lower than the pH of an equal concentration of a weak monoprotic acid, yet equal volumes of both require the same volume of basic titrant to reach the equivalence point. Explain why.

Problems

A 25.0 mL sample of 0.100 *M* acetic acid is titrated with 0.125 *M* NaOH at 25°C. What is the pH of the solution after 10.0, 15.0, 20.0, 25.0, and 35.0 mL of the base have been added?

A 25.0 mL sample of a 0.100 *M* solution of aqueous trimethylamine is titrated with a 0.125 *M* solution of HCl. What is the pH of the solution after 10.0, 15.0, 20.0, 25.0, and 30.0 mL of acid have been added?

Window Cleaner (a) What is the concentration of ammonia in a popular window cleaner if 25.34 mL of 1.162 *M* HCl is needed to titrate a 10.00 mL sample of the cleaner? (b) Suppose that the sample was diluted to about 50 mL with deionized water prior to the titration to make it easier to mount a pH electrode in it. What effect did this dilution have on the volume of titrant needed?

In an alkalinity titration of a 100.0 mL sample of water from a hot spring, 2.56 mL of a 0.0355 *M* solution of HCl is needed to reach the first equivalence point ($pH = 8.3$) and another 10.42 mL is needed to reach the second equivalence point ($pH = 4.0$). If the alkalinity of the spring water results only from the presence of carbonate and bicarbonate, what are the concentrations of each?

Sketch a titration curve for the titration of 50.0 mL of 0.250 *M* HNO_2 with 1.00 *M* NaOH. What is the pH at the equivalence point?

Sketch a titration curve for the titration of 40.0 mL of a 0.100 *M* solution of oxalic acid with a 0.100 *M* solution of NaOH. What is the pH of the titration reaction mixture at the last equivalence point?

For each titration, predict whether the equivalence point is less than, equal to, or greater than pH = 7.

1. Quinine titrated with nitric acid
2. Pyruvic acid titrated with calcium hydroxide
3. Hydrobromic acid titrated with strontium hydroxide

For each titration, predict whether the equivalence point is less than, equal to, or greater than pH = 7.

1. HCN titrated with $Ca(OH)_2$
2. LiOH titrated with HI
3. C_5H_5N titrated with KOH

When 100 mL of 0.0125 *M* ascorbic acid is titrated with 0.010 *M* NaOH, how many equivalence points will the titration curve have, and what pH indicator(s) could be used? Refer to Figure 16.8 for colors of indicators.

Red cabbage juice is a sensitive acid–base indicator; its colors range from red at acidic pH to yellow in alkaline solutions. What color would red cabbage juice have at the equivalence point when 25 mL of a 0.10 *M* solution of acetic acid is titrated with 0.10 *M* NaOH?

Lewis Acids and Bases

Concept Review

Are all Lewis bases also Brønsted–Lowry bases? Explain why or why not.

Are all Brønsted–Lowry bases also Lewis bases? Explain why or why not.

Are all Brønsted–Lowry acids also Lewis acids? Explain why or why not.

Why is BF_3 a Lewis acid but not a Brønsted–Lowry acid?

Problems

Draw Lewis structures that show how electron pairs move and bonds form and break during the autoionization of water. Label the appropriate H_2O molecules as the Lewis acid and Lewis base.

Draw Lewis structures that show how electron pairs move and bonds form and break in the following reaction and identify the Lewis acid and Lewis base.

$MgO(s) + CO_2(g) \rightarrow MgCO_3(s)$

Draw Lewis structures that show how electron pairs move and bonds form and break in the following reaction and identify the Lewis acid and Lewis base.

$SO_2(g) + H_2O(\ell) \rightarrow H_2SO_3(aq)$

Draw Lewis structures that show how electron pairs move and bonds form and break in the following reaction and identify the Lewis acid and Lewis base.

$SeO_3(g) + H_2O(\ell) \rightarrow H_2SeO_4(aq)$

Draw Lewis structures that show how electron pairs move and bonds form and break in the following reaction and identify the Lewis acid and Lewis base.

$B(OH)_3(aq) + H_2O(\ell) \rightleftharpoons B(OH)_4^-(aq) + H^+(aq)$

Draw Lewis structures that show how electron pairs move and bonds form and break in the following reaction and identify the Lewis acid and Lewis base. (*Note*: $HSbF_6$ is an ionic compound and one of the strongest Brønsted–Lowry acids known.)

$SbF_5(s) + HF(g) \rightarrow HSbF_6(s)$

Formation of Complex Ions

Concept Review

When $CaCl_2$ dissolves in water, which molecules or ions occupy the inner coordination sphere around the Ca^{2+} ions?

When $AgNO_3$ dissolves in water, which molecules or ions occupy the inner coordination sphere around the Ag^+ ions?

A lab technician cleaning glassware that contains residues of AgCl washes the glassware with an aqueous solution of ammonia. The AgCl, which is insoluble in water, rapidly dissolves in the ammonia solution. Why?

The procedure used in Problem 16.63 dissolves AgCl but not AgI. Why?

Problems

A solution is prepared in which 0.00100 mol of $Ni(NO_3)_2$ and 0.500 mol of NH_3 are dissolved in a total volume of 1.00 L. What is the concentration of $Ni(H_2O)_6^{2+}$ ions in the solution at equilibrium?

A 1.00 L solution contains $5.00 \times 10^{-5} M$ $Cu(NO_3)_2$ and $1.00 \times 10^{-3} M$ ethylenediamine, $H_2NCH_2CH_2NH_2$. What is the concentration of $Cu(H_2O)_6^{2+}$ ions in the solution at equilibrium?

Suppose a solution contains 1.00 mmol of $Co(NO_3)_2$, 0.100 mol of NH_3, and 0.100 mol of ethylenediamine in a total volume of 0.250 L. What is the concentration of $Co(H_2O)_6^{2+}$ ions in the solution?

If 1.00 mL of 0.0100 *M* $AgNO_3$, 1.00 mL of 0.100 *M* NaBr, and 1.00 mL of 0.100 *M* NaCN are diluted to 250 mL with deionized water in a volumetric flask and shaken vigorously, will the contents of the flask be cloudy or clear? Support your answer with the appropriate calculations. (*Hint*: The K_{sp} of AgBr is 5.4×10^{-13}.)

Hydrated Metal Ions as Acids

Concept Review

Which, if any, aqueous solutions of the following chloride compounds are acidic? (a) $CaCl_2$; (b) $CrCl_3$; (c) NaCl; (d) $FeCl_3$

If 0.100 *M* aqueous solutions of each of these compounds were prepared, which one would have the lowest pH? (a) $BaCl_2$; (b) LiCl; (c) KCl; (d) $TiCl_4$

When ozone is bubbled through an aqueous solution of Fe^{2+} ions, the ions are oxidized to Fe^{3+} ions. How does the oxidation process affect the pH of the solution?

As an aqueous solution of KOH is slowly added to a stirred solution of $AlCl_3$, the mixture becomes cloudy but then clears when more KOH is added.

Explain the chemical changes responsible for the changes in the appearance of the mixture.

2. Would you expect to observe the same changes if KOH were added to a solution of $FeCl_3$? Explain why or why not.

Chromium(III) hydroxide is amphiprotic. Write chemical equations showing how an aqueous suspension of this compound reacts to the addition of a strong acid and a strong base.

Zinc hydroxide is amphiprotic. Write chemical equations showing how an aqueous suspension of this compound reacts to the addition of a strong acid and a strong base.

Refining Aluminum To remove impurities such as calcium and magnesium carbonates and iron(III) oxides from aluminum ore (which is mostly Al_2O_3), the ore is treated with a strongly basic solution. In this treatment, Al^{3+} dissolves but the other metal ions do not. Why?

Exactly 1.00 g of $FeCl_3$ is dissolved in each of four 0.500 L samples: 1 *M* HNO_3, 1 *M* HNO_2, 1 *M* CH_3COOH, and pure water. Is the concentration of $Fe(H_2O)_6{}^{3+}$ ions the same in all four solutions? Explain why or why not.

Problems

What is the pH of 0.25 *M* $Al(NO_3)_3$?

What is the pH of 0.50 *M* $CrCl_3$?

What is the pH of 0.100 *M* $Fe(NO_3)_3$?

What is the pH of 1.00 *M* $Cu(NO_3)_2$?

Sketch the titration curve (pH versus volume of 0.50 *M* NaOH) for a 25 mL sample of 0.25 *M* $FeCl_3$.

Sketch the titration curve that results from the addition of 0.50 *M* NaOH to a sample containing 0.25 *M* $KFe(SO_4)_2$.

Solubility Equilibria

Concept Review

What is the difference between *molar solubility* and *solubility product*?

Give an example of how the common-ion effect limits the dissolution of a sparingly soluble ionic compound.

Which cation will precipitate first as a carbonate mineral from an equimolar solution of Mg^{2+}, Ca^{2+}, and Sr^{2+}?

If the solubility of a compound increases with increasing temperature, does K_{sp} increase or decrease?

The K_{sp} of strontium sulfate increases from 2.8×10^{-7} at 37°C to 3.8×10^{-7} at 77°C. Is the dissolution of strontium sulfate endothermic or exothermic?

Identify any of the following solids that are more soluble in acidic solution than in neutral water: $CaCl_2$, $Ba(HCO_3)_2$, $PbSO_4$, $Cu(OH)_2$. Explain your choices.

Chemistry of Tooth Decay Tooth enamel is composed of a mineral known as hydroxyapatite, which has the formula $Ca_5(PO_4)_3(OH)$. Explain why tooth enamel can be eroded by acidic substances released by bacteria growing in the mouth.

Fluoride and Dental Hygiene Fluoride ions in drinking water and toothpaste convert hydroxyapatite in tooth enamel into fluorapatite:

$$Ca_5(PO_4)_3(OH)(s) + F^-(aq) \rightleftharpoons Ca_5(PO_4)_3F(s) + OH^-(aq)$$

Why is fluorapatite less susceptible than hydroxyapatite to erosion by acids?

Problems

At a particular temperature the $[Ba^{2+}]$ in a saturated solution of barium sulfate is $1.04 \times 10^{-5} M$. Starting with this information, calculate the K_{sp} value of barium sulfate at this temperature.

If only 0.160 g of $Ca(OH)_2$ dissolves in 0.100 L of water, what is the K_{sp} value for calcium hydroxide at that temperature?

What are the equilibrium concentrations of Cu^+ and Cl^- in a saturated solution of copper(I) chloride at 25°C?

What are the equilibrium concentrations of Pb^{2+} and F^- in a saturated solution of lead fluoride at 25°C?

What is the pH at 25°C of a saturated solution of silver hydroxide?

pH of Milk of Magnesia What is the pH at 25°C of a saturated solution of magnesium hydroxide (the active ingredient in the antacid milk of magnesia)?

Suppose you have 100 mL of each of the following solutions. In which will the most $CaCO_3$ dissolve? (a) 0.1 *M* NaCl; (b) 0.1 *M* Na_2CO_3; (c) 0.1 *M* NaOH; (d) 0.1 *M* HCl

In which of the following solutions will CaF_2 be most soluble? (a) 0.010 *M* $Ca(NO_3)_2$; (b) 0.01 *M* NaF; (c) 0.001 *M* NaF; (d) 0.10 *M* $Ca(NO_3)_2$

Composition of Seawater The average concentration of sulfate in surface seawater is about 0.028 *M*. The average concentration of Sr^{2+} is $9 \times 10^{-5} M$. Is the concentration of strontium in the sea significantly controlled by the insolubility of its sulfate salt?

Fertilizing the Sea to Combat Climate Change Some scientists have proposed adding iron(III) compounds to large expanses of the open ocean to promote the growth of phytoplankton that would in turn remove CO_2 from the atmosphere through photosynthesis. Assuming the average pH of open ocean water is 8.13, what is the maximum value of $[Fe^{3+}]$ in seawater if the K_{sp} value of $Fe(OH)_3$ is 1.1×10^{-36}?

Will calcium fluoride precipitate when 125 mL of 0.375 *M* $Ca(NO_3)_2$ is added to 245 mL of 0.255 *M* NaF at 25°C?

Will lead(II) chloride precipitate if 185 mL of 0.025 *M* sodium chloride is added to 235 mL of 0.165 *M* lead(II) perchlorate at 25°C?

A solution is 0.010 *M* in both Br^- and SO_4^{2-}. A 0.250 *M* solution of lead(II) nitrate is slowly added to it with a buret.

1. Which anion will precipitate first?
2. What is the concentration in the solution of the first ion when the second one starts to precipitate at 25°C?

Solution A is 0.0200 *M* in Ag^+ ions and Pb^{2+} ions. You have access to two other solutions: (B) 0.250 *M* NaCl and (C) 0.250 *M* NaBr.

1. Which solution, B or C, would be the better one to add to solution A to separate Ag^+ ions from Pb^{2+} by selective precipitation?
2. Using the solution you selected in part (a), is the separation of the two ions complete?

Additional Problems

Fluoride in Drinking Water Hydrogen fluoride (HF) behaves as a weak acid in aqueous solution. Two equilibria influence which fluorine-containing species are present in solution.

$$HF(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + F^-(aq) \qquad K_a = 6.8 \times 10^{-4}$$

$$F^-(aq) + HF(aq) \rightleftharpoons HF_2^-(aq) \qquad K_c = 2.6 \times 10^{-1}$$

1. Is fluoride in pH 7.00 drinking water more likely to be present as F^- or HF_2^-?
2. What is the equilibrium constant for the following equilibrium?

$$2\,HF(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + HF_2^-(aq)$$

3. What are the pH and equilibrium concentration of HF_2^- in a 0.150 *M* solution of HF?

A 125.0 mg sample of an unknown monoprotic acid was dissolved in 100.0 mL of distilled water and titrated with a 0.050 *M* solution of NaOH. The pH of the solution was monitored throughout the titration, and the following data were collected.

1. What is the K_a value for the acid?
2. What is the molar mass of the acid?

Volume of OH^- Added (mL)	pH
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]

When silver oxide dissolves in water, the following reaction occurs:

$$Ag_2O(s) + H_2O(\ell) \rightarrow 2\,Ag^+(aq) + 2\,OH^-(aq)$$

If the pH of a saturated aqueous solution of silver oxide is 10.20, what is the K_{sp} of silver oxide?

Greenhouse Gases and Ocean pH Some climate models predict the pH of the oceans will decrease by as much as 0.77 pH units as a result of increases in atmospheric carbon dioxide.

1. Explain, by using the appropriate chemical reactions and equilibria, how an increase in atmospheric CO_2 could produce a decrease in oceanic pH.
2. How much more acidic (in terms of $[H_3O^+]$) would the oceans be if their pH dropped this much?
3. Oceanographers are concerned about how a drop in oceanic pH would affect the survival of oysters. Why?

Glossary

common-ion effect

a shift in the position of an equilibrium caused by an ion taking part in the reaction.

pH buffer

a solution that resists changes in pH when acids or bases are added to it; typically a solution of a weak acid and its conjugate base or a weak base and its conjugate acid.

pH indicator

a water-soluble weak organic acid that changes color as it ionizes.

Lewis base

a substance that *donates* a lone pair of electrons in a chemical reaction.

Lewis acid

a substance that *accepts* a lone pair of electrons in a chemical reaction.

coordinate bond

a covalent bond formed when one anion or molecule donates a pair of electrons to another ion or molecule.

complex ion

an ionic species consisting of a metal ion bonded to one or more Lewis bases.

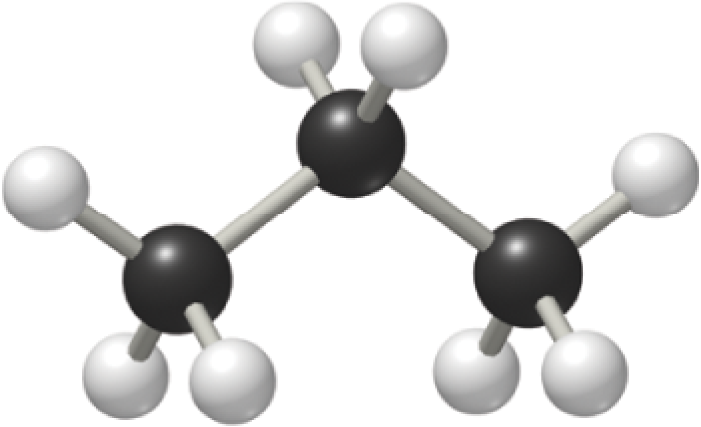
formation constant (K_f)

an equilibrium constant describing the formation of a metal complex from a free metal ion and its ligands.

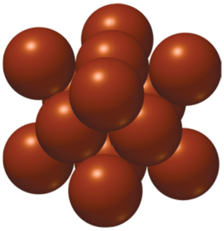
solubility product (K_{sp}) (also called *solubility-product constant*)

an equilibrium constant that describes the formation of a saturated solution of a slightly soluble salt.

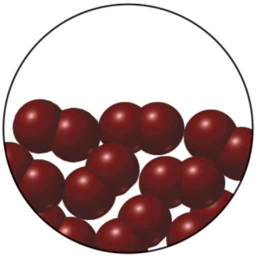
CORROSION Most metal objects in the sea, including the remains of this shipwreck, corrode as a result of spontaneous chemical reactions. Iron metal is converted into iron(III) oxide.



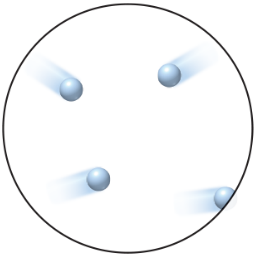
Propane



Copper



Bromine



Helium

Thermodynamics Spontaneous and Nonspontaneous Reactions and Processes

---

PARTICULATE REVIEW

Endothermic or Exothermic?

In Chapter 17 we examine fundamental ideas about why some reactions happen spontaneously but others do not. In doing so, we revisit the concepts of thermochemistry from Chapter 6. Propane is a common fuel used for cooking on outdoor grills.

- Is the combustion of propane an endothermic or exothermic process?
- What bonds are broken in the combustion of propane? Is the breaking of bonds an endothermic or exothermic process?
- What bonds are formed in the combustion of propane? Is the forming of bonds an endothermic or exothermic process?

(Review Sections 6.3 and 8.7 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Motion and Dispersion of Energy

We learned in Chapter 6 that the total energy of atoms and molecules is the sum of their kinetic energy (from random motion of particles) and potential energy (from their arrangement). Consider the elements copper, bromine, and helium at room temperature. As you read Chapter 17, look for ideas that will help you answer the following questions:

- Compare the possible number of arrangements of the atoms or molecules in 1 mole of each element. Which has the most possible arrangements? The fewest?
- Which element(s) have vibrational motion of bonds at room temperature?
- Which element can disperse its energy in the most ways?

Learning Outcomes

- LO1 Predict the signs of entropy changes for spontaneous and nonspontaneous chemical reactions and physical processes

  Sample Exercise 17.1

- LO2 Predict the relative entropies of substances on the basis of their molecular structures

  Sample Exercise 17.2

- LO3 Calculate entropy changes in chemical reactions using standard molar entropies

Sample Exercise 17.3

- LO4 Calculate free-energy changes and standard free-energy changes in chemical reactions and physical processes

  Sample Exercises 17.4, 17.5

- LO5 Predict the spontaneity of a chemical reaction or physical process as a function of temperature and in terms of changes in its enthalpy and entropy

  Sample Exercises 17.6, 17.7

- LO6 Relate the value of the equilibrium constant of a reaction to its change in free energy under standard conditions

  Sample Exercise 17.8

- LO7 Determine the value of the equilibrium constant K at any temperature from thermodynamic data

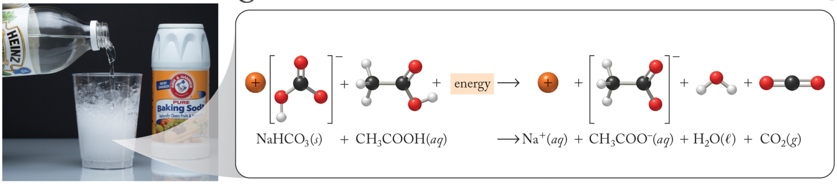
  Sample Exercise 17.9

- LO8 Calculate the net change in free energy of coupled spontaneous and nonspontaneous reactions

  Sample Exercise 17.10

- LO9 Use microstates to explain why a perfect crystalline solid has zero entropy

$$4\ \mathrm{Fe}(s) + 3\ \mathrm{O_2}(g) \rightarrow 2\ \mathrm{Fe_2O_3}(s) \qquad \Delta H^\circ = -1648\ \mathrm{kJ}$$



energy
$\mathrm{NaHCO_3}(s) + \mathrm{CH_3COOH}(aq) \longrightarrow \mathrm{Na^+}(aq) + \mathrm{CH_3COO^-}(aq) + \mathrm{H_2O}(\ell) + \mathrm{CO_2}(g)$

FIGURE 17.1 Adding vinegar to baking soda produces sodium acetate, water, and carbon dioxide in an endothermic ($\Delta H^\circ = +48.5$ kJ), yet spontaneous, reaction.

Liquid
Energy in
Energy out
Solid
(a) Vibrational motion

FIGURE 17.3 Molecules of water have three types of motion: (a) vibrational—which is their only motion in solids; (b) translational; and (c) rotational. Molecules in all three phases experience vibrations; translational and rotational motion is also seen in the liquid phase, with much more of both in the gas phase.

17.1 Spontaneous Processes

Some processes are so familiar that we rarely consider why they happen. If a car tire is punctured, the air inside rushes out and the tire goes flat; air does not rush back into a punctured tire and reinflate it. Objects made of iron left on the ground or underwater for months or years become clumps of rust; they do not turn back into shiny metal after even more time. A tray of ice cubes left on a kitchen counter melts into a tray of liquid water. As long as the kitchen remains at the same temperature, there is no way the water in the tray will resolidify into ice cubes.

All three of these processes are spontaneous, which means that they all happen without any ongoing intervention and without work being done on the system. In each case, the reverse process is nonspontaneous because it cannot happen on its own. Why are some processes spontaneous and others not?

The first law of thermodynamics (Section 6.3) states that energy cannot be created or destroyed. This means that when we play the game of energy conversion, we can't win. Furthermore, the second law of thermodynamics—which we explore more closely in Section 17.2—says, in effect, that not all of the energy released by a spontaneous reaction, such as burning gasoline in a car engine, is available to do useful work. In the game of energy conversion, then, not only can we *not* win—we can't even break even.

If energy cannot be destroyed, what happens to the energy that is unavailable to do useful work? It turns out this energy spreads out, becoming less concentrated. In this chapter we explore the meaning and some of the impacts of the second law of thermodynamics on familiar processes. We also explore the component of the energy that is available to do work and explain how it is related to reaction spontaneity and equilibrium. We will see how spontaneous reactions can be coupled with nonspontaneous reactions to make multistep chemical and biochemical processes happen. This coupling is important to us because it powers the molecular processes that sustain life.

The word "spontaneous" can be a bit misleading because many spontaneous reactions do not start all by themselves; they need a little energy boost, such as a spark or external flame. For example, before Thomas Edison invented the lightbulb in 1879, city streets were often illuminated at night by gas-fueled lamps. Once lit, they burned through the night until their fuel was cut off as dawn approached. Chemical reactions such as the combustion of gas-lamp fuel are examples of spontaneous reactions: once started, they proceed without outside intervention, as long as reactants are available. It is the self-sustaining nature of these reactions that earns them the label *spontaneous*. The reverse reaction—in this case, converting carbon dioxide and water into fuel and oxygen—is nonspontaneous: it cannot happen on its own without the continuous addition of energy from an external source.

In addition, spontaneous does not necessarily mean rapid. Though combustion reactions are fast, other spontaneous reactions, such as the formation of a layer of rust on an object made of iron, can take a very long time, depending on temperature and the rate at which O_2 reaches the iron surface:

Spontaneity has nothing to do with kinetics. Still, rust formation does proceed without intervention and meets the definition of thermodynamic spontaneity.

Spontaneous is also *not* a synonym for exothermic, although many scientists once thought so. In the mid-19th century, many chemists thought that exothermic reactions, in which high-enthalpy reactants formed low-enthalpy (more stable) products, should always be spontaneous. Many exothermic reactions, including combustion reactions and metal corrosion, *are* spontaneous. However, some exothermic processes may not be spontaneous, and some endothermic processes may be spontaneous, depending on reaction conditions.

CONNECTION Enthalpy change (ΔH) is a thermodynamic quantity that describes energy flow into or out of a system (Section 6.4).

Familiar examples of spontaneous endothermic processes include the phase changes that occur when ice melts and water boils. Both are endothermic processes, but both can be spontaneous, depending on the temperature and pressure. Another spontaneous endothermic reaction occurs when room-temperature vinegar (dilute acetic acid) is added to baking soda (sodium bicarbonate), as shown in **Figure 17.1**. The foaming mixture indicates that a reaction is taking place, and the decrease in temperature of the mixture indicates that the reaction is endothermic ($\Delta H > 0$).

Yet another spontaneous endothermic process makes instant cold packs cold (**Figure 17.2**). An instant cold pack has two compartments. One is filled with water, whereas the other contains a water-soluble compound such as ammonium nitrate that has a positive enthalpy of solution ($\Delta H_{\text{soln}} > 0$). When the membrane separating the two compartments is ruptured, the solid compound

(NH_4NO_3) mixes with and dissolves in the water. The resulting solution gets very cold, becoming an effective anti-inflammation treatment for bruises and muscle sprains.

CONNECTION The ion–dipole interactions that promote the solubility of ionic compounds in water are described in Section 10.3.

Why are endothermic processes such as these spontaneous? The answer is that the particles that make up their products are more spread out and have more freedom of motion than the particles in their starting materials—something that all these processes have in common. Consider the molecular changes that accompany ice melting and water boiling (**Figure 17.3**). The molecules of H_2O in ice occupy fixed positions. Their motion (Figure 17.3a), like that of particles in all crystalline solids, is limited to vibrating in place, not going anywhere. When ice melts, its H_2O molecules become more mobile, acquiring translational motion and rotational motion (Figure 17.3b and c). When liquid water evaporates and the molecules enter the gas phase, their translational motion and rotational motion increase even more. The water vapor molecules are now also able to expand to fill their container, as are all gas particles at atmospheric pressure, which is why gases are compressible, whereas liquids and solids are not.

The particles that make up the reaction mixtures in spontaneous endothermic chemical reactions experience increased freedom of motion. In Figure 17.1, for example, a portion of the bicarbonate ions in the solid reactant ($NaHCO_3$) becomes liberated as a gaseous product of the reaction (CO_2), resulting in increased movement for the system. In the instant cold pack (Figure 17.2), the particles of the solid solute acquire more freedom of motion and can move throughout the resulting solution. These particles experience increases in motion similar to those of a melting solid.

CONCEPT TEST

In which of the following processes do particles experience an increase in freedom of motion?

1. A glass of water evaporates.
2. Dew forms overnight on grass and other surfaces.
3. Table salt is added to water for cooking spaghetti.
4. A log of wood burns in a fireplace.

(Answers to Concept Tests are in the back of the book.)

Glossary

spontaneous process	a process that occurs without outside intervention.
nonspontaneous process	a process that occurs only as long as energy is continually added to the system.

$$\Delta S_{\text{univ}} = \Delta S_{\text{sys}} + \Delta S_{\text{surr}} \tag{17.1}$$

$$|\Delta S_{\text{surr}}| > |\Delta S_{\text{sys}}|$$

$$\Delta S = \frac{q_{\text{rev}}}{T} \tag{17.2}$$

$$\Delta S_{\text{sys}} = \frac{q_{\text{sys}}}{T} \tag{17.3}$$

$$\Delta S_{\text{sys}} = \frac{q_{\text{sys}}}{T} = \frac{(1.00\ \cancel{\text{mol}})(6.01 \times 10^3\ \text{J}/\cancel{\text{mol}})}{273\ \text{K}} = 22.0\ \text{J/K}$$

$$\Delta S_{\text{surr}} = \frac{q_{\text{surr}}}{T} = \frac{(1.00\ \cancel{\text{mol}})(-6.01 \times 10^3\ \text{J}/\cancel{\text{mol}})}{295\ \text{K}} = -20.4\ \text{J/K}$$

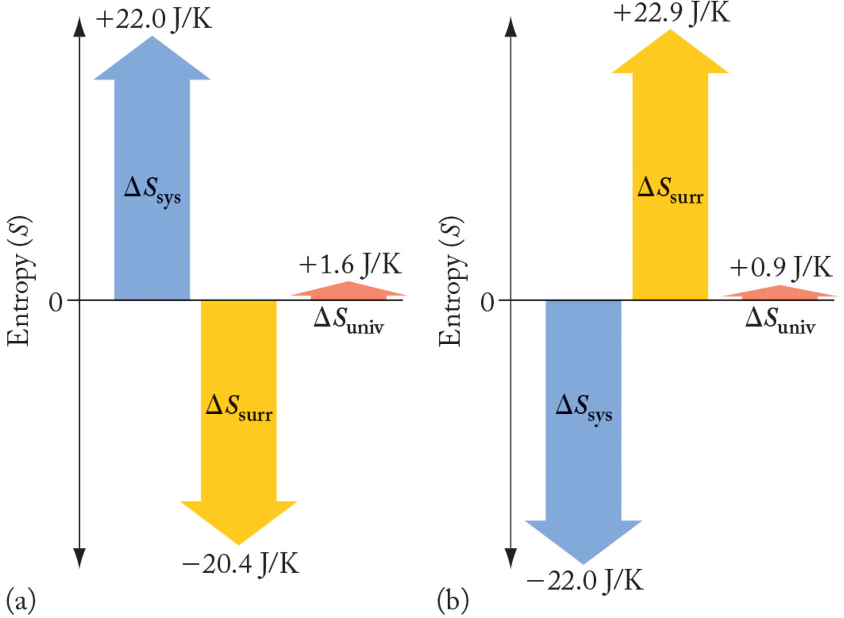

FIGURE 17.4 (a) If the surroundings experience a decrease in entropy ($\Delta S_{\text{surr}} = -20.4$ J/K), and the system (ice) experiences an increase in entropy ($\Delta S_{\text{sys}} = +22.0$ J/K) that more than offsets the decrease, then the process (melting) is spontaneous ($\Delta S_{\text{univ}} = \Delta S_{\text{sys}} + \Delta S_{\text{surr}} = 22.0\ \text{J/K} - 20.4\ \text{J/K} = +1.6$ J/K). (b) $\Delta S_{\text{univ}} = \Delta S_{\text{sys}} + \Delta S_{\text{surr}} = +0.9$ J/K because the decrease in entropy for the

system ($\Delta S_{\text{sys}} = -22.0\ \text{J/K}$) is more than offset by the increase in entropy for the surroundings ($\Delta S_{\text{surr}} = +22.9\ \text{J/K}$).

$$\begin{aligned}\Delta S_{\text{univ}} &= \Delta S_{\text{sys}} + \Delta S_{\text{surr}} \\ &= \frac{(1.00\ \cancel{\text{mol}})(-6.01 \times 10^{3}\ \text{J}/\cancel{\text{mol}})}{273\ \text{K}} + \frac{(1.00\ \cancel{\text{mol}})(+6.01 \times 10^{3}\ \text{J}/\cancel{\text{mol}})}{263\ \text{K}} \\ &= (-22.0\ \text{J/K}) + (+22.9\ \text{J/K}) \\ &= 0.9\ \text{J/K}\end{aligned}$$

FIGURE 17.5 Water vapor exhaled by this Inuit hunter in the Northwest Territories of Canada was spontaneously deposited on his facial hair as frost—evidence of how cold it was when this photo was taken.

17.2 Entropy and the Second Law of Thermodynamics

When particles spread out and gain freedom of motion, the kinetic energy associated with their motion also spreads out. This spreading out, or dispersion, of energy turns out to be a key characteristic of all spontaneous processes. It even has a name: entropy (S). Entropy is a thermodynamic property that provides a measure of the dispersal of energy in a system at a specific temperature. The second law of thermodynamics states that entropy of an *isolated* thermodynamic system *always increases* during a spontaneous process.

The second law also covers thermodynamic systems that are not isolated (most systems are not isolated; they are either open or closed, as discussed in Section 6.3). Recall from Chapter 6 that in thermodynamics we divide the universe into two parts: the part we are interested in (the system) and everything else (the system’s surroundings). Mathematically:

Universe = System + Surroundings

Logically, then, the overall change in the entropy of the universe is the sum of the entropy changes experienced by the system and by its surroundings:

For a spontaneous process in an isolated system, ΔS_{sys} is greater than zero ($\Delta S_{\text{sys}} > 0$) and the entropy of its surroundings is unchanged ($\Delta S_{\text{surr}} = 0$). According to Equation 17.1, then, ΔS_{univ} must also be greater than zero ($\Delta S_{\text{univ}} > 0$). The positive value of ΔS_{univ} is the basis for another way of expressing the second law of thermodynamics that applies to all systems (not just isolated ones): *a spontaneous process produces an overall increase in the entropy of the universe.*

CONNECTION Recall from Section 6.3 that an isolated thermodynamic system exchanges neither energy nor matter with its surroundings, a closed system exchanges energy but not matter, and an open system exchanges both.

This version of the second law assumes that a physical or chemical change in a closed or open thermodynamic system can alter the entropies of both the system and its surroundings. The second law says that a process is spontaneous when one or the other of these entropy changes is greater than zero, so that their sum, ΔS_{univ}, is also greater than zero. The second law provides a thermodynamic requirement for reaction spontaneity as well as a criterion for *nonspontaneity*: a process that results in a *decrease* in the entropy of the universe does not occur spontaneously. Summarizing these relationships:

- If $\Delta S_{\text{univ}} > 0$, then a process is spontaneous.
- If $\Delta S_{\text{univ}} < 0$, then a process is nonspontaneous.

To see how a process affects the entropy of its surroundings, let's focus on a familiar exothermic reaction, the combustion of natural gas (methane):

As written, the reaction consumes 3 moles of gases and produces 2 moles of a liquid product and 1 mole of gas. As a result, there are fewer moles of gas on the product side of the reaction equation than on the reactant side. Given the much greater freedom of motion of particles in the gas phase, we can accurately predict that there will be a decrease in entropy of the reaction mixture, which is our thermodynamic system:

$\Delta S_{\text{sys}} < 0$

The reaction is spontaneous, however, so

$\Delta S_{\text{univ}} > 0$

How do we reconcile these opposing inequalities? Equation 17.1 supplies an explanation. If $\Delta S_{\text{univ}} > 0$, then $\Delta S_{\text{sys}} + \Delta S_{\text{surr}}$ must also be greater than zero. Because $\Delta S_{\text{sys}} < 0$, then ΔS_{surr} is not only greater than zero, but it must also have a large enough positive value to more than offset the negative value of ΔS_{sys}. Expressing this relationship in terms of the absolute values of ΔS_{surr} and ΔS_{sys}:

Is the combustion of methane likely to produce a large, positive ΔS_{surr}? Absolutely, because the reaction is highly exothermic: combustion of only 1 mole (16 g) of methane generates 890 kJ of thermal energy. As energy flows from the system into its surroundings, a dispersion of energy occurs, producing a positive ΔS_{surr} that more than compensates for the unfavorable (negative) value of ΔS_{sys}.

All exothermic reactions have the capacity to increase the entropy of their surroundings. The more energy that flows into the surroundings in the form of heat (q), or into any collection of particles, the greater the dispersion of energy among the particles and the greater the increase in their entropy (ΔS). However, adding energy to particles that are at a higher temperature produces a smaller change in entropy than does adding the same quantity of energy to the same particles at a lower temperature. Equation 17.2 represents this inverse relationship between entropy change and temperature:

The subscript “rev” means that the heating process is reversible. Theoretically, a reversible process happens so slowly that equilibrium is constantly maintained. For example, after an incremental change in the system has occurred in the forward direction, the process can be reversed by an incremental change in reaction conditions that restores the original state of the system with no net flow of energy into or out of the system. In other words, everything about the system goes back to exactly as it was before the process began.

A reversible process is an idealization; it describes a theoretical limit. All real chemical reactions and physical processes are irreversible, but many of them approximate reversibility closely enough that we can adapt Equation 17.2 to calculate ΔS_{sys}:

For example, it takes 6.01 kJ (or 6.01×10^3 J) of energy to melt 1.00 mol of ice at 0°C, a physical process. Assuming the process occurs reversibly, then

Because energy flows into the ice, q_{sys} is positive, which also makes ΔS_{sys} positive, as we would expect given the greater freedom of motion of particles in the liquid phase. The units of entropy in this calculation are joules per kelvin. We use these units in all entropy calculations in Chapter 17.

Suppose 1.00 mol of ice melts as 6.01×10^3 J of energy flows into it from room-temperature (22°C or 295 K) surroundings. We can calculate the change in entropy of the surroundings by using another adaptation of Equation 17.2:

The sign of q_{surr} is negative because energy flows from the surroundings into the system (ice cube). Moreover, the value of ΔS_{surr} is less than zero, and the magnitude of the decrease in ΔS_{surr} is less than the increase in ΔS_{sys} because the same absolute value of q was divided by a higher temperature to calculate ΔS_{surr}. Therefore, when we sum ΔS_{sys} and ΔS_{surr} (**Figure 17.4a**), we get a positive value of ΔS_{univ}:

$$\Delta S_{\text{univ}} = \Delta S_{\text{sys}} + \Delta S_{\text{surr}} = (22.0 - 20.4)\ \text{J/K} = 1.6\ \text{J/K}$$

The result of this calculation is one example of a general truth about energy flow—namely, energy flows spontaneously into a system that is cooler than its surroundings. Even more generally, energy flows spontaneously from a warm object to an adjacent cooler object. Entropy and the second law of thermodynamics simply provide a mathematical explanation of why.

Why didn’t we consider the change in temperature of the surroundings as energy flowed from it into the melting ice? The answer lies in the sheer size of the surroundings (the universe minus a small cube of ice). The temperature of such an enormous mass is not likely to change significantly.

Now let’s consider how entropy changes when the temperature of the surroundings is *lower* than the temperature of the system. Suppose a tray containing 1.00 mol of liquid water at 0°C (273 K) is placed in a freezer at $-$ 10°C (263 K). Because the temperature of the surroundings (the freezer) is lower than the temperature of the liquid water, energy spontaneously flows from the water into its surroundings. The water freezes and the net entropy change for this process is

Once again the entropy of the universe increases (**Figure 17.4b**) as energy flows spontaneously from the warmer object (liquid water at 0°C) into the colder surroundings (the freezer at $-$ 10°C).

CONCEPT TEST

Is ΔS_{univ} greater than, less than, or equal to zero when water vapor exhaled by the Inuit hunter in **Figure 17.5** is deposited as crystals of ice on his beard?

Entropy-change calculations based on Equation 17.2 assume process reversibility, which, as we have discussed, is an idealized, theoretical concept. In reality, the ΔS values calculated in this way are *minimum* ΔS values. When processes take place in the real world, the accompanying changes in entropy are inevitably greater than those calculated using Equation 17.2.

TABLE 17.1 Spontaneity of Process as a Function of ΔS_{sys} and ΔS_{surr}

ΔS_{sys}	ΔS_{surr}	Spontaneity of Process
> 0	> 0	Always spontaneous
> 0	< 0	Spontaneous if $\lvert \Delta S_{sys} \rvert > \lvert \Delta S_{surr} \rvert$ Nonspontaneous if $\lvert \Delta S_{sys} \rvert > \lvert \Delta S_{surr} \rvert$
< 0	> 0	Spontaneous if $\lvert \Delta S_{sys} \rvert > \lvert \Delta S_{surr} \rvert$ Nonspontaneous if $\lvert \Delta S_{sys} \rvert > \lvert \Delta S_{surr} \rvert$
< 0	< 0	Always nonspontaneous

According to the second law, spontaneous processes *always* produce an increase in the entropy of the universe. **Table 17.1** shows how the spontaneity of a process depends on the sign and magnitude of ΔS_{sys} and ΔS_{surr}. Note how processes in which ΔS_{sys} and ΔS_{surr} are both greater than zero inevitably result in an increase in ΔS_{univ}, which means they are always spontaneous. On the other hand, processes in which ΔS_{sys} and ΔS_{surr} are both less than zero always produce a decrease in ΔS_{univ}, which means they are always nonspontaneous. Between these extremes are four possible combinations of ΔS_{sys} and ΔS_{surr} in which these changes have opposite signs. These combinations may or may not produce positive ΔS_{univ} values, depending on the absolute values of ΔS_{sys} and ΔS_{surr}. If the larger of the two is the one with the positive value, then $\Delta S_{\text{univ}} > 0$ and the process is spontaneous.

SAMPLE EXERCISE 17.1 Predicting the Sign of Entropy Change LO1

Predict whether ΔS_{sys} is greater or less than zero when each of these processes occurs at constant temperature:

1. $H_2O(\ell) \rightarrow H_2O(g)$
2. $NH_3(g) + HCl(g) \rightarrow NH_4Cl(s)$
3. $C_{12}H_{22}O_{11}(s) \rightarrow C_{12}H_{22}O_{11}(aq)$

Collect, Organize, and Analyze To predict the signs of the accompanying entropy changes, we can compare the freedom of motion of the reactant particles to the freedom of motion of the product particles:

1. Molecules of liquid water become molecules of water vapor, which means the molecules have increased freedom of motion.
2. Two gaseous compounds form a single solid compound, which means the particles of product occupy much less space and have much less freedom of motion.
3. A solid dissolves in water, forming molecules dispersed in an aqueous solution that have more freedom of motion.

Solve

1. $\Delta S_{\text{sys}} > 0$, because the kinetic energies of water molecules are more dispersed in the gas state than they are in the liquid state.
2. $\Delta S_{\text{sys}} < 0$, because formation of a solid causes the loss of the translational and rotational motion the gas-phase particles had.
3. $\Delta S_{\text{sys}} > 0$, because particles in a solution have translational and rotational motion that particles in crystalline solids do not have.

Think About It Entropy increases when solids melt and liquids vaporize because of the increased freedom of motion of their particles and the increased dispersion of their particles' kinetic energies. When gases combine to form a solid, they lose freedom of motion and entropy decreases. When solids dissolve in liquids, however, they gain freedom of motion and experience an increase in entropy.

Practice Exercise Predict whether these chemical reactions result in an increase or decrease in the entropy of the system. Assume the reactants and products are at the same temperature and pressure.

1. $CaCO_3(s) + 2\ HCl(aq) \rightarrow CaCl_2(aq) + CO_2(g) + H_2O(\ell)$
2. $NH_3(g) + BF_3(g) \rightarrow NH_3BF_3(s)$

(Answers to Practice Exercises are in the back of the book.)

Glossary

entropy (S)

a measure of the dispersion of energy in a system at a specific temperature.

second law of thermodynamics

the principle that the total entropy of the universe increases in any spontaneous process.

reversible process

a process that can be run in the reverse direction in such a way that, once the system has been restored to its original state, no net energy has flowed either to the system or to its surroundings.

Learning Objectives

- Predict the signs of entropy changes for spontaneous and nonspontaneous chemical reactions and physical processes

17.3 Absolute Entropy and the Third Law of Thermodynamics

The entropy of a system depends on temperature because higher temperatures mean higher particle kinetic energies, which mean the particles have more vibrational, rotational, and translational motion—and more entropy. Conversely, lower temperatures mean that all these quantities are smaller. If we lower the temperature of a substance to absolute zero, in principle all translational motion should cease. If we assume that the substance forms a perfect crystalline solid (**Figure 17.6**), in which each particle is locked in one and only one site within the crystal, then each particle has zero freedom of motion. There is no dispersion of translational kinetic energy because there is none to disperse. As a result, the *absolute* entropy of a perfect crystalline solid is zero at absolute zero (0 K). This conclusion is known as the third law of thermodynamics.

Setting a zero point on the entropy scale allows scientists to establish absolute entropy values for pure substances at any temperature. The absolute entropy of a substance is often expressed as its standard molar entropy ($S°$)—that is, the entropy of 1 mole of the substance at 298 K and 1 bar (~1 atm) of pressure in its standard state (**Table 17.2**). For example, the standard molar entropy of solid NaCl is 72.1 J/(mol · K) at 298 K. Absolute entropies are determined from careful determinations of the molar heat capacity (or specific heat) of substances as a function of temperature. Our ability to determine absolute entropy values of substances and systems contrasts with the observation in Chapter 6 that we cannot measure absolute enthalpy (H), and the best we can do is calculate *changes* in enthalpy, ΔH.

The $S°$ values for liquid water and water vapor in **Table 17.3** illustrate an important difference between the entropies of liquids and gases that we have discussed before in this chapter: the molecules in a gas under standard conditions are much more widely dispersed than the molecules in a liquid, and the entropies of the different phases of a given substance at a given temperature follow the order $S_{\text{solid}} < S_{\text{liquid}} < S_{\text{gas}}$.

The entropy changes that occur as 1 mole of ice at 0 K is heated are shown in **Figure 17.7**. Note the jump in entropy as the ice melts and the even bigger jump as the liquid water vaporizes. Note, too, that the lines between the phase changes are curved. The change in entropy (ΔS) with temperature is not linear because, as described by Equation 17.2, heating a substance at a higher temperature produces a smaller entropy increase than does transferring the same quantity of heat to the same substance at a lower temperature.

Let's summarize the factors that affect entropy change:

1. Entropy increases when temperature increases.
2. Entropy increases when volume increases.[1]
3. Entropy increases when the number of independent particles increases.

In all three cases, entropy increases because each change increases the dispersion of the kinetic energy of a system's particles. We can often make qualitative predictions about entropy changes that accompany chemical reactions on the basis of these three factors, even if we have no thermodynamic data about the reactants and products. For example, when propane burns in air, 6 moles of gaseous reactants react to form 7 moles of gaseous products:

CONNECTION As defined in Section 6.5, molar heat capacity (c_P) is the quantity of energy required to raise the temperature of 1 *mole* of a substance by 1°C at constant pressure, whereas specific heat (c_s) is the quantity of energy required to raise the temperature of 1 *gram* of a substance by 1°C at constant pressure.

$CH_3CH_2CH_3(g) + 5\ O_2(g) \rightarrow 3\ CO_2(g) + 4\ H_2O(g)$

CONNECTION According to Avogadro's law (Section 5.3), the number of moles of a gas is directly proportional to the volume occupied by the gas at constant temperature and pressure.

The number of moles of gaseous particles increases as the reaction proceeds, so entropy also increases ($\Delta S_{sys} > 0$).

Entropy and Structure

The data in Table 17.3 demonstrate that the standard molar entropies of substances are strongly linked to molecular structure. Note, for example, how the standard molar entropies of the C_1 to C_4 alkanes in natural gas (**Figure 17.8**) increase as the number of atoms per molecule increases. This trend can be explained by the freedom of motion of the atoms inside their molecules. The more bonds within a molecule, the more opportunities for internal (vibrational) motion, and the greater the standard molar entropy.

Another structural feature that influences entropy is rigidity. The two most common forms of carbon—diamond and graphite—are both polymeric network solids. However, the rigid three-dimensional structure of diamonds results in much less entropy [$S^\circ = 2.4$ J/(mol · K)] than that of the less rigid, layered structure of graphite [$S^\circ = 5.7$ J/(mol · K)].

SAMPLE EXERCISE 17.2 Comparing Absolute Entropy Values LO2

Select the component in each of the following pairs of compounds that has the greater absolute entropy per mole at a pressure of 1 bar and 298 K.

1. HCl(*g*), HCl(*aq*)
2. $CH_3OH(\ell)$, $CH_3CH_2OH(\ell)$
3. Amorphous and crystalline forms of $SiO_2(s)$ (**Figure 17.9**)

Collect, Organize, and Analyze Particles in the gaseous state have more freedom of motion and entropy than they do in the liquid state, and particles in the liquid state have more freedom of motion and entropy than they do in the solid state. Substances composed of more particles, contributing to more freedom of motion, have more absolute entropy than substances made of fewer particles with less freedom of motion.

Solve

1. HCl gas loses freedom of motion when it dissolves in water, so HCl gas has a greater S° value at 298 K.
2. Both compounds are liquids with similar formulas, but 1 mole of ethanol (CH_3CH_2OH) has more atoms and more covalent bonds between atoms than does 1 mole of methanol (CH_3OH). Therefore, ethanol has a greater S° value at 298 K.
3. Both forms of SiO_2 are solids with extended covalent networks of atoms. Quartz, however, has a crystalline structure and obsidian has an irregular arrangement of bonds and atoms. The randomness of the obsidian structure gives it a greater S° value at 298 K.

Think About It The comparison in part (a) is complicated because HCl(*aq*) is a strong acid, which means that each molecule produces two ions in solution. However, they are aqueous ions and have less combined entropy than does half as many gas-phase HCl molecules. (Compare the S° values of HCl(*g*), $H^+(aq)$, and $Cl^-(aq)$ in Appendix 4 to see for yourself.)

Practice Exercise Ball-and-stick models of four hydrocarbons that each contain six carbon atoms per molecule are shown in **Figure 17.10**. Rank these compounds in order of decreasing S° values.

Glossary

third law of thermodynamics	the entropy of a perfect crystal is zero at absolute zero.
standard molar entropy (S°)	the absolute entropy of 1 mole of a substance in its standard state.

Endnotes

- Water is a notable exception to this observation; the molar volume of ice is larger than for liquid water even though the absolute entropy of ice is less than the absolute entropy of liquid water. Return to reference 1
- The thermodynamic data in Appendices 4 to 6 and used elsewhere in this book are based on a temperature of 298.15 K (25°C). Note that this temperature is not the STP temperature we use for gases (see Chapter 5), which is 273 K.Return to reference a
- Since 1982, 1 bar has been the standard pressure for tabulating all thermodynamic data. Before 1982, standard pressure was 1 atmosphere (atm) = 1.01325 bar.Return to reference b

17.4 Calculating Entropy Changes

The entropy of a system (like its enthalpy and internal energy) is a state function, which means that the change in entropy that accompanies a process depends only on the initial and final states of the system, not on the pathway of the process. As a result, the change in entropy experienced by a system is simply the difference between its initial and final absolute entropy levels:

We can adapt Equation 17.4 to calculate the change in entropy that accompanies a chemical reaction under standard conditions, $\Delta S°_{\text{rxn}}$, from the difference in the standard molar entropies of moles of reactants, $n_{\text{reactants}}$ (the equivalent of S_{initial} in Equation 17.4), and the molar entropies of moles of products, n_{products} (i.e., S_{final}):

Each $S°$ value for a product or reactant is multiplied by the appropriate number of moles from the balanced chemical equation. In other words, just as we saw for $\Delta H°$ in Section 6.8 (see Equation 6.19), entropy is an extensive thermodynamic property that depends on the quantities of substances consumed or produced in a reaction. Standard molar entropies of selected substances are listed in Appendix 4.

SAMPLE EXERCISE 17.3 Calculating Entropy Changes LO3

What is ΔS° when ammonium nitrate dissolves (**Figure 17.11**, $\Delta H^\circ > 0$) under standard conditions, given the following standard molar entropy values:

Collect, Organize, and Analyze We are given the standard molar entropy values of a solid ionic compound and its ions in aqueous solution, and we want to calculate the change in entropy that occurs when the compound dissolves under standard conditions. Entropy changes associated with chemical reactions depend on the entropies of the reactants and products, as described in Equation 17.5. Dissolving an ionic solid in water increases the freedom of motion of the solute ions, so ΔS° should be greater than zero.

Solve

Think About It As predicted, ΔS° is greater than zero because the freedom of motion and the dispersion of the kinetic energy of solute particles increase when the solid solute dissolves. The dissolution of ammonium nitrate is an example of an endothermic reaction that results in an increase in entropy.

Practice Exercise Calculate the standard molar entropy change for the combustion of methane gas by using S° values from Appendix 4. Before carrying out the calculation, predict whether the entropy of the system increases or decreases.

$CH_4(g) + 2\ O_2(g) \rightarrow CO_2(g) + 2\ H_2O(\ell)$

$$\begin{aligned}\Delta G^\circ_{\text{rxn}} &= \sum n_{\text{products}}\Delta G^\circ_{\text{products}} - \sum n_{\text{reactants}}\Delta G^\circ_{\text{reactants}} \\ &= [2\ \cancel{\text{mol CO}_2} \times (-394.4\ \text{kJ}/\cancel{\text{mol CO}_2}) + 3\ \cancel{\text{mol H}_2\text{O}} \times (-237.2\ \text{kJ}/\cancel{\text{mol H}_2\text{O}})] \\ &\quad -1\ \cancel{\text{mol CH}_3\text{CH}_2\text{OH}} \times (-174.9\ \text{kJ}/\cancel{\text{mol CH}_3\text{CH}_2\text{OH}}) + 3\ \cancel{\text{mol O}_2} \\ &\quad \times (0.0\ \text{kJ}/\cancel{\text{mol O}_2}) \\ &= -1325.5\ \text{kJ}\end{aligned}$$

$$\Delta E = q + w \tag{6.5}$$

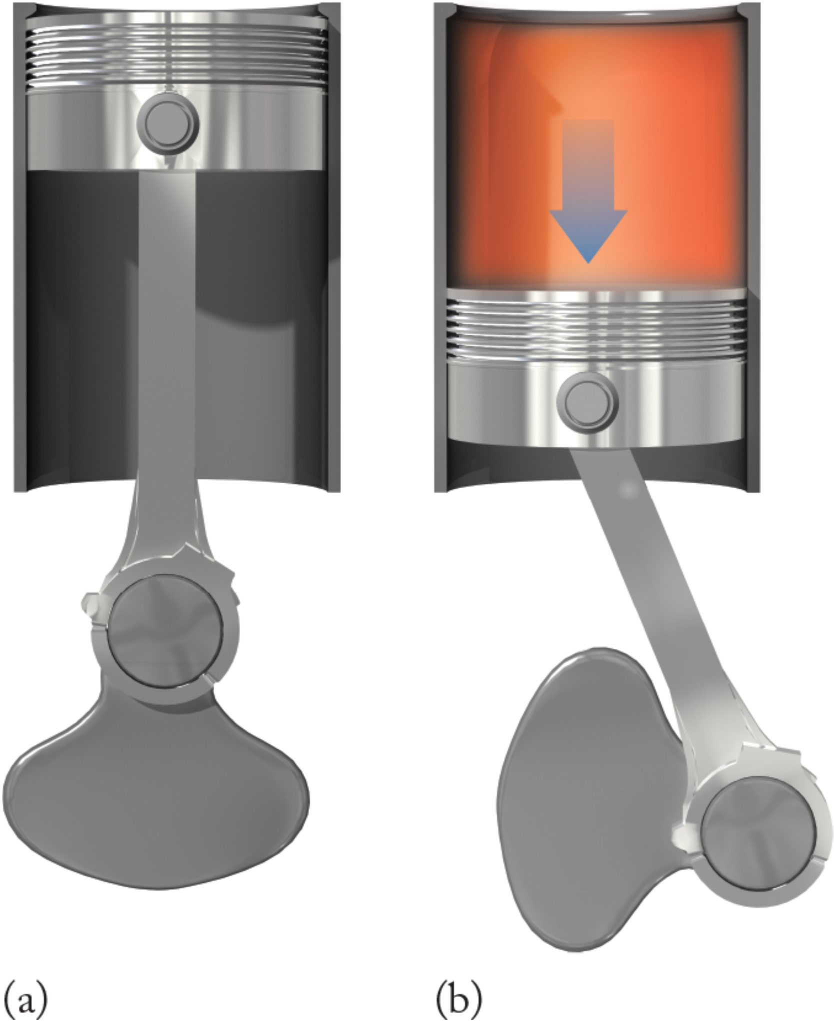

FIGURE 17.14 (a) In a car engine, thermal expansion causes the gases in a cylinder to (b) push down on a piston with a pressure (P) represented by the blue arrow. The product of P and the change in

volume of the gases (ΔV) is the work done by the expanding gases that propels the car.

$$\Delta H = \Delta G + T\Delta S \qquad (17.13)$$

17.5 Free Energy

In Sample Exercise 17.3 we used standard molar entropy values to calculate ΔS°. The solute, solvent, and resulting solution together constituted a closed thermodynamic system, which meant that energy could flow into it as its temperature dropped, but matter was not exchanged with its surroundings. Therefore, the ΔS° value that we calculated applied only to the system. There was no evaluation of the change in the entropy of the system's surroundings accompanying the dissolution process, though we might predict that energy flowing from the surroundings into the system would produce a decrease in S_{surr}. (Had the dissolution process been exothermic, energy would have flowed from the system into its surroundings, and ΔS_{surr} would have been greater than zero.)

CONNECTION In Section 6.4 we defined a change in enthalpy (ΔH) as the heat gained or lost in a reaction carried out at constant pressure.

Thus, the entropy change experienced by the surroundings of any chemical thermodynamic system depends on whether the process occurring in the system is exothermic or endothermic. When energy in the form of heat flows from an exothermic process occurring at constant pressure into a system's surroundings, the quantity of heat is equal in magnitude but opposite in sign to the enthalpy change of the system:

When an endothermic process occurs in the system, as in Sample Exercise 17.3, the direction of energy flow is reversed, but Equation 17.6 still applies. Assuming these transfers of energy occur reversibly, we can calculate the value of ΔS_{surr} by using the following modification of Equation 17.2:

Combining Equations 17.6 and 17.7 yields:

We can then substitute this expression into Equation 17.1 ($\Delta S_{\text{univ}} = \Delta S_{\text{sys}} + \Delta S_{\text{surr}}$):

The beauty of Equation 17.8 is that it allows us to predict whether a process is spontaneous at a particular temperature once we calculate the enthalpy and entropy changes accompanying the process. The downside of Equation 17.8 is that spontaneity relies on the value of a parameter (ΔS_{univ}) that is impossible to determine directly and that has little physical meaning. It would be better if we could substitute a thermodynamic parameter for ΔS_{univ} that is based only on the system and not the entire universe. Such a parameter exists and is called the change in the system's *free energy*.

In chemistry we focus on a particular kind of free energy called Gibbs free energy (G)—named in honor of American scientist J. Willard Gibbs (1839–1903). Gibbs free energy is the energy released by processes happening at constant temperature and pressure that is available to do useful work.

Like many of the thermodynamic properties we have examined, absolute free energy values of substances are often of less interest than the *changes* in free energy that accompany chemical reactions and other processes. Gibbs defined the change in free energy (ΔG_{sys}) of a process occurring at constant temperature and pressure in terms of T and ΔS_{univ} as:

$$\Delta G_{\text{sys}} = -T\Delta S_{\text{univ}}$$

Because of the $-T$ multiplier, *negative* values of ΔG_{sys} correspond to *positive* values of ΔS_{univ}. Therefore,

- If $\Delta G_{\text{sys}} < 0$, then $\Delta S_{\text{univ}} > 0$, and the reaction is spontaneous.
- If $\Delta G_{\text{sys}} > 0$, then $\Delta S_{\text{univ}} < 0$, and the reaction is nonspontaneous. Instead, the reaction running in reverse is spontaneous.
- If $\Delta G_{\text{sys}} = 0$, then $\Delta S_{\text{univ}} = 0$, and the composition of the reaction mixture does not change. In other words, the

reaction has reached chemical equilibrium.

We can combine Gibbs' equation with Equation 17.8 by multiplying all of the terms in Equation 17.8 by $-T$:

The left side of Equation 17.9 is equal to ΔG_{sys}. Making that substitution and rearranging the terms on the right side gives us

$$\Delta G_{\text{sys}} = \Delta H_{\text{sys}} - T\Delta S_{\text{sys}}$$

Because all of the parameters in this equation apply to the system, we typically simplify the equation by eliminating the "sys" subscripts:

CONCEPT TEST

(a) Given the thermodynamic data in Table A4.3 in the Appendix, is the conversion of diamond to graphite spontaneous? Explain your answer. (b) If yes, does knowing that the conversion is spontaneous tell you how rapid the conversion is?

Equation 17.10 highlights the two thermodynamic driving forces that contribute to a decrease in free energy and to making a process spontaneous at constant temperature and pressure:

1. 1. The system experiences an increase in entropy ($\Delta S > 0$).
2. 2. The process is exothermic ($\Delta H < 0$).

One or both of these conditions must be true for a reaction to be spontaneous.

Using Equation 17.10, we can calculate the change in Gibbs free energy of a process if we first calculate the values of ΔH and ΔS. For a chemical reaction occurring under standard conditions, we can calculate the *standard* change in Gibbs free energy $\Delta G^\circ_{\text{rxn}}$ by using the following modified version of Equation 17.10:

In Section 6.8 we calculated $\Delta H^\circ_{\text{rxn}}$ values from the differences in standard enthalpies of formation $\Delta \text{H}^\circ\text{f}$ of products and reactants:

The value of $\Delta S^\circ_{\text{rxn}}$ can be calculated using Equation 17.5:

We can combine the results of these two calculations in Equation 17.11 to calculate $\Delta G^\circ_{\text{rxn}}$, as illustrated in Sample Exercise 17.4.

SAMPLE EXERCISE 17.4 Predicting Reaction Spontaneity under Standard Conditions LO4

Consider the reaction of nitrogen gas and hydrogen gas (**Figure 17.12**) at 298 K to make ammonia at the same temperature:

$N_2(g) + 3\ H_2(g) \rightarrow 2\ NH_3(g)$

1. Before doing any calculations, predict the sign of $\Delta S^\circ_{\text{rxn}}$.
2. What is the actual value of $\Delta S^\circ_{\text{rxn}}$?
3. What is the value of $\Delta H^\circ_{\text{rxn}}$?
4. What is the value of $\Delta G^\circ_{\text{rxn}}$ at 298 K?
5. Is the reaction spontaneous under standard conditions?

Collect and Organize For a given reaction, we want to predict the sign of the standard entropy change and then calculate the changes in entropy, enthalpy, and Gibbs free energy. We can then determine the spontaneity of the reaction under standard conditions. Standard molar entropies and standard enthalpies of formation of the reactants and product are found in Table 17.3 and Appendix 4, respectively. Figure 17.12 reinforces the point that there are more molecules of gaseous reactants than products in the reaction.

Analyze We can use Equation 17.5 to calculate entropy changes under standard conditions, Equation 6.19 to calculate $\Delta H^\circ_{\text{rxn}}$ from standard enthalpy of formation values (in Appendix 4), and then use these values in Equation 17.11 to calculate the free energy change in the reaction. The sign of $\Delta G^\circ_{\text{rxn}}$ will indicate whether the reaction is spontaneous under standard conditions ($T = 298$ K).

Solve

1. The number of gas-phase molecules decreases as the reaction proceeds, so $\Delta S^\circ_{\text{rxn}}$ will be negative.
2. We use data from Table 17.3 in Equation 17.5 to calculate $\Delta S^\circ_{\text{rxn}}$:

$$\begin{aligned}\Delta S^\circ_{\text{rxn}} &= \sum n_{\text{products}} S^\circ_{\text{products}} - \sum n_{\text{reactants}} S^\circ_{\text{reactants}} = \Delta S^\circ_{\text{sys}}\\ &= \left\{\left[2\ \cancel{\text{mol}} \times \left(\frac{192.5\ \text{J}}{\cancel{\text{mol}} \cdot \text{K}}\right)\right] - \left[1\ \cancel{\text{mol}} \times \left(\frac{191.5\ \text{J}}{\cancel{\text{mol}} \cdot \text{K}}\right) + 3\ \cancel{\text{mol}} \times \left(\frac{130.6\ \text{J}}{\cancel{\text{mol}} \cdot \text{K}}\right)\right]\right\}\\ &= -198.3\ \text{J/K}\end{aligned}$$

The entropy change is negative, as predicted in part (a).

3. The change in enthalpy that accompanies the reaction under standard conditions is

$$\begin{aligned}\Delta H^\circ_{\text{rxn}} &= \sum n_{\text{products}} \Delta H^\circ_{\text{f,products}} - \sum n_{\text{reactants}} \Delta H^\circ_{\text{f,reactants}}\\ &= \left\{\left[2\ \cancel{\text{mol}} \times \left(\frac{-46.1\ \text{kJ}}{\cancel{\text{mol}}}\right)\right] - \left[1\ \cancel{\text{mol}} \times \left(\frac{0.0\ \text{kJ}}{\cancel{\text{mol}}}\right) + 3\ \cancel{\text{mol}} \times \left(\frac{0.0\ \text{kJ}}{\cancel{\text{mol}}}\right)\right]\right\}\\ &= -92.2\ \text{kJ}\end{aligned}$$

4. We insert the values of $\Delta S^\circ_{\text{rxn}}$ and $\Delta H^\circ_{\text{rxn}}$ calculated in parts (a) and (b) into Equation 17.11:

$$\begin{aligned}\Delta G^\circ_{\text{rxn}} &= \Delta H^\circ_{\text{rxn}} - T\Delta S^\circ_{\text{rxn}}\\ &= -92.2\ \text{kJ} - \left[(298\ \cancel{\text{K}}) \times \left(-198.3\ \frac{\cancel{\text{J}}}{\cancel{\text{K}}} \times \frac{1\ \text{kJ}}{1000\ \cancel{\text{J}}}\right)\right]\\ &= -33.1\ \text{kJ}\end{aligned}$$

Note that the units on $\Delta H^\circ_{\text{rxn}}$ and $\Delta S^\circ_{\text{rxn}}$ are different: kJ and J/K, respectively. We needed to multiply the $\Delta S^\circ_{\text{rxn}}$ value by the temperature to convert to units of kJ.

5. The decrease in Gibbs free energy tells us that the reaction is spontaneous under standard conditions.

Think About It We predicted that the sign of $\Delta G^\circ_{\text{rxn}}$ would be diagnostic of the spontaneity of a reaction. After substituting for $\Delta H^\circ_{\text{rxn}}$ and $\Delta S^\circ_{\text{rxn}}$ in Equation 17.11, $\Delta G^\circ_{\text{rxn}} < 0$ indicating that the reaction is spontaneous at 298°C and $P = 1$ bar. In this reaction, a decrease in entropy ($\Delta S^\circ_{\text{rxn}} < 0$) is more than offset by a favorable enthalpy change ($\Delta H^\circ_{\text{rxn}} < 0$) so that overall, $\Delta G^\circ_{\text{rxn}} < 0$.

Practice Exercise For the reaction 2 $H_2(g) + O_2(g) \rightarrow 2\ H_2O(\ell)$

1. Predict the sign of the entropy change for the reaction.
2. What is the value of ΔS°_{rxn}?
3. What is the value of ΔH°_{rxn}?
4. Is the reaction spontaneous under standard conditions?

CONCEPT TEST

The preparation of ammonia from nitrogen and hydrogen in Sample Exercise 17.4 is determined to be spontaneous under standard conditions, yet if we mix the two gases at 298 K, no reaction is observed. Suggest a reason why.

Another way to calculate the change in Gibbs free energy of a reaction under standard conditions is based on another thermodynamic property of substances listed in Appendix 4: standard free energy of formation(ΔG°_f). A compound's ΔG°_f value is the change in free energy associated with the formation of 1 mole of it in its standard state from its elements in their standard states.

In Equation 6.19 we calculated standard enthalpies of reaction (ΔH°_{rxn}) from the difference in the standard enthalpies of formation (ΔH°_f) of their products and reactants. We can also calculate the change in standard free energy of a reaction under standard conditions from the difference in the standard free energies of formation of its products and reactants. As with standard enthalpies of formation, standard free energies of formation of the most stable forms of elements in their standard states are defined to be zero. The similarities between the two calculations can be seen from the similar formats of the equations used to calculate ΔG°_{rxn},

---

and $\Delta H^\circ rxn$,

Sample Exercise 17.5 illustrates just how similar the two calculations are.

CONCEPT TEST

Molecular models and standard free energies of formation for three structural isomers with the molecular formula C_8H_{18} are shown in **Figure 17.13**. All three isomers burn in air, as described by the same chemical equation:

$$2\ C_8H_{18}(\ell) + 25\ O_2(g) \rightarrow 16\ CO_2(g) + 18\ H_2O(g)$$

Are the ΔG°_{rxn} values for the three combustion reactions also the same? Why or why not?

SAMPLE EXERCISE 17.5 Calculating DG°_{rxn} by Using Appropriate DG°_f Values LO4

Use the appropriate standard free energy of formation values from Appendix 4 to calculate the change in Gibbs free energy as ethanol burns under standard conditions. Assume the reaction proceeds as described by the following chemical equation:

$$CH_3CH_2OH(\ell) + 3\ O_2(g) \rightarrow 2\ CO_2(g) + 3\ H_2O(\ell)$$

Collect and Organize We can calculate the value of ΔG°_{rxn} for the combustion of ethanol according to Equation 17.12, using the ΔG°_f values of the reactants and products in the combustion reaction:

[illegible] $CH_3CH_2OH(\ell)$	[illegible]	[illegible]	[illegible]	[illegible]
ΔG°_f (kJ/mol) [illegible]	[illegible]	[illegible]	[illegible]	[illegible]

Analyze The reaction consumes 1 mole of liquid ethanol and 3 moles of oxygen, and it produces 2 moles of CO_2 gas and 3 moles of *liquid* H_2O. Substituting the above ΔG°_f values and the appropriate numbers of moles into Equation 17.12 yields the value of ΔG°_{rxn}. The combustion of ethanol, a common additive in gasoline in the United States and Canada, is spontaneous, so ΔG°_{rxn} should be less than zero.

Solve We insert the appropriate numbers of moles and ΔG°_f values into Equation 17.12:

Think About It The calculated value represents that part of the total energy released by the combustion of 1 mole of ethanol under standard conditions that is available to do useful work.

Practice Exercise Use the appropriate standard free energy of formation values in Appendix 4 to calculate the value of ΔG°_{rxn} for the steam-reforming reaction used to produce H_2 gas:

$CH_4(g) + H_2O(g) \rightarrow CO(g) + 3\ H_2(g)$

What exactly does "energy available to do useful work" mean? Let's attempt to answer this question, using as our model the internal combustion (gasoline) engines that power most automobiles.

A combustion reaction is a thermodynamic system that experiences a decrease in internal energy (ΔE) as energy in the form of heat (q) flows from it into its surroundings and as it does work (w) on its surroundings. These three variables are related by Equation 6.5:

From the perspective of the system, all three quantities are less than zero. Internal combustion engines have cooling systems to manage the dissipation of heat, which is wasted energy that does nothing to power the car. The energy that moves the car is derived from the rapid expansion of the gaseous products of combustion in the cylinders of the engine. As **Figure 17.14** shows, this expansion pushes down on the piston of a cylinder, increasing the volume of the reaction mixture. The pressure exerted by the reacting gases and their products on the pistons in a car's engine, multiplied by the volumes they displace, constitutes the $P–V$ work (see Equation 6.6), which propels the car:

$$w = -P\Delta V$$

Gibbs free energy is a measure of the *maximum* amount of work that can be done by the energy released during combustion. To see how this theoretical quantity of work compares with the total energy released, let's rearrange Equation 17.10 by isolating the ΔH term:

Equation 17.13 tells us that the enthalpy change that accompanies making and breaking chemical bonds during a chemical reaction may be divided into two parts. The ΔG part is the energy that can theoretically be converted into motion and other useful work (such as propelling a car or generating electricity for its electrical system). The $T\Delta S$ part, on the other hand, is not usable: it is the portion of energy that disperses when, for example, hot gases flow out of an automobile exhaust pipe. This part of ΔH is wasted.

Consequently, the conversion of chemical energy into useful mechanical energy (ΔG) is never 100% efficient. A portion of ΔG is also wasted because combustion and the energy conversion happen quickly and therefore irreversibly. Maximum efficiency comes with very slow and reversible reactions (see Section 17.2), but that is not how automobile engines operate. It turns out that gasoline engines convert only about 30% of the energy produced during combustion into useful work.

Glossary

Gibbs free energy (G)

the maximum energy released by a process occurring at constant temperature and pressure that is available to do useful work.

standard free energy of formation (ΔG°_f)

the change in free energy associated with the formation of 1 mole of a compound in its standard state from its component elements.

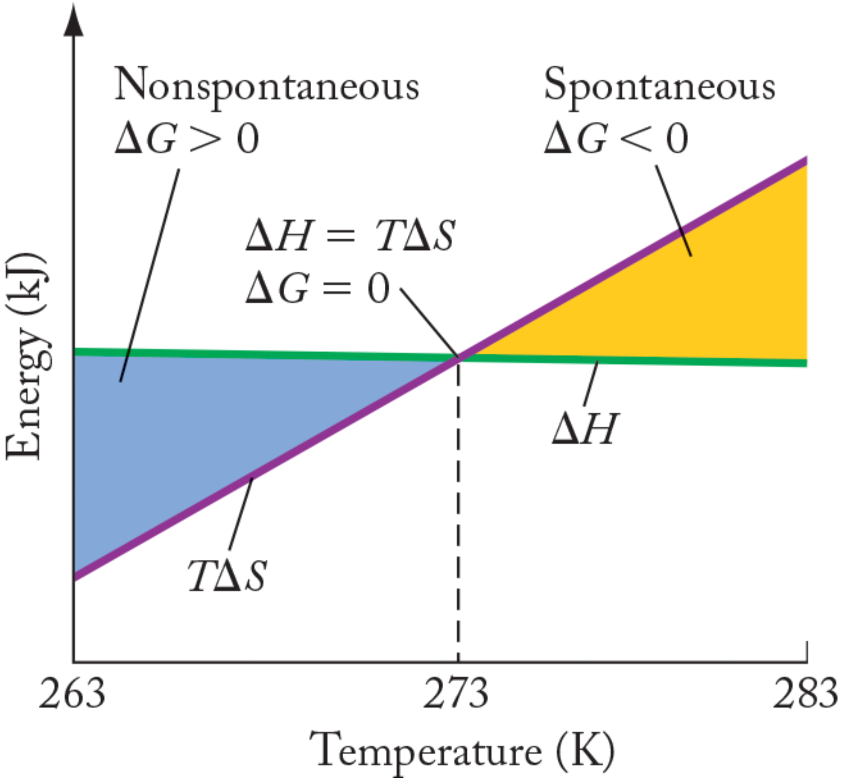

FIGURE 17.15 Changes in the values of ΔH, the quantity $T\Delta S$, and ΔG for ice melting as temperature increases from $-10°C$ (263 K) to $+10°C$ (283 K).

$H_2O(s) \rightarrow H_2O(\ell)$ $\qquad \Delta H^\circ_{fus} = 6.01 \times 10^3$ J/mol; $\Delta S^\circ_{fus} = 22.0$ J/(mol · K)

$$\Delta G = (6.01 \times 10^3 \text{ J/mol}) - T[22.0 \text{ J/(mol} \cdot \text{K)}] = 0$$

$$T = \frac{6.01 \times 10^3 \cancel{\text{J}}/\cancel{\text{mol}}}{22.0 \cancel{\text{J}}/(\cancel{\text{mol}} \cdot \text{K})} = 273 \text{ K} = 0°\text{C}$$

$$T = \frac{\Delta H^\circ}{\Delta S^\circ} \qquad T > \frac{\Delta H^\circ_{rxn}}{\Delta S^\circ_{rxn}}$$

$$\begin{aligned}\Delta H^\circ_{\text{rxn}} &= [\Delta H^\circ_{\text{CO}_2,g} + 3\,\Delta H^\circ_{\text{H}_2,g}] - [\Delta H^\circ_{\text{CH}_3\text{OH},g} + \Delta H^\circ_{\text{H}_2\text{O},g}] \\ &= [(1\ \cancel{\text{mol CO}_2})(-393.5\ \text{kJ}/\cancel{\text{mol}}) + (3\ \cancel{\text{mol H}_2})(0.0\ \text{kJ}/\cancel{\text{mol}})] \\ &\quad -[(1\ \cancel{\text{mol CH}_3\text{OH}})(-200.7\ \text{kJ}/\cancel{\text{mol}}) + (1\ \cancel{\text{mol H}_2\text{O}})(-241.8\ \text{kJ}/\cancel{\text{mol}})] \\ &= 49.0\ \text{kJ}\end{aligned}$$

$$T > \frac{\Delta H^\circ_{\text{rxn}}}{\Delta S^\circ_{\text{rxn}}} > \frac{49.0\ \cancel{\text{kJ}}}{0.1769\ \cancel{\text{kJ}}/\text{K}} = 277\ \text{K}$$

17.6 Temperature and Spontaneity

Let’s revisit the process of ice melting, this time focusing on how the values of the three terms ΔH, $T\Delta S$, and ΔG in Equation 17.10 change as the temperature of a mixture of ice and water increases from -10°C to $+10^\circ\text{C}$ (**Figure 17.15**). As the temperature rises over this range, there is little impact on the enthalpy of fusion, ΔH, as shown by the nearly flat green line in Figure 17.15. However, increasing the value of T does increase the value $T\Delta S$ (as shown by the upward slope of the purple line). After all, the ΔS of melting ice (or any melting solid)[2] has a positive value, so $T\Delta S$ must increase as T increases.

The green and purple lines intersect at 0°C, which means $\Delta H = T\Delta S$ at that temperature. Put another way, the difference between ΔH and $T\Delta S$ at 0°C is zero, and so is ΔG (because $\Delta G = \Delta H - T\Delta S$). The temperature at the point in Figure 17.15 where $\Delta G = 0$ defines the melting (or freezing) point, which by definition is the temperature at which the solid melts at the same rate as the liquid freezes. The two phases are in *equilibrium*. At 0°C, no net change takes place, and both phases coexist.

We also know that ice melts spontaneously above 0°C (273 K), which means that ΔG for the melting process must be less than zero. The graph in Figure 17.15 shows that indeed it is. Above 0°C, the value of $T\Delta S$ is greater than ΔH. Therefore, the difference between them ($\Delta H - T\Delta S$) is less than zero and becomes more negative with increasing temperature, as illustrated by the increasing distance from the purple line to the green line in that region of the graph.

CONNECTION In Chapter 10 we discussed the equilibrium between phases of a substance and used phase diagrams to illustrate which physical states are stable at various combinations of temperature and pressure.

Below 0°C, ice does not melt spontaneously, which means ΔG is greater than zero. The graph shows why this is true: at $T < 273$ K (0°C), $T\Delta S$ values (purple line) are less than ΔH values (green line), which means that $\Delta H - T\Delta S$ (and ΔG) is greater than zero. The positive ΔG values mean the process is nonspontaneous below 273 K, and ice does not melt below its freezing point. However, the opposite process—liquid water freezing—*is* spontaneous because reversing a process keeps the absolute values but switches the signs of ΔH, ΔS, and ΔG. Therefore, if the melting process is nonspontaneous, then the exothermic freezing process *is* spontaneous at low temperatures.

CONCEPT TEST

A given process is spontaneous at lower temperature and nonspontaneous at higher temperature. What does a graph like the one in Figure 17.15 look like for such a process?

Equilibrium also exists for water at 100°C and 1 atm pressure, which are the temperature and pressure at which $\Delta G_{\text{vaporization}}$ and $\Delta G_{\text{condensation}}$ both equal zero. At 100°C, liquid water vaporizes and water vapor condenses at the same rate; the two phases coexist.

The temperature at which $\Delta G = 0$ for a process can be calculated from Equation 17.10 if we know the values of ΔH and ΔS. For example, the values for the fusion of water are

In doing this calculation, we assume that the values of ΔH° and ΔS° do not change significantly with small changes in temperature. For this process, as well as for most other physical and chemical processes, this assumption is acceptable. We can assume, therefore, that $\Delta G = \Delta H - T\Delta S < \Delta H^\circ - T\Delta S^\circ$. Inserting the values of ΔH° and ΔS° and using $\Delta G = 0$ for a process at equilibrium, we get

This is the familiar value for the melting point of ice.

Like physical processes, chemical reactions under standard conditions may be spontaneous below or above a characteristic temperature (T) at which $\Delta G^\circ = 0$, and

TABLE 17.4 Effects of ΔH° and ΔS° on ΔG° and Spontaneity

ΔH°	ΔS°	ΔG°	Spontaneity
< 0	> 0	Always < 0	Always spontaneous
< 0	< 0	< 0 at lower temperature	Spontaneous at lower temperature
> 0	> 0	< 0 at higher temperature	Spontaneous at higher temperature
> 0	< 0	Always > 0	Never spontaneous

As summarized in **Table 17.4**, an exothermic process ($\Delta H^\circ < 0$) for which ΔS° is also less than zero is spontaneous only below a characteristic temperature, such as the freezing of liquid water. An endothermic process ($\Delta H^\circ > 0$) for which ΔS° is also greater than zero is spontaneous only above a characteristic temperature, such as the melting of ice into liquid water. This pattern makes sense because lower temperatures make the value of the $T\Delta S^\circ$ term in Equation 17.11 less negative if $\Delta S^\circ < 0$. This helps make ΔG° more negative because of the minus sign in front of the $T\Delta S^\circ$ term. Higher temperatures make the value of $T\Delta S^\circ$ more positive if $\Delta S^\circ > 0$, which again helps make ΔG° more negative.

SAMPLE EXERCISE 17.6 Relating Reaction Spontaneity to ΔH_{rxn} and ΔS_{rxn}LO5

The gas-phase reaction between methanol and water that produces carbon dioxide and 3 moles of hydrogen is accompanied by an increase in entropy, $\Delta S^\circ_{rxn} = 176.9$ J/K, under standard conditions.

$CH_3OH(g) + H_2O(g) \rightarrow CO_2(g) + 3\ H_2(g)$

At what temperatures is this reaction spontaneous?

Collect and Organize We are asked to determine the temperatures at which a reaction with a positive entropy change is spontaneous. Equation 17.11 relates spontaneity ($\Delta G^\circ_{\text{rxn}} < 0$) to $\Delta H^\circ_{\text{rxn}}$, $\text{D}S^\circ_{\text{rxn}}$, and T.

$$\Delta G^\circ_{\text{rxn}} < \Delta H^\circ_{\text{rxn}} - T\Delta S^\circ_{\text{rxn}} < 0$$

Analyze According to Table 17.4, a reaction in which entropy increases ($\Delta S^\circ_{\text{rxn}} > 0$) will be spontaneous at all temperatures if it is also exothermic ($\Delta H^\circ_{\text{rxn}} < 0$). However, if the reaction is accompanied by a positive enthalpy change, (endothermic), then the reaction will only be spontaneous above a certain temperature. We need to calculate using standard enthalpies of formation and then solve the relationship:

Solve The enthalpy change for the reaction is calculated as follows:

Substituting into the relationship between T, $\Delta H^\circ_{\text{rxn}}$, and $\Delta S^\circ_{\text{rxn}}$:

Thus, the conversion of methanol vapor and steam to hydrogen and carbon dioxide should be spontaneous above 277 K or 4°C.

Think About It The enthalpy change for the reaction is a relatively small value so we do not require an enormously high temperature for the reaction to be spontaneous.

Practice Exercise Hydrazine, N_2H_4, is used as a rocket fuel reacting with oxygen to produce nitrogen gas and liquid water.

$$N_2H_4(g) + O_2(g) \rightarrow N_2(g) + 2\ H_2O(\ell)$$

At what temperatures is this reaction spontaneous?

SAMPLE EXERCISE 17.7 Relating Reaction Spontaneity to ΔH and ΔSLO5

A certain chemical reaction is spontaneous at low temperatures but not at high temperatures. Use Equation 17.10 ($\Delta G = \Delta H - T\Delta S$) to determine the signs of the enthalpy and entropy changes for this reaction.

Collect, Organize, and Analyze We are asked to determine the signs of ΔH (enthalpy change) and ΔS (entropy change) on the basis of the change in spontaneity of a reaction as temperature changes. This means we need to think about not only the signs of ΔH and ΔS but also how the relative magnitude of ΔH and $T\Delta S$ varies with temperature.

Solve The importance of ΔS increases with increasing temperature because the product $T\Delta S$ appears in Equation 17.10. The given reaction is known to be spontaneous ($\Delta G < 0$) at low temperatures, meaning that the magnitude of the enthalpy term is more likely to be larger than the magnitude of $T\Delta S$, in which case ΔH must be negative for the reaction to be spontaneous. The given reaction is known to be nonspontaneous ($\Delta G > 0$) at higher temperatures, where the magnitude of $T\Delta S$ is more likely to be larger than the magnitude of ΔH, in which case ΔS must also be negative in order for $\Delta G > 0$.

Think About It In this reaction, the impact of a negative ΔS value is more than offset by a decrease in enthalpy—a change that favors the reaction. Table 17.4 confirms that a process that is spontaneous only at low temperatures is one in which there is a decrease in both entropy and enthalpy. Recall that the freezing of water below 0°C is an exothermic reaction ($\Delta H < 0$) that is accompanied by a decrease in entropy ($\Delta S < 0$).

Practice Exercise At high temperatures, ammonia decomposes to nitrogen and hydrogen gases:

$2\ NH_3(g) \rightarrow N_2(g) + 3\ H_2(g)$

ΔH for the reaction is positive and ΔS is positive. Predict whether the reaction is spontaneous at all temperatures, or only at high temperatures.

Endnotes

- Helium-3, ^{3}He, is an exception to this observation: $\Delta H_{\text{fus},\,^{3}\text{He}} < 0.$ Return to reference 2

&= [1\ \cancel{\text{mol}}\ (51.3\text{ kJ}/\cancel{\text{mol}})] - [1\ \cancel{\text{mol}}\ (86.6\text{ kJ}/\cancel{\text{mol}}) + \tfrac{1}{2}\ \cancel{\text{mol}}\ (0.0\text{ kJ}/\cancel{\text{mol}})]\\
&= (51.3 - 86.6)\text{ kJ}\\
&= -35.3\text{ kJ, or } -35{,}300\text{ J per mol of } NO_2 \text{ produced}
\end{aligned}$$

$$-\frac{\Delta G^\circ_{rxn}}{RT} = -\frac{\left(\dfrac{-35{,}300\ \cancel{\text{J}}}{\cancel{\text{mol}}}\right)}{\left(\dfrac{8.314\ \cancel{\text{J}}}{\cancel{\text{mol}}\cdot\cancel{\text{K}}}\right)(298\ \cancel{\text{K}})} = 14.2$$

$$K_p = e^{\frac{-\Delta G^\circ_{rxn}}{RT}} = e^{14.2} = 1.47 \times 10^6$$

17.7 Free Energy and Chemical Equilibrium

We have just seen that equilibrium exists when the free energy change that accompanies a process is zero. For chemical reactions *not* at equilibrium, the magnitude of ΔG—how far it is from zero in either a negative or positive direction—indicates how far a system is from its equilibrium position.

In Chapter 14 we showed how the reaction quotient (Q) can be used to determine whether a reaction is at chemical equilibrium. When the value of Q is much larger or smaller than the value of the reaction's equilibrium constant (K), we know that the reaction is far from chemical equilibrium. When $Q < K$, for example, the ratio of product concentrations to reactant concentrations (raised to the appropriate powers) is less than it would be at equilibrium. To reach equilibrium, the reaction proceeds (spontaneously!) in the forward direction until the ratio of product to reactant concentrations matches the value of K. In other words, when $Q < K$, ΔG_{rxn} must be less than zero.

CONNECTION In Section 14.5 the reaction quotient (Q) is defined as the ratio of the concentrations (or partial pressures) of products to reactants in a chemical reaction, each term raised to a power equal to the coefficient of that substance in the balanced chemical equation describing the reaction.

On the other hand, when $Q > K$, the ratio of product to reactant concentrations is greater than it would be at equilibrium. To reach equilibrium, the reaction must proceed in reverse, so that products are consumed and reactants form, until the ratio of product to reactant concentrations matches the value of K. When $Q > K$, then, the forward reaction is *not* spontaneous because the *reverse* reaction is spontaneous, which means ΔG_{rxn} for the forward reaction must be greater than zero.

To summarize these points for any reaction:

When $Q = K$, $\Delta G_{rxn} = 0$ and the reaction is at equilibrium.
- When $Q < K$, $\Delta G_{rxn} < 0$ and the reaction is spontaneous.
- When $Q > K$, $\Delta G_{rxn} > 0$ and the reaction is nonspontaneous.

The key concept here is that the value of ΔG_{rxn} for any chemical reaction depends not only on the standard free energy of formation values of its reactants and products—that is, on the value of ΔG°_{rxn}—but also on the concentrations of the reactants and products in the reaction mixture. In other words, the value of ΔG_{rxn} depends on the value of Q. This dependency is expressed in Equation 17.14:

To illustrate the dependency of ΔG_{rxn} on Q, let's use as our chemical model the dimerization of NO_2:

$2\ NO_2(g) \leftrightharpoons N_2O_4(g)$

We can calculate the change in standard free energy for the reaction (ΔG°_{rxn}) using standard free energy of formation (ΔG°_f) values from Table A4.3 in Appendix 4 and Equation 17.12:

The negative value of ΔG°_{rxn} indicates that the reaction as written should, under standard conditions, proceed spontaneously in the forward direction at 298 K. However, this value of ΔG°_{rxn} applies only when $P_{NO2} = P_{N2O4} = 1$ bar, which rarely happens.

Let's consider what happens in a reaction vessel at 298 K if it initially contains pure NO_2 at a partial pressure of 2.0 bar with no (or hardly any) N_2O_4 present. Under these conditions, $Q_p = 0$:

The natural log (ln) of zero is undefined, so we can't use Equation 17.14 to calculate the value of ΔG_{rxn}. However, if the reaction mixture contained a trace of N_2O_4 so that, for example, its partial pressure was 1.0 mbar, then Q_p would be $0.0010/4.0 = 0.00025$, and ΔG_{rxn} would be

This value of ΔG_{rxn} is plotted as point ① on the graph in **Figure 17.16**. Its negative value tells us that the reaction will proceed spontaneously, consuming molecules of NO_2 at twice the rate at which it produces molecules of N_2O_4. As the reaction proceeds, P_{NO2} decreases and P_{N2O4} increases as does the value of Q, which makes the $RT \ln Q$ term in Equation 17.14 greater and the value ΔG_{rxn} less negative. Eventually, P_{NO2} falls to 0.49 bar; P_{N2O4} increases to 0.75 bar, and the value of $Q_p = 0.75/(0.49)^2 = 3.1$. At point ② on the graph, the value of $RT \ln Q = 8.314 \times 298 \times \ln 3.1 = +2.8$ kJ, which means $\Delta G_{rxn} = (-2.8 + 2.8) = 0$. The reaction has come to chemical equilibrium, which means $Q_p = 3.1 = K_p$.

At equilibrium Equation 17.14 becomes

$$\Delta G_{rxn} = \Delta G^{\circ}{}_{rxn} + RT \ln K = 0$$

or

We can use Equation 17.15 to confirm that the above K_p value is consistent with the value of $\Delta G^{\circ}{}_{rxn}$ for the dimerization reaction:

Starting with a reaction mixture that is essentially pure reactant is a common way to run a reaction, but Figure 17.16 shows the results of another approach: starting with (nearly) pure product. Consider what would happen if a reaction vessel at 298 K contained a reaction mixture in which the partial pressure of N_2O_4 was 1.0 bar with a trace amount (2.0 mbar) of NO_2. Using these values in Equation 17.14 yields a ΔG_{rxn} value of +28.0 kJ for the reaction. This positive value, which is plotted at point ③ in Figure 17.16, indicates that the forward reaction is not spontaneous. However, the reverse reaction is: the dimer spontaneously dissociates into molecules of NO_2, causing P_{N2O4} to decrease, P_{NO2} to increase, and the values of Q_p (of the dimerization reaction) and $RT \ln Q_p$ to decrease. When ($RT \ln Q_p$) falls to +2.8 kJ/mol, the value of ΔG_{rxn} has again reached $(-2.8 + 2.8) = 0$ at point ② on the graph, but this time as N_2O_4 decomposed into NO_2:

$$N_2O_4(g) \leftrightharpoons 2\ NO_2(g)$$

Rearranging Equation 17.15 allows us to calculate the K value for a reaction from its change in standard free energy and absolute temperature. First, we rearrange the terms:

Then we take the antilogarithm of both sides:

Equation 17.17 provides the following interpretation of reaction spontaneity under standard conditions: whenever ΔG° is negative, the exponent $-\ \Delta G^\circ/RT$ in Equation 17.17 is positive, and $e^{-\Delta G^\circ/RT} > 1$, making $K > 1$. Therefore, any reversible reaction with an equilibrium constant greater than 1 is spontaneous under standard conditions, as shown in **Figure 17.17a**. This spontaneity has its limits. As reactants are consumed and products are formed, the value of the reaction quotient increases, making the value of ΔG less negative. When it reaches zero, there is no further change in the composition of the reaction mixture because chemical equilibrium has been achieved.

It follows that a reversible reaction with a less negative value of ΔG° (**Figure 17.17b**) is still spontaneous but has a smaller equilibrium constant, so less reactant is consumed, and less product is formed before the value of ΔG reaches 0. Finally, a reaction that has a positive value of ΔG° (**Figure 17.17c**) has $K < 1$, and the reaction is not spontaneous under standard conditions. Instead, the reverse of the reaction is spontaneous.

Let's apply this concept to the equilibrium between NO_2 and N_2O_4:

We focus on the composition of the reaction mixture of these two gases at equilibrium in Figure 17.16. We start by calculating the value of the exponent in Equation 17.17:

Inserting this value into Equation 17.17 gives

$K = e^{-\Delta G^\circ_{\text{rxn}}/RT} = e^{1.13} = 3.1$

This result is consistent with the composition of the reaction mixture at equilibrium in Figure 17.16, where $P_{N2O4} \approx 0.75$ atm and $P_{NO2} \approx 0.49$ atm. Inserting these values into the equilibrium constant expression for the reaction gives us an approximate value of K_p that is close to the one we calculated from ΔG°_{rxn}:

In this example, a negative ΔG°_{rxn} value of only few kilojoules corresponds to an equilibrium constant value that is slightly greater than 1. As a result, the equilibrium reaction mixture contains more product than reactant, but less than an order of magnitude more. Similarly, an equilibrium reaction mixture produced by a reaction with a positive ΔG°_{rxn} value of only a few kilojoules is likely to contain more reactants than products, but with significant quantities of both.

CONCEPT TEST

Suppose the ΔG°_{rxn} value of the hypothetical chemical reaction A $\leftrightharpoons$ B is − 3.0 kJ/mol. Which of the following statements about an equilibrium mixture of A and B at 298 K is true?

1. There is only A present.
2. There is only B present.
3. There is an equimolar mixture of A and B present.
4. There is more A than B present.
5. There is more B than A present.

SAMPLE EXERCISE 17.8 Calculating the Value of *K* from DG°_f Values LO6

Use ΔG°_f values from Table A4.3 in the Appendix to calculate ΔG°_{rxn} and the value of K_p for the formation of NO_2 from NO and O_2 at 298 K:

Collect, Organize, and Analyze The ΔG°_f values we need from Table A4.3 are 51.3 kJ/mol for NO_2 and 86.6 kJ/mol for NO.

Because O_2 gas is the most stable form of the element, its $\Delta G^\circ_{\text{f}}$ value is 0.0 kJ/mol. We can use Equation 17.12 to calculate $\Delta G^\circ_{\text{rxn}}$ and then use Equation 17.17 to calculate the value of K. We predict that a large, negative value for $\Delta G^\circ_{\text{rxn}}$ will lead to a large equilibrium constant, K. Similarly, if $\Delta G^\circ_{\text{rxn}} > 0$, then K will be small.

Solve

The exponent in Equation 17.17 is

The corresponding value of K_{p} is

Think About It The value for K, 10^6, is much greater than 1, which is consistent with $\Delta G^\circ_{\text{rxn}} = -35.3$ kJ, a large, negative value.

Practice Exercise The standard free energy of formation of ammonia at 298 K is -16.5 kJ/mol. What is the value of K_{p} for the following reaction at 298 K?

$N_2(g) + 3\,H_2(g) \leftrightharpoons 2\,NH_3(g)$

CONNECTION The relationship between K_{c} and K_{p}, derived in Section 14.3, is $K_{\text{p}} = K_{\text{c}}(RT)^{\Delta n}$ (Equation 14.7), where Δn is the change in the number of moles of gases between the products and reactants. $K_{\text{p}} = K_{\text{c}}$ when $\Delta n = 0$.

We have yet to explain which kind of equilibrium constant, K_{c} or K_{p}, is related to ΔG° by Equation 17.17. The symbol ΔG° represents a change in free energy under standard conditions. The standard state of a gaseous reactant or product is one in which its *partial pressure* is 1 bar. Thus, the ΔG° of a reaction *in the gas phase* is linked by Equation 17.17 to its K_{p} value. However, standard conditions for reactions in solution (the focus of Chapters 15 and 16) mean that all dissolved reactants and products are present at a concentration of 1.00 *M*. Thus, the ΔG° of a reaction *in solution* is related by Equation 17.17 to its K_c value.

$$\ln\left(\frac{K_2}{6.09 \times 10^5}\right) = -22.87$$

$$\frac{K_2}{6.09 \times 10^5} = e^{-22.87} = 1.17 \times 10^{-10}$$

$$K_2 = 7.12 \times 10^{-5} \text{ at } 773\ \text{K}$$

17.8 Influence of Temperature on Equilibrium Constants

We noted on many occasions in Chapter 14 that the value of K changes with temperature. In this section we use the thermodynamics of chemical reactions to explain how and why.

Let's begin with a simplified version of Equation 17.11 (leaving out all the "rxn" subscripts):

$$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$$

We can combine it with a similarly simplified version of Equation 17.16:

The result is an equation that relates K to ΔH° and ΔS°:

Note how a negative value of ΔH° or a positive value of ΔS° contributes to a large value of K. These dependencies are consistent with negative values of ΔH° and positive values of ΔS° because these two factors contribute to making reactions spontaneous.

CONNECTION Recall from Section 6.3 that exothermic reactions give off energy—they have a negative enthalpy change ($\Delta H < 0$)—whereas endothermic reactions absorb energy ($\Delta H > 0$).

Because we are discussing the influence of temperature on K, let's identify the factors affected by changes in T in Equation 17.18. The ΔS° term is unaffected, but the influence of ΔH° does depend on temperature: the higher the temperature, the larger the denominator of the ΔH° term, and the smaller the influence of a favorable ΔH°—that is, a ΔH° value that is negative. This temperature dependence is consistent with Le Châtelier's principle and the notion that energy is produced in exothermic reactions and required for endothermic reactions to proceed. Increasing temperature inhibits exothermic reactions, but promotes endothermic reactions.

If ΔH° and ΔS° do not vary much with temperature, then Equation 17.18 predicts that ln K will be a linear function of $1/T$. Furthermore, we expect a graph of ln K versus $1/T$ to have a positive slope for an exothermic process and a negative slope for an endothermic process. We can determine ΔH° from the slope of the line and ΔS° from its y intercept. Thus, we can calculate fundamental thermodynamic values of a reaction at equilibrium by determining its equilibrium constant at different temperatures.

What, for example, are the values of ΔH° and ΔS° for the following reaction?

$2\ CO_2(g) \leftrightarrows 2\ CO(g)\ +\ O_2(g)$

We start with the K_p values of 2.75×10^{-11} at 1500 K, 1.42×10^{-3} at 2500 K, and 0.112 at 3000 K. K_p increases as temperature increases, indicating that energy is a reactant and the reaction is endothermic. We can use these data to determine the values of ΔH° and ΔS° by plotting ln K_p values versus $1/T$. To see how this graphical method works, let's rewrite Equation 17.18 so that it fits the form of the equation for a straight line ($y = mx + b$):

The graph of ln K_p versus $1/T$ (**Figure 17.18**) is indeed a straight line. The slope of this line is $-$ 66,662 K, which is equal to $-\ \Delta H$

$^{\circ}{}_{\text{rxn}}/R$. The corresponding value of $\Delta H^{\circ}{}_{\text{rxn}}$ is

The y intercept ($\Delta S^{\circ}{}_{\text{rxn}}/R$) of the graph is 20.1. The corresponding value of $\Delta S^{\circ}{}_{\text{rxn}}$ is

This positive entropy change is logical because the forward reaction converts 2 moles of gaseous CO_2 into 3 moles of gaseous products.

We can use a modified version of Equation 17.19 to relate the values of K at two different temperatures:

Equation 17.20 is called the *van 't Hoff equation* because it was first derived by Jacobus van 't Hoff. It is particularly useful for calculating the value of K at a very high or low temperature if we know what it is at a standard reference temperature (e.g., 298 K). We perform one such calculation in Sample Exercise 17.9.

SAMPLE EXERCISE 17.9 Calculating the Value of K at a Specific Temperature LO7

Use data from Appendix 4 to calculate the equilibrium constant K_p for the exothermic reaction

$N_2(g) + 3\ H_2(g) \leftrightharpoons 2\ NH_3(g)$

at 298 K and at 773 K, a typical temperature used in the Haber–Bosch process for synthesizing ammonia.

Collect and Organize We are asked to calculate the K_p value for a reaction at two temperatures. One of the temperatures is 298 K, which is the reference temperature for the standard thermodynamic data in Appendix 4. The $\Delta G^{\circ}{}_{\text{f}}$ value of NH_3 is -16.5 kJ/mol.

Analyze We can use Equation 17.17 to calculate the value of K_p at 298 K from the value of $\Delta G^{\circ}{}_{\text{rxn}}$. Then we can use Equation 17.20 to calculate the value of K_p at 773 K from the value of K_p at 298 K and the value of $\Delta H^{\circ}{}_{\text{rxn}}$. The value of $\Delta H^{\circ}{}_{\text{rxn}}$ can be calculated from the enthalpy of formation of NH_3 (-46.1 kJ/mol). The negative value of ΔH°_f means that ΔH°_{rxn} is also negative, indicating that the reaction is exothermic. Because energy is a product of the reaction, we predict that the value of K_p is smaller at 773 K than at 298 K.

Solve The value of ΔG°_{rxn} for the reaction is

Using this value in Equation 17.17 to calculate the value of K_p gives us

Once we know the value of K_p at 298 K, we can calculate K_p at 773 K by using Equation 17.20. To do this, we must first calculate the value of ΔH°_{rxn}, which is twice the ΔH°_f of NH_3 (use Equation 6.19 to confirm this for yourself):

After substituting $K_1 = 6.09 \times 10^5$, $T_1 = 298$ K, and $T_2 = 773$ K into Equation 17.20, we solve for K_2:

Think About It The equilibrium constant decreases 10 orders of magnitude when the temperature of the reaction is raised from 298 K to 773 K. This huge decrease fits our prediction for this exothermic reaction. Note that the standard thermodynamic data for the reaction (ΔH°_{rxn} and ΔG°_{rxn}) are expressed per mole of the reactant with a coefficient of 1 in the balanced chemical equation for N_2.

Practice Exercise Use data from Appendix 4 to calculate the value of K_p for the reaction

$2\ N_2(g) + O_2(g) \rightleftharpoons 2\ N_2O(g)$

at 298 K and 2000 K.

17.9 Driving the Human Engine: Coupled Reactions

CONNECTION In nutrition, 1 Calorie, the “calorie” used in discussing food, is equivalent to 1 kcal (see Section 6.3): 1 Cal = 1 kcal = 1000 cal.

The laws of thermodynamics that govern chemical reactions in the laboratory also govern all the chemical reactions that take place in living systems (**Figure 17.19**). Organisms carry out reactions that release energy by oxidizing compounds derived from the nutrients they consume and then use that energy to do work and sustain an array of other essential biological functions. Just like mechanical engines, however, humans and other life-forms are far from 100% efficient, which means that life requires a continual input of energy in terms of the caloric content of the food we eat. Thus, we must constantly absorb energy in the form of food and release energy and waste products into our surroundings. Young women have an average daily nutritional need of 2100 Cal; for young men the need is 2900 Cal. This level of caloric intake provides the energy we need in order to function at all levels, from thinking to getting out of bed in the morning.

In living systems, spontaneous reactions ($\Delta G < 0$) typically involve metabolizing food, whereas nonspontaneous reactions ($\Delta G > 0$) involve building molecules needed by the body. Living systems use the energy from spontaneous reactions to run nonspontaneous reactions; we say that the spontaneous reactions are *coupled* to the nonspontaneous reactions. Part of the study of biochemistry involves deciphering the molecular mechanisms that enable reaction coupling. This topic is covered in Chapter 20, but for now it is sufficient to know that elegant molecular processes have evolved to enable living systems to couple chemical reactions so that the energy obtained from spontaneous reactions can be used to drive the nonspontaneous reactions that maintain life. The metabolic chemical reactions we look at here are *not* presented for you to memorize. Rather, the intent is to aid your understanding of how changes in free energy allow spontaneous reactions to drive nonspontaneous reactions and to illustrate operationally what the phrase “coupled reactions” actually means.

As noted at the beginning of Chapter 6, all the energy contained in the food we eat has sunlight as its ultimate source. Green plants store energy from sunlight in their tissues as molecules such as glucose ($C_6H_{12}O_6$), which they produce from CO_2 and H_2O during photosynthesis.

Production of glucose by green plants is a nonspontaneous process, which is why the plants require the energy of sunlight to carry out this reaction. Animals that consume plants use the energy stored in the chemical bonds of glucose and other molecules and release CO_2 and H_2O back into the environment. This reaction,

$$C_6H_{12}O_6(s) + 6\ O_2(g) \rightarrow 6\ CO_2(g) + 6\ H_2O(l)$$

also releases energy, an event that increases the entropy of the universe, and is therefore spontaneous. Thus, the processes of life increase the entropy of the universe by converting chemical energy into energy (heat) that flows into the surroundings.

As a result, the free-energy change for the breakdown of glucose must be less than zero—it is actually $\Delta G^\circ = -880$ kJ/mol. This spontaneous process is highly controlled in living systems, however, so that the energy it produces can be directed into the nonspontaneous processes essential to organisms that do not carry out photosynthesis. **Figure 17.20** summarizes one portion of glucose metabolism—glycolysis—that involves coupled reactions.

CONNECTION Photosynthesis and the carbon cycle were introduced in Section 3.5 (see Figure 3.21).

In glycolysis, each mole of glucose is converted into 2 moles of pyruvate ion (CH_3COCOO^-). An early step is the conversion of glucose into glucose-6- phosphate (**Figure 17.21**), an example of a phosphorylation reaction. Glucose reacts with the hydrogen phosphate ion (HPO_4^{2-}), producing glucose-6-phosphate and water. This reaction is not spontaneous ($\Delta G^\circ = +13.8$ kJ/mol), and the energy needed to make it happen comes from adenosine triphosphate (ATP), which functions in our cells both as a storehouse of energy and as an energy-transfer agent. ATP hydrolyzes to adenosine diphosphate (ADP) in a reaction (**Figure 17.22**) that produces a hydrogen phosphate ion and energy: $\Delta G^\circ_{rxn} = -30.5$ kJ/mol. As can be seen in Figure 17.22, both ATP and ADP are ions, and as such their formulas are written as ATP^{4-} and ADP^{3-}, respectively, when used in chemical equations.

In a living system, spontaneous hydrolysis of ATP consumes water and produces HPO_4^{2-} and H^+, whereas the nonspontaneous phosphorylation of glucose consumes HPO_4^{2-} and produces water. The two reactions are coupled so that the spontaneous ATP → ADP reaction supplies the energy that drives the nonspontaneous formation of glucose-6-phosphate (**Figure 17.23**).

This example demonstrates that the ΔG° values for coupled reactions (and for sequential reactions) are additive. This is true for any set of reactions, not just those occurring in living systems.

The first two steps in glycolysis are

CONNECTION Hess's law (i.e., the enthalpy change of a reaction that is the sum of two or more reactions equals the sum of the enthalpy changes of the constituent reactions) was introduced in Section 6.7 to calculate ΔH. We apply a similar principle here when adding ΔG° values of coupled reactions.

If we add these reactions and their free energies, we get

Because equal quantities of H_2O and HPO_4^{2-} appear on both sides of the combined equation, they cancel out, leaving the following net reaction:

Because ΔG° for the net reaction is negative, the reaction is spontaneous.

SAMPLE EXERCISE 17.10 Calculating ΔG° of Coupled Reactions LO8

The body would rapidly run out of ATP if there were not some process for regenerating ATP from ADP. That process is the hydrolysis of 1,3-diphosphoglycerate^{4-} (1,3-DPG^{4-}) to 3-phosphoglycerate^{3-} (3-PG^{3-}; **Figure 17.24**):

$$\text{ADP}^{3-} + \text{1,3-diphosphoglycerate}^{4-} \rightarrow \text{3-phosphoglycerate}^{3-} + \text{ATP}^{4-}$$

This hydrolysis is spontaneous. Calculate its ΔG° value from the following values:

Collect and Organize We can calculate ΔG° for a reaction that is the sum of two reactions. If the reactions in equations 1 and 2 add up to the overall reaction, then the overall ΔG° is the sum of the ΔG° values for the individual reactions.

Analyze First we add the reactions described by equations 1 and 2. Assuming that the overall reaction between ADP and 1,3-diphosphoglycerate^{4-} is the sum of the reactions describing the hydrolysis of 1,3-diphosphoglycerate^{4-} and the phosphorylation of ADP, we know that the sum of ΔG°_1 and ΔG°_2 will be less than zero because the overall reaction is spontaneous.

Solve We add the reactions in equations 1 and 2 and confirm that they equal the overall reaction:

We then sum the ΔG° values for steps 1 and 2 to determine ΔG° for the overall reaction:

$$\Delta G^\circ_{\text{overall}} = \Delta G^\circ_1 + \Delta G^\circ_2 = [(-49.0) + (30.5)]\ \text{kJ} = -18.5\ \text{kJ}$$

Think About It The hydrolysis of 1,3-diphosphoglycerate^{4-} provides more than sufficient energy, $G^\circ_{\text{overall}} < 0$, for the conversion of ADP into ATP to be spontaneous.

Practice Exercise The conversion of glucose into lactic acid drives the phosphorylation of 2 moles of ADP to ATP:

What is ΔG° for the conversion of glucose into lactic acid?

$C_6H_{12}O_6(aq) \rightarrow 2\ CH_3CH(OH)COOH(aq)$

The ATP produced from the breakdown of glucose (such as that formed via the first reaction in the preceding practice exercise) is used to drive nonspontaneous reactions in cells. The metabolism of fats and proteins relies on a series of cycles, all of which involve coupled reactions. The ATP–ADP system is a carrier of chemical energy because ADP requires energy to accept a phosphate group and thus is coupled to reactions that yield energy, whereas ATP donates a phosphate group, releases energy, and is coupled to reactions that require energy. All energy changes in living systems are governed by the first and second laws of thermodynamics, as are all the energy changes in the inanimate world.

Glossary

glycolysis

a series of reactions that converts glucose into pyruvate; a major anaerobic (no oxygen required) pathway for the metabolism of glucose in the cells of almost all living organisms.

phosphorylation
: a reaction resulting in the addition of a phosphate group to an organic molecule.

17.10 Microstates: A Quantized View of Entropy

In Chapter 17 we have described entropy as a measure of how energy is distributed throughout a system: the more spread out the energy is, the greater the system's entropy. This thermodynamic view evolved in the middle of the 19th century, largely through the work of the German physicist Rudolf Clausius (1822–1888), who was a leader in establishing the field of thermodynamics and who introduced the concept of entropy in 1865.

Clausius's thermodynamic approach views entropy from a macroscopic, systemwide perspective. In much the same way as we use such parameters as pressure, volume, and temperature to describe a quantity of a gaseous substance, the change in a system's entropy is defined in terms of the quantity of energy flowing out from or into the system and its temperature (Equation 17.2). However, just as the kinetic molecular theory of gases provides a particle-based explanation of why gases exhibit the macroscopic properties they do, we can also understand entropy changes from the viewpoint of the dispersion of particles and their energies.

In 1877 an Austrian physicist named Ludwig Boltzmann (1844–1906) developed a microscopic view of Clausius's concept of entropy. His theory would eventually incorporate quantum mechanics to explain how energy was dispersed not only throughout a system but also within its molecules. Let's examine Boltzmann's microscopic definition of entropy by using two models: a single molecule of O_2 and a room full of them.

As shown in **Figure 17.25**, a molecule of a gas such as O_2 is free to undergo three types of motion: (1) *translational motion* as it zips around the space it occupies; (2) *rotational motion* as it spins about imaginary axes perpendicular to the O□O bond; and (3) *vibrational motion* as its bonded atoms move toward and away from each other, like balls on the ends of a spring. Each of these modes of motion increases as the thermal energy of the molecule increases.

In our discussion of quantum mechanics in Chapter 7, we saw that energy is not continuous on the atomic scale. Instead, the energies and motion of atoms and molecules are quantized. At temperatures near room temperature, the differences between the translational energy levels of atoms and molecules in the gas phase are so small that we may consider them a continuum of energy. However, the gaps in vibrational and rotational energy levels are large enough that we must take quantization into account.

To investigate these gaps, let's revisit the change in electrostatic potential energy that occurs when two oxygen atoms approach each other and a covalent bond forms between them (see Figure 8.2). Energy reaches a minimum (**Figure 17.26a**) when the nuclei of the two atoms are 121 pm apart—a distance that corresponds to the length of the O□O bond. Figure 17.26a also contains additional energy levels represented by horizontal red lines. These are vibrational energy levels. Notice that the length of the red lines increases as the vibrational energy increases. Greater length corresponds to greater variation in intermolecular distance; that is, more energetic oscillations of the O□O bond occur with increasing vibrational energy.

Superimposed on each vibrational energy level is a set of rotational energy levels, shown for the first vibrational energy level in **Figure 17.26b**. Similar sets of rotational energy levels are associated with all the other vibrational energy levels, creating a multitude of energy states that are accessible to every O_2 molecule at room temperature.

Now let's focus on one oxygen molecule as it collides with others, sometimes gaining and other times losing translational kinetic energy. At room temperature and pressure, a single O_2 molecule experiences billions of collisions per second, each collision altering its speed and changing its vibrational and rotational energies. At any instant, the overall quantized energy of the molecule is a particular combination of translational, vibrational, and rotational energy states. The number of possible combinations of energy states accessible to an O_2 molecule is enormous at room temperature, and the number increases as temperature increases.

In a room full of O_2 molecules (our second model), the number of different quantized total-molecule energy states is so large (e raised to a power that is many times Avogadro's number) that it is beyond the capacity of your calculator to compute. The entirety of all the quantized energy states occupied by all the atoms in the room at a particular instant is called a microstate. Each microstate represents one discrete way for the system to disperse all the energy in the system. The vast number of microstates to which a system has access defines its entropy: the more microstates, the higher its entropy. This correlation between the number of accessible microstates (W) and entropy (S) is defined by a simple mathematical equation developed by Boltzmann:

Here k_B is the Boltzmann constant, which is equal to the gas constant divided by Avogadro's number:

Boltzmann's definition of entropy, based on access to energy microstates, is conceptually compatible with the thermodynamic, macroscopic view based on energy dispersion because each microstate represents one of the multitude of ways that energy can be dispersed in a thermodynamic system. In fact, some facets of entropy are easier to understand using the microstate model. One of them is the concept of absolute entropy, the notion embedded in the third law of thermodynamics that a perfect crystalline solid has zero entropy at a temperature of absolute zero. If the particles of a crystalline solid are perfectly aligned at 0 K, only one distribution of the particles is possible in the space occupied by the crystal. Therefore, the crystal has only one microstate, and, according to Equation 17.21, its entropy is zero:

$$S = k_B (\ln W) = k_B (\ln 1) = 0$$

In Chapter 17 we have addressed the reasons why some reactions and processes are spontaneous, whereas others are not. We have seen that the value of free-energy change (ΔG) determines the spontaneity of a chemical reaction or process. Together, enthalpy and entropy changes for chemical reactions allow us to determine the ΔG for a chemical reaction or process. The free-energy change represents the maximum amount of work that can be done by the energy associated with a change. For changes carried out in the real world, the maximum amount of work is always less than ΔG.

CONCEPT TEST

Predict which of the following values comes closest to the number of microstates accessible to 1 mole of liquid water molecules at 25°C: (a) 1; (b) 10^2; (c) 10^{10}; (d) 10^{23}; (e) $> .10^{23}$. Use the appropriate $S°$ value in Appendix 4 and Equation 17.21 to determine whether your selection was the best one.

SAMPLE EXERCISE 17.11 Integrating Concepts: Ötzi's Axe and the Chemistry of Copper Refining

In 1991 two hikers discovered the remains of a prehistoric man frozen in a glacier high in the Ötztal Alps, near the Italy–Austria border. Ötzi the Iceman, as he came to be known, lived about 5300 years ago. Among his possessions was an axe with a head made of nearly pure (99.7%) copper (**Figure 17.27**). The purity of the copper, as well as other clues, told scientists that the copper had been skillfully extracted and refined. Though copper does occur in its native elemental state in Earth's crust, ancient artisans usually had to extract the metal from copper-containing minerals such as chalcocite (Cu_2S). The process required that they find a way to add a lot of energy to a sulfide mineral like Cu_2S because its decomposition reaction has a large, positive ΔG° value:

However, when Cu_2S is roasted in a furnace that provides an ample supply of very hot air, any sulfur produced by the decomposition reaction is then oxidized to SO_2 gas in a decidedly spontaneous reaction:

1. Can these two reactions be coupled so that the spontaneous second reaction drives the nonspontaneous first reaction?
2. Is there likely to be an increase in entropy during the overall reaction?
3. What is the equilibrium constant of the first reaction under standard conditions?
4. Does the value of the equilibrium constant, K_P, for the overall reaction change if we carry out the reaction in two sealed vessels, one with twice the volume of the other?

Collect and Organize We are given two chemical reactions and asked to determine whether the free energy released by the spontaneous one can be coupled to and drive the nonspontaneous reaction. We also need to calculate the equilibrium constant of the nonspontaneous reaction and to decide how reaction conditions shift the equilibrium state. Equation 17.17 relates the equilibrium constant of a chemical reaction to its $\Delta G^\circ_{\text{rxn}}$ value.

Analyze Sulfur is a product of the first reaction and a reactant in the second one, so it should be possible to couple the two reactions. Given the large positive value of $\Delta G^\circ_{\text{rxn}}$ for the first reaction, its K value should be much less than 1. An effect of volume on an equilibrium constant, K_P, is observed if there are different numbers of moles of gas on either side of the chemical equation.

Solve

1. One mole of sulfur is produced in the first reaction and consumed in the second, so the two reactions can be coupled. The result is an overall reaction with a $\Delta G^\circ_{\text{rxn}}$ value that is the sum of the first two:

$$\begin{array}{lr}
\quad Cu_2S(s) \rightarrow 2\,Cu(s) + \cancel{\tfrac{1}{8}\,S_8(s)} & \Delta G^\circ_{\text{rxn}} = 86.2\text{ kJ} \\
+\cancel{\tfrac{1}{8}\,S_8(s)} + O_2(g) \rightarrow SO_2(g) & \Delta G^\circ_{\text{rxn}} = -300.1\text{ kJ} \\
\hline
Cu_2S(s) + O_2(g) \rightarrow 2\,Cu(s) + SO_2(g) & \Delta G^\circ_{\text{rxn}} = -213.9\text{ kJ}
\end{array}$$

The calculated negative $\Delta G^\circ_{\text{rxn}}$ value means that the overall reaction is spontaneous.

2. The reactants and products both contain 1 mole of gas, but SO_2 is triatomic and has a larger standard molar entropy [248.2 J/(mol · K)] than that of diatomic O_2 [205.0 J/(mol · K)]. Also, the other reactant is 1 mole of a binary ionic solid, but the products include 2 moles of solid metal. Therefore, from the S° values in Appendix 4, we can safely predict that the system entropy increases in the overall reaction.
3. Using Equation 17.17 to calculate the equilibrium constant for the decomposition reaction under standard conditions (and letting $T = 298$ K) gives us:

$$K = e^{-\Delta G^\circ_{\text{rxn}}/RT}$$

First calculate the exponent:

$$-\frac{\Delta G^\circ_{\text{rxn}}}{RT} = -\frac{86.2\,\dfrac{\cancel{\text{kJ}}}{\cancel{\text{mol}}} \times 1000\,\dfrac{\cancel{\text{J}}}{\cancel{\text{kJ}}}}{\left(8.314\,\dfrac{\cancel{\text{J}}}{\cancel{\text{mol}}\cdot\cancel{\text{K}}}\right)(298\,\cancel{\text{K}})} = -34.79$$

Then the value of K is

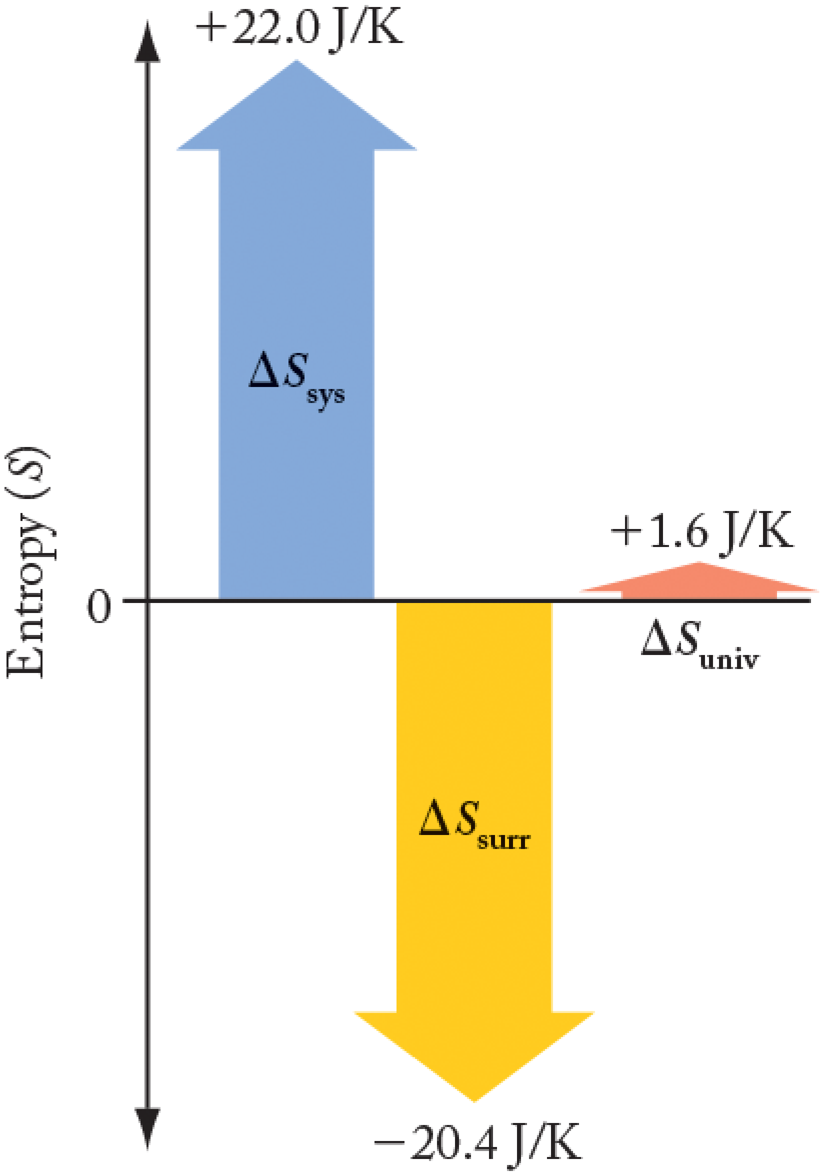
$$K = e^{-34.79} = 7.8 \times 10^{-16}$$

4. The chemical equation for the overall reaction has equal numbers of moles of gas on the reactant and product sides, which means that there will be no effect of volume changes on K_P.

Think About It As predicted, the nonspontaneous first reaction has a small K value; however, the reaction becomes spontaneous when coupled to the spontaneous second reaction. Le Châtelier's principle predicts that there will be no change in K_P if we change the volume, but here 1 mole of gaseous reactant is converted to 1 mole of a gas-phase product.

Glossary

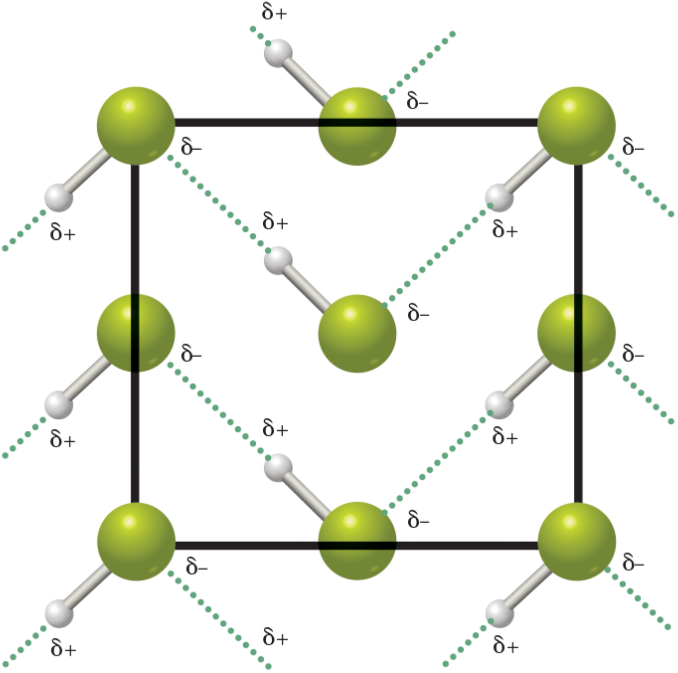
microstate	a unique distribution of particles among energy levels.



SUMMARY

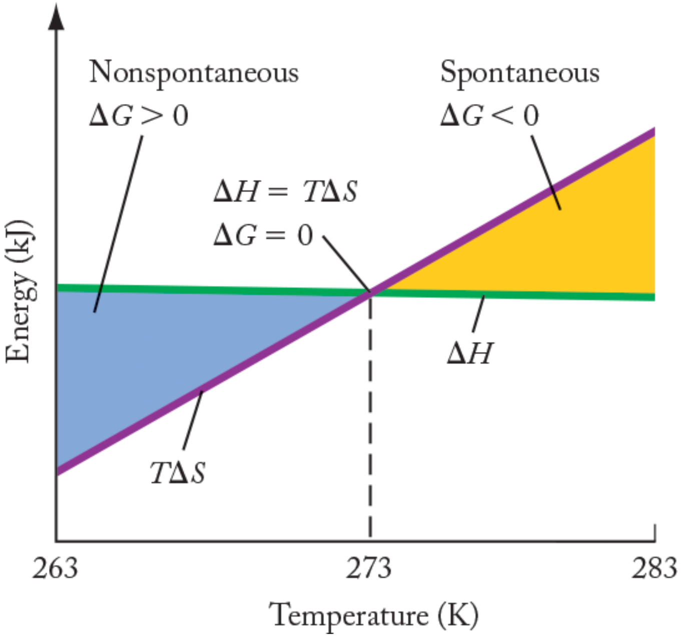
- LO1 Spontaneous processes happen on their own without continual outside intervention. Nonspontaneous processes, which are spontaneous processes in reverse, do *not* happen on their own. Spontaneous processes may be exothermic or endothermic and are often accompanied by an increase in the freedom of motion of the particles involved in the process. Spontaneous reactions are not necessarily rapid. (Section 17.1)

- LO2 According to the third law of thermodynamics, a perfect crystal of a pure substance has zero entropy at absolute zero. All substances have positive entropies at temperatures above absolute zero. Standard molar entropies ($S°$) are entropy values for substances in their standard states. The entropy of a system increases with increasing molecular complexity and with increasing temperature. (Section 17.3)

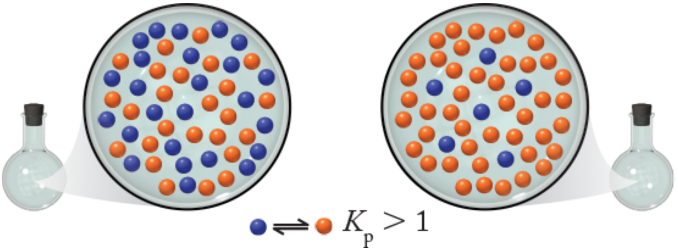


- LO3 Entropy (S) is a thermodynamic property that provides a measure of how dispersed the energy is in a system at a given temperature. According to the second law of thermodynamics, a spontaneous process is accompanied by an increase in the entropy of an isolated system, or an increase in entropy of the universe for a process occurring in any system. A reversible process takes place in very small steps and very slowly so that the system can be restored to its initial state with no net flow of energy to or from its surroundings. The entropy change in a reaction under standard conditions can be calculated from the standard entropies of the products and reactants and their coefficients in the balanced chemical equation. (Sections 17.2 and 17.4)

- LO4 Gibbs free energy (G) is the energy available to do useful work. The change in free energy of a process is a state function defining the maximum useful work the system can do on its surroundings. When a process results in a decrease in free energy of a system ($\Delta G < 0$), the process is spontaneous; when $\Delta G > 0$, the process is nonspontaneous. Reversing a process changes the sign of ΔG, and $\Delta G = 0$ for a process at equilibrium. The change in free energy of a reaction under standard conditions can be calculated either from the standard free energies of formation (ΔG°_f) of the products and reactants or from the enthalpy and entropy changes. (Section 17.5)



- LO5 The temperature range over which a process is spontaneous depends on the relative magnitudes of ΔH and ΔS. (Section 17.6)
- LO6 Negative values of ΔG° correspond to $K > 1$ and equilibrium reaction mixtures composed mostly of products. Positive values of ΔG° correspond to $K < 1$. As spontaneous reactions proceed, the free energy of the reaction mixture increases from an initial negative value and reaches zero when the reaction comes to chemical equilibrium. (Section 17.7)



- LO7 Higher reaction temperatures increase the equilibrium constant of an endothermic reaction but decrease the equilibrium constant of an exothermic reaction. The slope of a plot of ln K versus $1/T$ for an equilibrium system is used to determine the standard enthalpy for the equilibrium, and the y intercept of the plot is used to determine the standard entropy change. (Section 17.8)
- LO8 Many important biochemical processes, including glycolysis and phosphorylation, are made possible by coupled spontaneous and nonspontaneous reactions. The free energy released in the spontaneous processes going on in the body is used to drive nonspontaneous processes. (Section 17.9)
- LO9 As temperature increases, the translational motion, rotational motion, and vibrational motion of molecules increase. A microstate is defined as one discrete way for a system to disperse all its energy. As the number of microstates increases, so does the entropy of a system. (Section 17.10)

PARTICULATE PREVIEW WRAP-UP

Cu is a solid, Br_2 is a liquid, and He is a gas. The number of possible arrangements increases from the copper atoms (with the fewest) to the bromine molecules to the helium atoms (with the most). Br_2 molecules in the liquid phase and Cu atoms in the solid phase have vibrational motion, whereas atoms of He(*g*) do not. Br_2 molecules also have rotational and translational motion (Cu atoms do not), so Br_2 molecules have more ways to disperse their energy than the atoms of the other two elements.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts and Equations	Sample Exercises
Predicting the sign of entropy change	[illegible] phases or precipitation of a solute from solution ($\Delta S < 0$ for both). For the reverse processes, $\Delta S > 0$.	17.1
Comparing absolute entropy values	[illegible] rigid molecules have more entropy. Among substances with similar molar masses, gases have more entropy than liquids, which have more entropy than solids.	17.2
Calculating entropy changes	Use $\Delta S^\circ_{rxn} = \sum n_{products} S^\circ_{products} - \sum n_{reactants} S^\circ_{reactants}$ (17.5) where $S^\circ_{products}$ and $S^\circ_{reactants}$ are the standard molar entropies and $n_{products}$ and $n_{reactants}$ are the stoichiometric coefficients for the process.	17.3
Predicting reaction spontaneity under standard conditions	Reaction is spontaneous if $\Delta S_{univ} = (\Delta S_{sys} + \Delta S_{surr}) > 0$	17.4
Calculating ΔG°_{rxn} by using appropriate ΔG°_f values	Use $\Delta G^\circ_{rxn} = \sum n_{products} \Delta G^\circ_{f,products} - \sum n_{reactants} \Delta G^\circ_{f,reactants}$ (17.12) where $\Delta G^\circ_{f,products}$ and $\Delta G^\circ_{f,reactants}$ are the standard molar free energies of formation, and $n_{products}$ and $n_{reactants}$ are the stoichiometric coefficients for the process.	17.5
Relating reaction spontaneity to ΔH and ΔS	Use $\Delta G^\circ_{rxn} = \Delta H^\circ_{rxn} - T\Delta S^\circ_{rxn}$ (17.11)	17.6, 17.7
Calculating the value of K from ΔG°_f values	$K = e^{-\Delta G^\circ_{rxn}/RT}$ (17.17)	17.8
Calculating the value of K at a specific temperature	Use $\ln\left(\frac{K_2}{K_1}\right) = -\frac{\Delta H^\circ_{rxn}}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$ (17.20) Convert ΔH°_{rxn} from kilojoules per mole to joules per mole to	17.10

match the units of R.

17.10 **Calculating $\Delta G°$ of coupled reactions**

Free-energy changes are additive If adding two reactions gives the desired overall reaction, add the free-energy changes of the two reactions to obtain the free-energy change of the overall reaction.

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

Two balloons are inflated at the same temperature to the same volume (Figure P17.1), though it takes more gas to inflate the balloon on the right. In which balloon is the gas under greater internal pressure? In which balloon does the gas have greater total entropy?

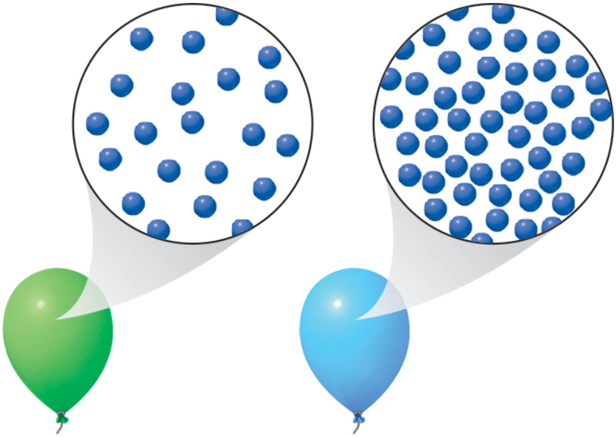


FIGURE P17.1

Two cubic containers (Figure P17.2) contain the same number of moles of gas at the same temperature. Which cube contains gas with more entropy? If the sample in container (b) is left unchanged but the sample in container (a) is cooled so that it condenses, which sample has the higher entropy?

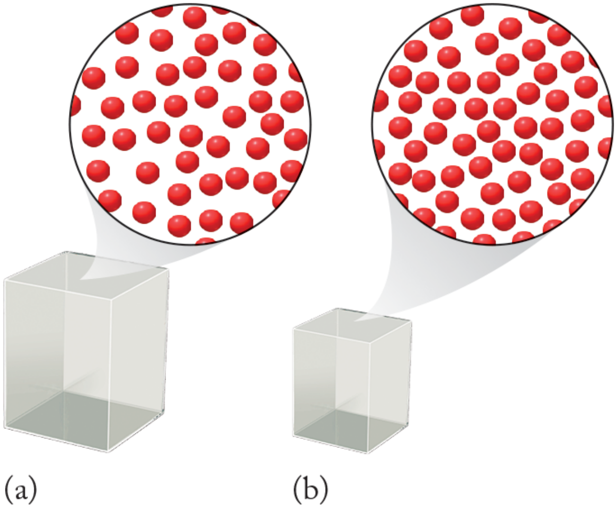

FIGURE
P17.2

Figure P17.3 shows a tank that has just been filled with a mixture of two ideal gases: A (red spheres) and B (blue spheres). If the molar mass of A is twice that of B, will the atoms of A eventually fill the bottom of the tank and the atoms of B fill the top of the tank? Why or why not? Does the tank represent an isolated system?

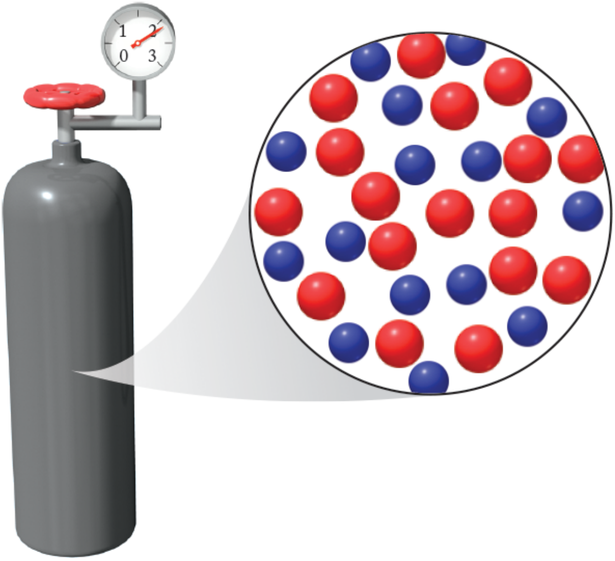

FIGURE P17.3

Predict whether an increase or decrease in entropy accompanies the physical change in Figure P17.4 when it occurs at constant temperature.

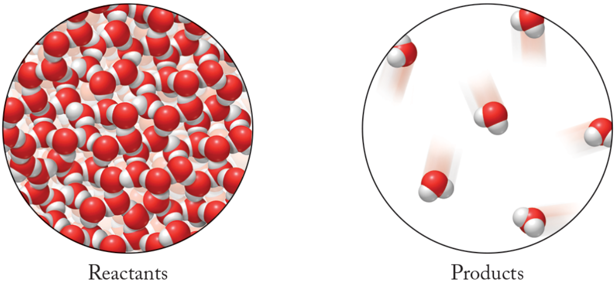

FIGURE P17.4

Predict whether an increase or decrease in entropy accompanies the chemical change in Figure P17.5 when it occurs at constant temperature.

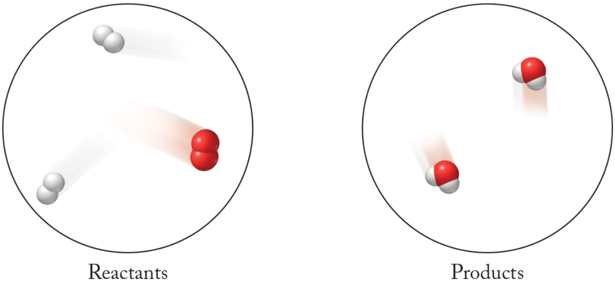

FIGURE P17.5

Does the chemical reaction in Figure P17.6 result in an increase or decrease in the entropy of the system? Assume the reactants and products are at the same temperature.

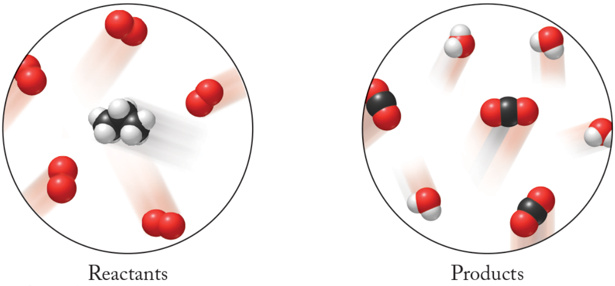

FIGURE P17.6

Does the entropy increase or decrease in the reaction in Figure P17.7 between hydrazine (N_2H_4) and dinitrogen tetroxide (N_2O_4) to yield a mixture of nitrogen and water?

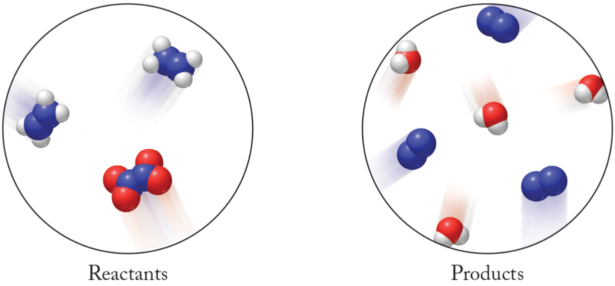

FIGURE P17.7

The box on the left of Figure P17.8 represents a mixture of two diatomic gases: A_2 (red spheres) and B_2 (blue spheres). As a result of the process depicted by the arrow, how do the entropies of A_2 and B_2 change?

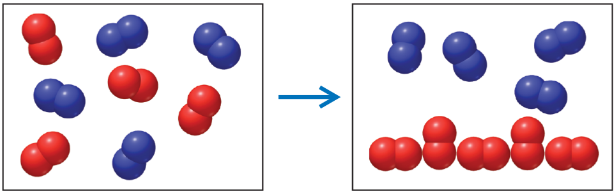

FIGURE P17.8

Is the process in Figure P17.8 more likely to be spontaneous at high temperature or low temperature, or is it unaffected by changing temperature?

Figure P17.10 shows the plots of ΔH and $T\Delta S$ for a phase change as a function of temperature.

1. What is the status of the process at the point where the two lines intersect?
2. Over what temperature range is the process spontaneous?

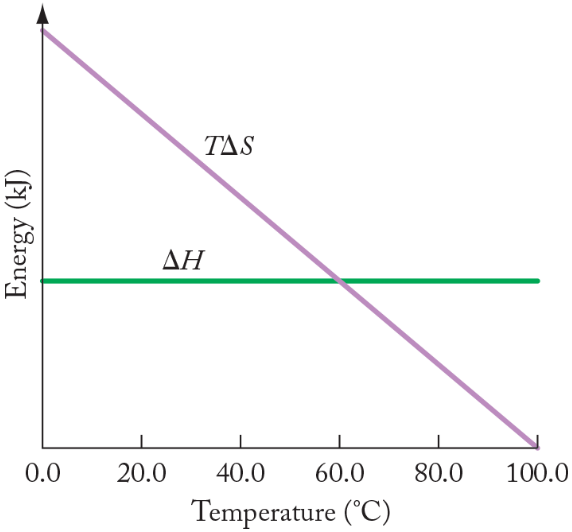

FIGURE P17.10

Figure P17.11 presents the ΔG°_f values of several elements and compounds selected from Appendix 4. Which of the following conversions are spontaneous? (a) $C_6H_6(\ell)$ to $CO_2(g)$ and $H_2O(\ell)$; (b) $CO_2(g)$ to $C_2H_2(g)$; (c) $H_2(g)$ and $O_2(g)$ to $H_2O(\ell)$. Explain your reasoning. *Hint*: Begin by writing a balanced equation describing the conversion. Add other substances as needed to complete the equation.

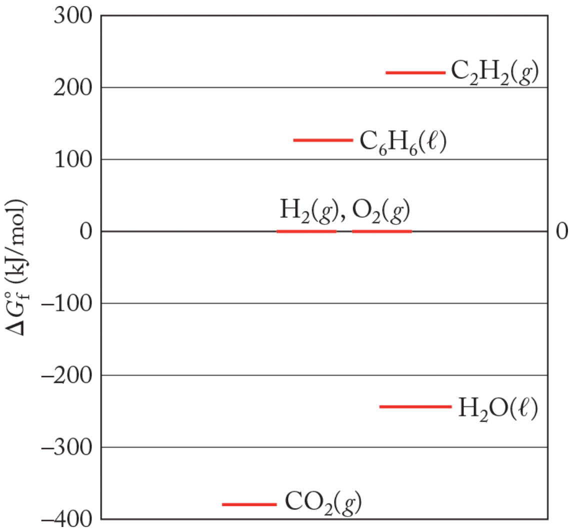

FIGURE P17.11

The three balloons in Figure P17.12 contain the same number of particles at the same temperature. Rank the balloons in order of increasing number of microstates accessible to the particles inside them.

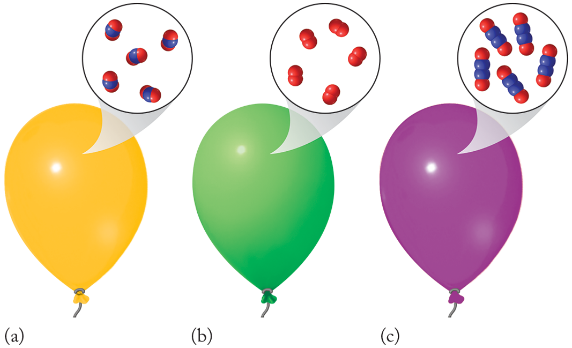

FIGURE P17.12

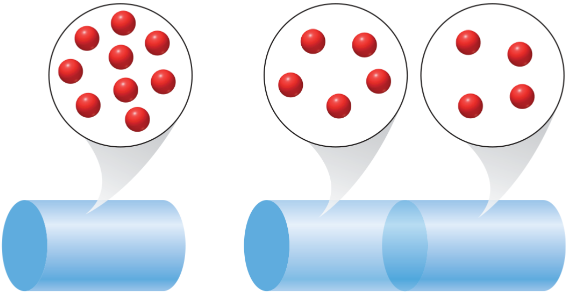
Figure P17.13a shows a cylinder within a cylinder that contains a population of gaseous molecules. The volume occupied by the molecules can be increased by pulling the inside cylinder out (Figure P17.13b), much like a telescope. The number of molecules within the cylinder remains the same during this operation. Compare the number of microstates available to the molecules in Figure P17.13a and b.



(a) (b)

FIGURE P17.13

Use representations [A] through [I] in Figure P17.14 to answer questions (a)–(f).

1. What is the sign of ΔS for image [F]?
2. The slime in image [H] is a cross-linked polymer of polyvinyl alcohol and borax. What is the sign of ΔS for the formation of slime?
3. What is the sign of ΔS for the sublimation of dry ice in image [B]? Under what conditions would this process *not* be spontaneous?
4. If you mix the particulate substances in [A] and [C] to create image [E], does the entropy increase, decrease, or remain unchanged? When you mix the particulate substances in [G] and [I] to create image [E], how does the change in volume affect the entropy?
5. Image [D] shows a shaken bottle of oil and water. After some time passes, what will happen to the oil and water? Will this process be spontaneous? Will the entropy increase or decrease?

6. Does all mixing lead to an increase in entropy of the system?

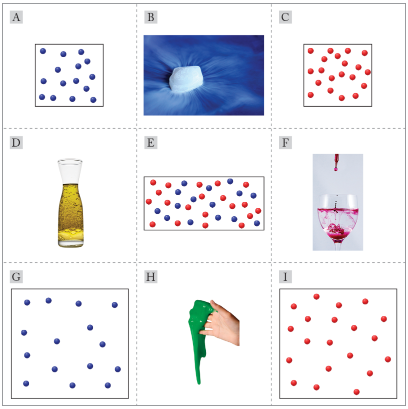


FIGURE P17.14

QUESTIONS AND PROBLEMS

Spontaneous Processes; Entropy and the Second Law of Thermodynamics

Concept Review

How is the entropy change that accompanies a reaction related to the entropy change that happens when the reaction runs in reverse?

Identify the following systems as isolated or not isolated, identify the processes as spontaneous or nonspontaneous, and explain your choice.

1. A photovoltaic cell in a solar panel produces electricity.
2. Helium gas escapes from a latex party balloon.
3. A sample of pitchblende (uranium ore) emits alpha particles.

Ice cubes melt in a glass of lemonade, cooling the lemonade from 10.0°C to 0.0°C. If the ice cubes are the system, what are the signs of ΔS_{sys} and ΔS_{surr}?

Adding sidewalk deicer (calcium chloride) to water lowers the freezing point of the water. If solid $CaCl_2$ is the system, what are the signs of ΔS_{sys} and ΔS_{surr}?

Problems

Which of the following combinations of entropy changes for a process are mathematically possible?

1. $\Delta S_{\text{sys}} > 0$, $\Delta S_{\text{surr}} > 0$, $\Delta S_{\text{univ}} > 0$
2. $\Delta S_{\text{sys}} > 0$, $\Delta S_{\text{surr}} < 0$, $\Delta S_{\text{univ}} > 0$
3. $\Delta S_{\text{sys}} > 0$, $\Delta S_{\text{surr}} > 0$, $\Delta S_{\text{univ}} < 0$

Which of the following combinations of entropy changes for a process are mathematically possible?

1. $\Delta S_{\text{sys}} < 0$, $\Delta S_{\text{surr}} > 0$, $\Delta S_{\text{univ}} > 0$
2. $\Delta S_{\text{sys}} < 0$, $\Delta S_{\text{surr}} < 0$, $\Delta S_{\text{univ}} > 0$
3. $\Delta S_{\text{sys}} < 0$, $\Delta S_{\text{surr}} > 0$, $\Delta S_{\text{univ}} < 0$

What are the signs of ΔS_{sys} and ΔS_{univ} for the photosynthesis of glucose from carbon dioxide and water?

What are the signs of ΔS_{sys}, ΔS_{surr}, and ΔS_{univ} for the complete combustion of propane in which the products include water vapor and carbon dioxide?

The nonspontaneous reaction $D + E \rightarrow F$ decreases the system entropy by 66.0 J/K. What is the maximum value of the entropy change of the surroundings?

The spontaneous reaction $A \rightarrow B + C$ increases the system entropy by 72.0 J/K. What is the minimum value of the entropy change of the surroundings?

For the following reactions, indicate whether the entropy of the system increases, decreases, or remains nearly the same.

1. $Al^{3+}(aq) + 3\ OH^{-}(aq) \rightarrow Al(OH)_3(s)$
2. $CaCO_3(s) \rightarrow CaO(s) + CO_2(g)$
3. $Mg(s) + Cu^{2+}(aq) \rightarrow Mg^{2+}(aq) + Cu(s)$

Which of the following processes would *not* result in an entropy increase for the indicated system?

1. Melting of an ice cube
2. Evaporation of a sample of an alcohol
3. Sublimation of a mothball
4. Cooling of hot water to room temperature

Absolute Entropy and the Third Law of Thermodynamics

Concept Review

Which component in each of the following pairs has the greater entropy?

1. 1 mole of $S_2(g)$ or 1 mole of $S_8(g)$
2. 1 mole of $S_2(g)$ or 1 mole of $S_8(s)$
3. 1 mole of $O_2(g)$ or 1 mole of $O_3(g)$
4. 1 gram of $O_2(g)$ or 1 gram of $O_3(g)$

Digestion During digestion, complex carbohydrates decompose into simple sugars. Do the carbohydrates experience an increase or decrease in entropy?

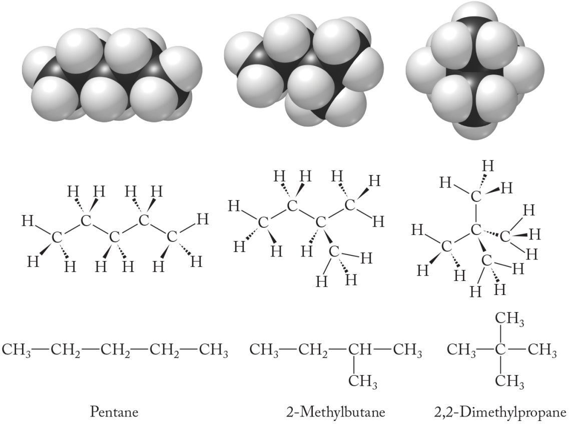
Diamond and the fullerenes are two allotropes of carbon. On the basis of their different structures and properties, predict which has the higher standard molar entropy.

Superfluids The 1996 Nobel Prize in Physics was awarded to Douglas Osheroff, Robert Richardson, and David Lee for discovering *superfluidity* (apparently frictionless flow) in ^{3}He. When ^{3}He is cooled to 2.7 mK, the liquid settles into an *ordered* superfluid state. What is the predicted sign of the entropy change for the conversion of liquid ^{3}He into its superfluid state?

Rank the compounds in each of the following groups in order of increasing standard molar entropy ($S°$):

1. $CH_4(g)$, $CF_4(g)$, and $CCl_4(g)$
2. $CH_2O(g)$, $CH_3CHO(g)$, and $CH_3CH_2CHO(g)$
3. $HF(g)$, $H_2O(g)$, and $NH_3(g)$

The hydrocarbon C_5H_{12} has three isomers, shown in Figure P17.32. Which isomer has the largest molar entropy, $S°$?



CH₃—CH₂—CH₂—CH₂—CH₃
CH₃—CH₂—CH—CH₃ CH₃
CH₃—C(CH₃)₂—CH₃
Pentane
2-Methylbutane
2,2-Dimethylpropane

FIGURE P17.32

Calculating Entropy Changes

Concept Review

Under standard conditions, the products of a reaction have, overall, greater entropy than the reactants. What is the sign of $\Delta S°_{rxn}$?

Do polymerization reactions tend to have $\Delta S^\circ_{\text{rxn}}$ values that are greater than zero or less than zero? Why?

Do precipitation reactions tend to have $\Delta S^\circ_{\text{rxn}}$ values that are greater than zero or less than zero? Why?

Suppose compound A(*s*) decomposes to substances B(*ℓ*) and C(*ℓ*) at moderately high temperatures. How would running the decomposition reaction at even higher temperatures (above the melting point of A, but still below the boiling points of B and C) affect the value of $\Delta S^\circ_{\text{rxn}}$?

Problems

Smog Use the standard molar entropies in Appendix 4 to calculate ΔS° values for each of the following atmospheric reactions that contribute to the formation of photochemical smog.

1. $N_2(g) + O_2(g) \rightarrow 2\ NO(g)$
2. $2\ NO(g) + O_2(g) \rightarrow 2\ NO_2(g)$
3. $NO(g) + \frac{1}{2}O_2(g) \rightarrow NO_2(g)$
4. $2\ NO_2(g) \rightarrow N_2O_4(g)$

Use the standard molar entropies in Appendix 4 to calculate the ΔS° value for each of the following reactions.

1. $CH_4(g) + N_2(g) \rightarrow HCN(g) + NH_3(g)$
2. $Cu_2S(s) + O_2(g) \rightarrow 2\ Cu(s) + SO_2(g)$
3. $SO_3(g) + H_2O(\ell) \rightarrow H_2SO_4(aq)$
4. $S(g) + O_2(g) \rightarrow SO_2(g)$

What is the entropy change to the surroundings when a small decorative ice sculpture at a temperature of 0°C and weighing 456 g melts on a granite tabletop, if the temperature of the granite is 12°C and the process occurs reversibly? Assume a final temperature for the water of

0°C. The enthalpy of fusion of ice is 6.01 kJ/mol.

Another decorative “ice” sculpture is carved from dry ice (solid CO_2) and held at its sublimation point of -78.5°C. What is the entropy change to the universe when the CO_2 sculpture, weighing 389 g, sublimes on a granite tabletop if the temperature of the granite is 12°C and the process occurs reversibly? Assume a final temperature for the CO_2 vapor of -78.5°C. The enthalpy of sublimation of CO_2 is 26.1 kJ/mol.

Free Energy

Concept Review

What single criterion allows us to determine whether a process is spontaneous at constant temperature and pressure?

1. The sign of the equilibrium constant, K
2. The sign of the enthalpy change, ΔH
3. The sign of the free-energy change, ΔG
4. The sign of the entropy change, ΔS

If ΔG for a reaction is negative, then which of the following is true?

1. The reaction is spontaneous in the forward direction as written.
2. The reaction system is at equilibrium.
3. The reverse of the given reaction is spontaneous.
4. No reaction would ever have a negative ΔG.

Many 19th-century scientists believed that all exothermic reactions were spontaneous. Why did so many scientists share this belief?

In which direction does a reaction proceed when its ΔG value is (a) less than zero; (b) equal to zero; (c) greater than zero?

What are the signs of ΔS, ΔH, and ΔG for the sublimation of dry ice (solid CO_2) at 25°C?

What are the signs of ΔS, ΔH, and ΔG for the formation of dew on a cool night?

Which of the following processes is/are spontaneous? (a) a hurricane forms; (b) a corpse decomposes; (c) you get an A in this course; (d) ice cream melts on a hot summer day

Which of the following processes is/are spontaneous? (a) wood burns in air; (b) water vapor condenses on the sides of a glass of iced tea; (c) salt dissolves in water; (d) photosynthesis

Problems

Calculate the free-energy change for the dissolution in water of 1 mole of NaBr and 1 mole of NaI at 298 K from the values in the following table.

	ΔH°_{soln} (kJ/mol)	ΔS°_{soln} [J/(mol·K)]
NaBr	−0.86	57
NaI	−7.5	74

The values of ΔH°_{rxn} and ΔS°_{rxn} for the reaction

$$2\ NO(g) + O_2(g) \rightarrow 2\ NO_2(g)$$

are − 12 kJ and − 146 J/K, respectively. (a) Use these values to calculate ΔG°_{rxn} at 298 K. (b) Explain why the value of ΔG°_{rxn} is negative.

A mixture of $CO(g)$ and $H_2(g)$ is produced by passing steam over hot charcoal:

$$H_2O(g) + C(s) \rightarrow H_2(g) + CO(g)$$

Calculate the ΔG°_{rxn} value for the reaction from the appropriate ΔG°_f data in Appendix 4.

Using appropriate data from Appendix 4, calculate ΔG° for the following reaction:

$N_2O_3(g) \rightarrow NO(g) + NO_2(g)$

Determine the value of ΔG° for the reduction of iron ore with hydrogen gas:

$Fe_2O_3(s) + 3\ H_2(g) \rightarrow 2\ Fe(s) + 3\ H_2O(g)$

given the following thermodynamic properties at 25°C:

[illegible] (s)				
[illegible] (kJ/mol)				
[illegible] (mol · K)]				

Determine the value of ΔG° for the reaction of the fuel gas acetylene with hydrogen gas:

$C_2H_2(g) + 2\ H_2(g) \rightarrow C_2H_6(g)$

given the following thermodynamic properties at 25°C:

[illegible] (g)			
[illegible] (kJ/mol)			
[illegible] (mol · K)]			

Acid Precipitation Aerosols (fine droplets) of sulfuric acid form in the atmosphere as a result of the following reaction.

$SO_3(g) + H_2O(g) \rightarrow H_2SO_4(\ell)$

Use the appropriate data from Appendix 4 to calculate ΔG° for the combination reaction.

One source of sulfuric acid aerosols in the atmosphere is combustion of high-sulfur fuels, which releases SO_2 gas that then is further oxidized to SO_3:

$2\ SO_2(g) + O_2(g) \rightarrow 2\ SO_3(g)$

Use the appropriate ΔG°_f data from Appendix 4 to calculate ΔG°_{rxn} for this combination reaction at 25°C. Is it spontaneous under standard conditions?

Temperature and Spontaneity

Concept Review

Are exothermic reactions spontaneous only at low temperature? Explain your answer.

Are endothermic reactions never spontaneous at low temperature? Explain your answer.

Would low temperature or high temperature cause a spontaneous reaction if ΔS is favorable but ΔH is unfavorable?

A reaction with $\Delta S > 0$ is spontaneous at high temperature. Under what conditions would it also be spontaneous at low temperature?

Problems

What is the lowest temperature at which the following reaction (see Problem 17.51) is spontaneous under standard conditions?

$$H_2O(g) + C(s) \rightarrow H_2(g) + CO(g)$$

Sulfur in Nature Deposits of elemental sulfur are often seen near active volcanoes. Their presence there may be due to the following reaction of SO_2 with H_2S:

$$SO_2(g) + 2\,H_2S(g) \rightarrow \tfrac{3}{8}\,S_8(s) + 2\,H_2O(g)$$

Assuming the values of ΔH°_{rxn} and ΔS°_{rxn} do not change appreciably with temperature, over what temperature range is the reaction spontaneous under standard conditions?

Use the data in Appendix 4 to calculate ΔH° and ΔS° for the vaporization of hydrogen peroxide:

$H_2O_2(\ell) \rightarrow H_2O_2(g)$

Assuming that the calculated values are independent of temperature, what is the boiling point of hydrogen peroxide at $P = 1.00$ atm?

Determine the normal melting point of carbon tetrachloride in degrees Celsius given the following data:

$\Delta H^\circ_{\text{fus}} = 2.67$ kJ/mol $\qquad \Delta S^\circ_{\text{fus}} = 10.86$ J/(mol · K)

Which of the following reactions is spontaneous (i) only at low temperatures; (ii) only at high temperatures; (iii) at all temperatures?

1. $2\ NO(g) + O_2(g) \rightarrow 2\ NO_2(g)$
2. $2\ NH_3(g) + 2\ O_2(g) \rightarrow N_2O(g) + 3\ H_2O(g)$
3. $NH_4NO_3(s) \rightarrow 2\ H_2O(g) + N_2O(g)$

Which of the following reactions is spontaneous (i) only at low temperatures; (ii) only at high temperatures; (iii) at all temperatures?

1. $2\ H_2S(g) + 3\ O_2(g) \rightarrow 2\ H_2O(g) + 2\ SO_2(g)$
2. $SO_2(g) + H_2O_2(\ell) \rightarrow H_2SO_4(\ell)$
3. $S(g) + O_2(g) \rightarrow SO_2(g)$

Free Energy and Chemical Equilibrium

Concept Review

If the value of K for a reaction is less than 1, what is the sign of $\Delta G^\circ_{\text{rxn}}$?

The equation $\Delta G^\circ = -RT \ln K$ relates the value of K_p, not K_c, to

ΔG° for gas-phase reactions. Explain why.

If a reaction mixture contains only reactants and no products, will the reaction proceed in the forward direction even if $\Delta G^\circ > 0$? Explain why or why not.

If a gas-phase reaction mixture contains 1 mole of each reactant and product and has a 1:1 stoichiometry, is the $\Delta G^\circ_{\text{rxn}}$ of the reaction mixture the same as $\Delta H^\circ_{\text{rxn}}$? Explain why or why not.

Problems

Which of the following reactions has the largest K_p value at 25°C?

1. $Cl_2(g) + F_2(g) \leftrightharpoons 2\ ClF(g)$ $\Delta G^\circ_{\text{rxn}} = 115.4$ kJ
2. $Cl_2(g) + Br_2(g) \leftrightharpoons 2\ ClBr(g)$ $\Delta G^\circ_{\text{rxn}} = -2.0$ kJ
3. $Cl_2(g) + I_2(g) \leftrightharpoons 2\ ICl(g)$ $\Delta G^\circ_{\text{rxn}} = -27.9$ kJ

Use the appropriate ΔG°_f value from Appendix 4 to calculate the value of K_p at 298 K for the reaction

$N_2(g) + 2\ O_2(g) \leftrightharpoons 2\ NO_2(g)$

Use the appropriate equilibrium constant from Appendix 5 to calculate the value of $\Delta G^\circ_{\text{rxn}}$ for the reaction

$NH_3(g) + H_2O(\ell) \leftrightharpoons NH_4^+(aq) + OH^-(aq)$

Use the appropriate equilibrium constant from Appendix 5 to calculate the value of $\Delta G^\circ_{\text{rxn}}$ for the reaction

$HClO(aq) + H_2O(\ell) \leftrightharpoons ClO^-(aq) + H_3O^+(aq)$

Influence of Temperature on Equilibrium Constants

Concept Review

The value of the equilibrium constant of a reaction decreases with increasing temperature. Is the reaction endothermic or exothermic?

The reaction

$2\ CO(g) + O_2(g) \leftrightharpoons 2\ CO_2(g)$

is exothermic. Does the value of K_p increase or decrease with increasing temperature?

The value of K_p for the water–gas shift reaction

$CO(g) + H_2O(g) \leftrightharpoons H_2(g) + CO_2(g)$

increases as the temperature decreases. Is the reaction exothermic or endothermic?

Does the value of K_p for the reaction

$CH_4(g) + H_2O(g) \leftrightharpoons 3\ H_2(g) + CO(g)\ \Delta H^\circ = 206\ \text{kJ}$

increase, decrease, or remain unchanged as temperature increases?

Problems

Air Pollution Automobiles and trucks pollute the air with NO. At 2000°C, the value of K_c for the reaction

$N_2(g) + O_2(g) \leftrightharpoons 2\ NO(g)$

is 4.10×10^{-4} and $\Delta H^\circ = 180.6$ kJ. What is the value of K_c at 25°C?

At 400 K the value of K_p for the reaction

$N_2(g) + 3\ H_2(g) \leftrightharpoons 2\ NH_3(g)$

is 41 and $\Delta H^\circ = -92.2$ kJ. What is the value of K_p at 700 K?

The equilibrium constant for the reaction

$NO(g) + O_2(g) \leftrightharpoons 2\ NO_2(g)$

decreases from 1.5×10^5 at 430°C to 23 at 1000°C. From these data, calculate the value of $\Delta H°$ for the reaction.

The value of K_c for the reaction A ⇆ B is 0.455 at 50°C and 0.655 at 100°C. Calculate $\Delta H°$ for the reaction.

Driving the Human Engine: Coupled Reactions

Concept Review

Describe the ways in which two chemical reactions must complement each other so that the decrease in free energy of the spontaneous reaction can drive the nonspontaneous reaction.

Why is it important that at least some of the spontaneous steps in glycolysis convert ADP to ATP?

The second step in glycolysis converts glucose-6-phosphate into fructose-6-phosphate (Figure P17.85). Suggest a reason why $\Delta G°$ for this reaction is close to zero.

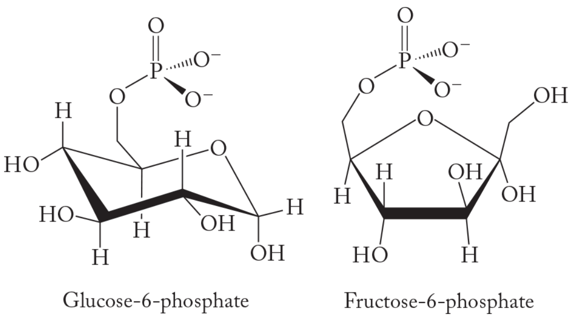


FIGURE P17.85

Problems

Uses of Methane The methane in natural gas is an important starting material, or feedstock, for producing industrial chemicals, including H_2 gas.

1. Use the appropriate ΔG°_f value(s) from Appendix 4 to calculate ΔG°_{rxn} for the reaction known as *steam–methane reforming*:

   $$CH_4(g) + H_2O(g) \rightarrow CO(g) + 3\ H_2(g)$$

2. To drive this nonspontaneous reaction, the CO that is produced can be oxidized to CO_2 by using more steam:

   $$CO(g) + H_2O(g) \rightarrow CO_2(g) + H_2(g)$$

   Use the appropriate ΔG°_f value(s) from Appendix 4 to calculate ΔG°_{rxn} for this reaction, which is known as the *water–gas shift reaction*.

3. Combine these two reactions and write the chemical equation of the overall reaction in which methane and steam combine to produce hydrogen gas and carbon dioxide.
4. Calculate the ΔG°_{rxn} value of the overall reaction. Is it spontaneous under standard conditions?

In addition to its role in the reactions described in Problem 17.86, methane can, in theory, be used to produce hydrogen gas by a process in which it decomposes into elemental carbon and hydrogen:

$$CH_4(g) \rightarrow C(s) + 2\ H_2(g)$$

The carbon produced in the first step is then oxidized to CO_2:

$$C(s) + O_2(g) \rightarrow CO_2(g)$$

1. Calculate the ΔG°_{rxn} values of these two reactions.

2. Write a balanced chemical equation describing the overall reaction obtained by coupling the two reactions, and calculate its $\Delta G^\circ_{\text{rxn}}$ value. Is the coupled reaction spontaneous under standard conditions?

Which of the following steps in glycolysis has the largest equilibrium constant?

1. Fructose-1,6-diphosphate $\leftrightharpoons$ 2 glyceraldehyde-3-phosphate $\Delta G^\circ_{\text{rxn}} = 24\ \text{kJ}$
2. 3-Phosphoglycerate $\leftrightharpoons$ 2-phosphoglycerate $\Delta G^\circ_{\text{rxn}} = 4.4\ \text{kJ}$
3. 2-Phosphoglycerate $\leftrightharpoons$ phosphoenolpyruvate $\Delta G^\circ_{\text{rxn}} = 1.8\ \text{kJ}$

The value of ΔG° for the phosphorylation of glucose in glycolysis is 13.8 kJ/mol. What is the value of the equilibrium constant for the reaction at 298 K?

In glycolysis, the hydrolysis of ATP to ADP drives the phosphorylation of glucose:

glucose + $\text{ATP}^{4-} \leftrightharpoons \text{ADP}^{3-}$ + glucose-6-phosphate

$\Delta G^\circ_{\text{rxn}} = -17.7\ \text{kJ}$

What is the value of K_c for this reaction at 298 K?

Sucrose enters the series of reactions in glycolysis after the reaction in which it is hydrolyzed, forming glucose and fructose:

sucrose + $H_2O \leftrightharpoons$ glucose + fructose $K_c = 5.3 \times 10^{12}$ at 298 K

What is the value of $\Delta G^\circ_{\text{rxn}}$?

Microstates: A Quantized View of Entropy

Concept Review

You flip three coins, assigning the values $+1$ for heads and -1 for tails. Each outcome of the three flips constitutes a microstate. How many different microstates are possible from flipping the three coins? Which value or values for the sums in the microstates are most likely? (*Hint*: The sequence HHT $[+1\ +1\ -\ 1]$ is one possible outcome, or microstate. Note, however, that this outcome differs from THH $[-\ 1\ +1\ +1]$, even though the two sequences sum to the same value.)

Imagine you have four identical chairs to arrange on four steps leading up to a stage, one chair on each step. The chairs have numbers on their backs: 1, 2, 3, and 4. How many different microstates for the chairs are possible? (Notice that when viewed from the front, all the microstates look the same. Viewed from the back, you can identify the different microstates because you can distinguish the chairs by their numbers.)

Problems

Use the appropriate standard molar entropy value from Appendix 4 to calculate how many microstates are accessible to a single molecule of N_2 at 298 K.

Use the appropriate standard molar entropy value from Appendix 4 to calculate how many microstates are accessible to a single molecule of liquid H_2O at 298 K.

Additional Problems

Methanogenic bacteria convert aqueous acetic acid (CH_3COOH) into $CO_2(g)$ and $CH_4(g)$. (a) Is this process endothermic or exothermic under standard conditions? (b) Is the reaction spontaneous under standard conditions?

Chlorofluorocarbons (CFCs) are no longer used as refrigerants because they catalyze the decomposition of stratospheric ozone. Trichlorofluoromethane (CCl_3F) boils at 23.8°C, and its molar enthalpy of vaporization is 24.8 kJ/mol.

What is the molar entropy of vaporization of $CCl_3F(\ell)$?

Consider the precipitation reactions described by the following net ionic equations:

$Mg^{2+}(aq) + 2\ OH^-(aq) \rightarrow Mg(OH)_2(s)$

$Ag^+(aq) + Cl^-(aq) \rightarrow AgCl(s)$

1. Predict the sign of $\Delta S°_{rxn}$ for the reactions.
2. Using the appropriate values for $S°$ from Appendix 4, calculate $\Delta S°$ for these reactions.
3. Do your calculations support your predictions?

(a) Using the appropriate values for $S°$ from Appendix 4, calculate $\Delta S°$ for the reaction of $Na(s)$ and $Cl_2(g)$ to form $NaCl(s)$. (b) Explain why this reaction takes place given your answer to part (a).

At what temperature is the standard free-energy change for the following reaction equal to zero?

$NH_4Cl(s) \rightarrow NH_3(g) + HCl(g)$

Which of these processes result in an entropy decrease of the system?

1. Diluting hydrochloric acid with water
2. Boiling water
3. $2\ NO(g) + O_2(g) \rightarrow 2\ NO_2(g)$
4. Making ice cubes in the freezer

Calculate the standard free-energy change of the following reaction. Is it spontaneous?

$2\ NO(g) + 2\ H_2(g) \leftrightharpoons N_2(g) + 2\ H_2O(g)$

Estimate the standard free-energy change of the following reaction at 225°C:

$C_2H_4(g) + 3\ O_2(g) \rightarrow 2\ CO_2(g) + 2\ H_2O(g)$

Show that hydrogen cyanide (HCN) is a gas at 25°C by estimating its normal boiling point from the following data:

	ΔH°_f (kJ/mol)	S° [J/(mol·K)]
HCN(ℓ)	108.9	[illegible]
HCN(g)	135.1	[illegible]

Making Methanol The element hydrogen (H_2) is not abundant on Earth, but it is a useful reagent in, for example, the potential synthesis of the liquid fuel methanol from gaseous carbon monoxide:

$2\ H_2(g) + CO(g) \rightarrow CH_3OH(\ell)$

Under what temperature conditions is this reaction spontaneous?

Lightbulb Filaments Tungsten (W) was the favored metal for incandescent lightbulb filaments, partly because of its high melting point of 3422°C. The enthalpy of fusion of tungsten is 35.4 kJ/mol. What is its entropy of fusion?

Over what temperature range is the reduction of tungsten(VI) oxide by hydrogen to give metallic tungsten and water spontaneous? The standard enthalpy of formation of $WO_3(s)$ is $-$ 843 kJ/mol, and its standard molar entropy is 76 J/(mol · K).

Two allotropes (A and B) of sulfur interconvert at 369 K and 1 atm of pressure:

$S_8(s, A) \rightarrow S_8(s, B)$

The enthalpy change in this transition is 297 J/mol. What is the entropy change?

Copper forms two oxides, Cu_2O and CuO.

1. Name these oxides.
2. Predict over what temperature range this reaction,

$Cu_2O(s) \rightarrow CuO(s) + Cu(s)$

is spontaneous by using the following thermodynamic data:

	ΔH°_f (kJ/mol)	S° [J/(mol · K)]
$Cu_2O(s)$	−170.7	92.4
$CuO(s)$	−156.1	42.6
$Cu(s)$	0	33.1

Why is the standard molar entropy of $Cu_2O(s)$ larger than that of $CuO(s)$?

Lime Enormous amounts of lime (CaO) are used in steel industry blast furnaces to remove impurities from iron. Lime is made by heating limestone and other solid forms of $CaCO_3(s)$. Why is the standard molar entropy of $CaCO_3(s)$ higher than that of $CaO(s)$? At what temperature is the pressure of $CO_2(g)$ over $CaCO_3(s)$ equal to 1.0 atm?

	ΔH°_f (kJ/mol)	S° [J/(mol · K)]
$CaCO_3(s)$	−1207	93
$CaO(s)$	−636	40
$CO_2(g)$	−394	214

According to *Trouton’s rule*, the ratio $\Delta H^\circ_{vap}/T_b$ for a liquid is approximately 88 J/(mol · K). Here, ΔH°_{vap} is the molar enthalpy of vaporization of a liquid, and T_b is its normal boiling point. (a) What idea suggests that $\Delta H^\circ_{vap}/T_b$ for a range of liquids should be approximately constant? (b) Check Trouton’s rule against the data in Figure P17.111. Which liquids deviate from Trouton’s rule, and why?

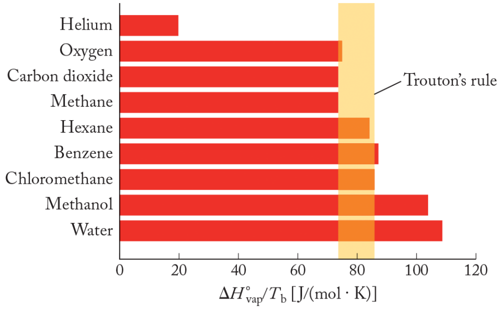

FIGURE P17.111

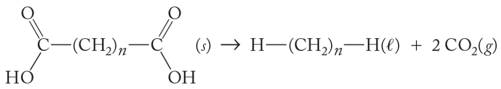
Melting DNA When a solution of DNA in water is heated, the DNA double helix separates into two single strands:

1 DNA double helix ⇋ 2 single strands

1. What is the sign of ΔS for the forward process as written?
2. The DNA double helix reforms as the system cools. What is the sign of ΔS for the process by which two single strands reform the double helix?
3. The melting point of DNA is defined as the temperature at which $\Delta G = 0$. At that temperature, the forward reaction produces two single strands as fast as two single strands recombine to form the double helix. Write an equation that defines the melting temperature (T) of DNA in terms of ΔH and ΔS.

Melting Organic Compounds When dicarboxylic acids (compounds with two –COOH groups in their structures) melt, they frequently decompose to produce 2 moles of CO_2 gas for every 1 mole of dicarboxylic acid melted (shown in Figure P17.113). (a) What are the signs of ΔH and ΔS for the process as written? (b) Problem 17.112 describes the DNA double helix reforming when the system cools after melting. Do you think the dicarboxylic acid will reform when the melted material cools? Why or why not?



$$HOOC{-}(CH_2)_n{-}COOH(s) \rightarrow H{-}(CH_2)_n{-}H(\ell) + 2\,CO_2(g)$$

FIGURE P17.113

Computer Chips The absolute entropy (S) of a perfect, defect-free solid equals zero and has one accessible microstate. It is impossible to make such a material, but silicon chip manufacturers strive for as few defects as possible in their products. Calculate the absolute molar entropy for a piece of silicon with a number of probable arrangements of (a) $W = 16$, (b) $W = 625$, and (c) $W = 2500$ per atom of Si.

Glossary

spontaneous process

a process that occurs without outside intervention.

nonspontaneous process

a process that occurs only as long as energy is continually added to the system.

third law of thermodynamics

the entropy of a perfect crystal is zero at absolute zero.

entropy (S)

a measure of the dispersion of energy in a system at a specific temperature.

second law of thermodynamics

the principle that the total entropy of the universe increases in any spontaneous process.

reversible process

a process that can be run in the reverse direction in such a way that, once the system has been restored to its original state, no net energy has flowed either to the system or to its surroundings.

Gibbs free energy (G)

the maximum energy released by a process occurring at constant temperature and pressure that is available to do useful work.

glycolysis

a series of reactions that converts glucose into pyruvate; a major anaerobic (no oxygen required) pathway for the metabolism of glucose in the cells of almost all living organisms.

phosphorylation

a reaction resulting in the addition of a phosphate group to an organic molecule.

microstate

a unique distribution of particles among energy levels.

standard molar entropy (S°)

the absolute entropy of 1 mole of a substance in its standard state.

standard free energy of formation ($\delta G^\circ{}_\mathrm{f}$)

the change in free energy associated with the formation of 1 mole of a compound in its standard state from its component elements.

AN ELECTRIFYING SEDAN The 2019 Chevrolet Bolt has a 60-kWh lithium-ion battery and driving range of about 383 km (238 mi).

Electrochemistry
The Quest for Clean Energy

PARTICULATE REVIEW

Redox: Metal versus Nonmetal

In Chapter 18 we investigate transformations between chemical energy and electrical energy via redox reactions. Rust (mostly Fe_2O_3) forms on old cars such as the one in this photo through a series of reactions between iron in the car and oxygen in the atmosphere.

Write a balanced chemical equation for the formation of Fe_2O_3 from its elements.
- Which element is oxidized and which is reduced during this reaction?
- Describe the direction of the electron transfer in the formation of Fe_2O_3.

(Review Section 4.8 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Redox: Electricity and Clean Fuel

The redox chemistry used to create fuel cells involves hydrogen gas and oxygen gas as pictured here. As you read Chapter 18, look for ideas that will help you answer these questions:

- Determine which half-reaction represents oxidation and which represents reduction. Write an overall equation for the chemistry of fuel cells.
- How do the electrons transferred in this reaction generate electricity to power cars?
- Cars powered by fuel cells are considered “zero-emission vehicles.” Explain this designation based on the chemistry of fuel cells.

Learning Outcomes

- LO1 Combine the appropriate half-reactions to write net ionic equations of spontaneous redox reactions

  Sample Exercises 18.1, 18.2, 18.3, 18.4

- LO2 Use cell diagrams to describe the components of electrochemical cells and their roles in interconverting chemical and electrical energy

  Sample Exercise 18.2

- LO3 Use the standard reduction potentials of two half-reactions to decide which occurs at the cathode and which at the anode and to calculate the standard potential of the electrochemical cell based on the half-reactions

  Sample Exercise 18.3

- LO4 Interconvert a cell’s potential and the change in free energy of the cell reaction

  Sample Exercise 18.4

- LO5 Use the Nernst equation to relate the concentrations of cell reaction components to cell potentials

Sample Exercise 18.5

- LO6 Relate standard cell potentials to the equilibrium constants of the cell reactions

Sample Exercise 18.6

- LO7 Use the Faraday constant to relate quantity of charge to changes in the quantities of reactants and products in cell reactions

Sample Exercises 18.7, 18.8

- LO8 Explain the applicability of the term zero-emission to electric vehicles

FIGURE 18.2 (a) This electrochemical cell consists of two compartments: the one on the left contains a zinc metal anode immersed in 1.00 *M* $ZnSO_4$; the one on the right contains a copper metal cathode immersed in 1.00 *M* $CuSO_4$. A salt bridge containing an aqueous solution of Na_2SO_4 provides an electrical connection through which ions (and their charges) can move from one compartment to the other. (b) In this apparatus, a porous bridge substitutes for the salt bridge, thus allowing ions from the background electrolyte (Na_2SO_4) to move between the two cells.

18.1 Running on Electrons: Redox Chemistry Revisited

In previous chapters we explored some of the environmental impacts of producing energy by burning fossil fuels. Concerns about these impacts have spurred the development of innovative propulsion systems for cars and trucks that reduce or eliminate the use of fossil fuels. Some vehicles are hybrids, which means that they are propelled by a combination of gasoline engines and electric motors powered by rechargeable batteries. Plug-in hybrids (such as the one in this chapter's opening photograph) are powered exclusively by electric motors, but they have a small gasoline engine to generate electricity and extend their driving range. Completely electric vehicles are powered by banks of high-performance batteries or by fuel cells. If these all-electric cars are to replace most of the vehicles powered by fossil fuels, scientists and engineers will need to develop lighter-weight, higher-capacity, more powerful, more reliable, and less expensive batteries and fuel cells. It will not be easy, but progress is being made.

Batteries and fuel cells are devices based on electrochemistry, the branch of chemistry that links chemical reactions to the production or consumption of electrical energy. At the heart of electrochemistry are chemical reactions in which electrons are transferred between substances. In other words, electrochemistry is based on *red*uction and *ox*idation reactions, or *redox* reactions, which were introduced in Section 4.8. There we noted the following:

- Each redox reaction is the sum of two half-reactions: a reduction half-reaction, in which a reactant gains electrons, and an oxidation half-reaction, in which a reactant loses electrons.
- Reduction and oxidation half-reactions happen simultaneously, and the number of electrons gained during reduction must exactly match the number lost during

oxidation.

CONNECTION Redox reactions, including how to balance them by using half-reactions, were first discussed in Section 4.8.

We begin our exploration of electrochemistry by reviewing the oxidation and reduction half-reactions involved in a redox reaction between copper and zinc. When a strip of Zn metal is placed in a solution of $CuSO_4$ (**Figure 18.1**), electrons spontaneously transfer from Zn atoms to Cu^{2+} ions, forming Zn^{2+} ions and Cu atoms. The shiny zinc surface turns dark brown as a textured layer of copper metal accumulates on it, and the distinctive blue color of $Cu^{2+}(aq)$ ions fades as these ions gain electrons and become atoms of copper metal.

The electron transfer in this spontaneous reaction can be represented through two half-reactions that occur simultaneously—the oxidation half-reaction of zinc atoms and the reduction half-reaction of copper ions:

$$Zn(s) \rightarrow Zn^{2+}(aq) + 2\ e^-$$

$$Cu^{2+}(aq) + 2\ e^- \rightarrow Cu(s)$$

For 1 mole of zinc atoms, 2 moles of electrons are “lost,” or transferred to 1 mole of copper ions. Because the number of moles of electrons lost and gained are the same in the two half-reactions, writing a net ionic equation to describe the overall redox reaction is simply a matter of adding the two half-reactions together:

Canceling out the equal numbers of electrons gained and lost, we get

Combining half-reactions is a convenient way to write net ionic equations for redox reactions. In Chapter 18 we use a valuable resource in this equation-writing process: a table of common half-reactions in Appendix 6. All these half-reactions are written as reduction half-reactions. There is no need for a separate table of *oxidation* half-reactions because any reduction half-reaction can always be reversed to obtain the corresponding oxidation half-reaction.

Having established that the redox reaction between zinc metal and $Cu^{2+}(aq)$ ions is the result of two distinct half-reactions, let's examine how chemists can *physically separate* the two half-reactions to produce electricity. To do this we use a device called an electrochemical cell (**Figure 18.2a**). Like nearly all electrochemical cells, it consists of two compartments. One compartment contains a strip of zinc metal immersed in 1.00 *M* $ZnSO_4$; the other compartment has a strip of copper metal immersed in 1.00 *M* $CuSO_4$. Sulfate ions are spectator ions in this reaction and are not included in the net ionic equation, although we will see that they do play an important role in cell function. The two metal strips function as the *electrodes* of the cell, providing pathways through which the electrons produced and consumed in the two half-reactions flow to and from an external circuit, converting chemical energy into electrical energy.

As the cell reaction proceeds, oxidation of Zn atoms produces electrons, which travel from the Zn electrode through the external circuit to the surface of the Cu electrode, where they combine with Cu^{2+} ions, forming atoms of Cu metal. In an electrochemical cell, the electrode at which the oxidation half-reaction takes place (the zinc electrode in this case) is called the anode, and the electrode at which the reduction half-reaction takes place (the copper electrode in this case) is called the cathode.

You might think that production of Zn^{2+} ions in the left compartment in Figure 18.2a would result in a buildup of positive charge on that side of the cell, and that conversion of Cu^{2+} ions to Cu metal would result in an excess of SO_4^{2-} ions and thus a negative charge in the Cu compartment. Creation of a net charge in each compartment would cause electron transfer to stop. However, no buildup of charge occurs because the two compartments in Figure 18.2a are connected by a salt bridge, a bent glass tube filled with a strong electrolyte (Na_2SO_4 in this example) not involved in either half-reaction. Porous plugs on both ends of the tube allow ions to migrate through the bridge, which allows electrical charge to move from one side of the cell to the other. Often a salt bridge is inconvenient to use, so scientists add a background electrolyte not involved in the cell reaction to each compartment and connect the compartments with a porous bridge (**Figure 18.2b**) that allows electrolyte ions to move from one side of the cell to the other. Migration of Na^+ ions toward the Cu compartment and $SO_4{}^{2-}$ ions toward the Zn compartment through the salt bridge or porous bridge balances the flow of electrons in the external circuit and eliminates any accumulation of ionic charge in either compartment.

CONCEPT TEST

As the cell reaction in Figure 18.2 proceeds, is the increase in mass of the copper strip the same as the decrease in mass of the zinc strip? Explain your answer.

(Answers to Concept Tests are in the back of the book.)

Glossary

electrochemistry	the branch of chemistry that examines the transformations between chemical and electrical energy.
electrochemical cell	an apparatus that can either generate electrical energy from a chemical reaction or use electrical energy to produce a chemical reaction.
anode	an electrode at which an oxidation half-reaction (loss of electrons) takes place.
cathode	an electrode at which a reduction half-reaction (gain of electrons) takes place.

$$2\ \mathrm{Ag}^{+}(aq) + \mathrm{Cu}(s) \rightarrow 2\ \mathrm{Ag}(s) + \mathrm{Cu}^{2+}(aq)$$

18.2 Voltaic and Electrolytic Cells

Cells like the Zn/Cu^{2+} cell, in which the chemical reactions inside the cell pump electrons from the anode, through an external circuit, and into the cathode, are called voltaic cells in honor of the Italian physicist Alessandro Volta (1745–1827; **Figure 18.3a**), who is credited with building the first battery. His battery and all the modern batteries that power familiar electric devices, from cell phones to flashlights to laptop computers, are examples of voltaic cells. Voltaic cells are also known as *galvanic cells* after Luigi Galvani (1737–1798; **Figure 18.3b**) whose discovery of *bio*electricity contributed to Volta's development of the battery shown in Figure 18.3a.

In this chapter we also investigate cells in which an external electrical power supply drives a nonspontaneous chemical reaction inside the cell. A reaction that is driven by the consumption of electrical energy is called electrolysis, and a cell in which electrolysis occurs is called an electrolytic cell (**Figure 18.4**). In electrolytic cells, electrons are pumped into the cathodes (making them the negative electrodes) and pulled away from the anodes (making them the positive electrodes). As we explain in Section 18.9, many of the batteries used to power familiar electronic devices are rechargeable, which means that not only do their cell reactions produce electricity, but these same reactions can also be forced to run in reverse when connected to an external power supply. When this happens, these voltaic cells become electrolytic cells as the products of the voltaic reaction become the reactants in the electrolytic reaction, regenerating the original reactants and recharging the battery.

Cell Diagrams

Chemists have developed a notation to efficiently convey what components are present in an electrochemical cell such as the Zn/Cu^{2+} one depicted in Figure 18.2: A cell diagram consists of both chemical formulas and symbols to show how the components of the cell are connected. A cell diagram does not convey stoichiometry, so any coefficients in the balanced equation for the cell reaction do not appear in the cell diagram. A cell diagram has the following components:

anode | anode solution ‖ cathode solution | cathode

There are three steps to drawing a cell diagram. (The symbols used to represent the cell diagram for the Zn/Cu^{2+} electrochemical cell in Figure 18.2 are included as an example with each step.)

1. Write the chemical symbol of the anode at the far left of the diagram, the symbol of the cathode at the far right, and double vertical lines for the connecting bridge halfway between them:

   $\mathrm{Zn}(s) \ldots\ldots\ldots \parallel \ldots\ldots\ldots \mathrm{Cu}(s)$

2. Work inward from the electrodes toward the connecting bridge, using vertical lines to indicate phase changes (such as that between a solid metal electrode and an aqueous solution). Represent the electrolytes surrounding the electrode by using the symbols of the ions or compounds that are changed by the cell reaction. Use commas to separate species in the same phase:

   $\mathrm{Zn}(s) \mid \mathrm{Zn}^{2+}(aq) \parallel \mathrm{Cu}^{2+}(aq) \mid \mathrm{Cu}(s)$

3. If known, use the concentrations of the dissolved species in place of (*aq*) phase symbols, and add the partial pressures of any gases within their (*g*) phase symbols:

   $\mathrm{Zn}(s) \mid \mathrm{Zn}^{2+}(1.00\ M) \parallel \mathrm{Cu}^{2+}(1.00\ M) \mid \mathrm{Cu}(s)$

CONCEPT TEST

Describe in your own words the meaning of the cell diagram for Figure 18.2. Start your description with: “The cell consists of a zinc anode, which is oxidized to . . .”.

To draw a cell diagram, we need to know the identities of both the reactants and products in both the anode and cathode half-reactions. As noted in Section 18.1, the half-reactions listed in Table A6.1 are a very handy reference in identifying the atoms, ions, and molecules involved not only in electrochemical reactions but also in redox reactions in general. Many of the half-reactions in Table A6.1

include H^+ ions because they occur in acidic solutions, and H^+ ions are often used to balance the number of H atoms in half-reactions in which water is a reactant or product. Although H^+ ions in aqueous solution are better represented as hydronium ions, $H_3O^+(aq)$, it is customary to write redox half-reactions by using the more simplistic $H^+(aq)$. For example, the reduction of O_2 to H_2O is written as

$$O_2(g) + 4\ H^+(aq) + 4\ e^- \rightarrow 2\ H_2O(\ell)$$

However, a few half-reactions in Table A6.1 contain OH^- ions, which tells us that these reactions occur in basic solutions. One such reaction involves another reduction of O_2:

$$O_2(g) + 2\ H_2O(\ell) + 4\ e^- \rightarrow 4\ OH^-(aq)$$

In Sample Exercise 18.1 and its accompanying practice exercise, we need to select half-reactions that match the pH conditions of the reaction.

SAMPLE EXERCISE 18.1 Writing Net Ionic Equations of Cell Reactions by Combining Half-Reactions LO1

Identify two half-reactions listed in Table A6.1 that could be combined to produce a net ionic equation describing the electrolysis of water into hydrogen gas and oxygen gas. Assume the pH of the solution is 12.0.

Collect and Organize The products of the electrolysis of water are $H_2(g)$ and $O_2(g)$, so our target net ionic equation is

$$2\ H_2O(\ell) \rightarrow 2\ H_2(g) + O_2(g)$$

Table A6.1 contains four half-reactions in which H_2O, H_2, and O_2 are either reactants or products:

$$2\ H^+(aq) + 2\ e^- \rightarrow H_2(g)$$

$$2\ H_2O\ (\ell) + 2\ e^- \rightarrow H_2(g) + 2\ OH^-\ (aq)$$

$$O_2(g) + 2\ H_2O\ (\ell) + 4\ e^- \rightarrow 4\ OH^-\ (aq)$$

$O_2(g) + 4\ H^+(aq) + 4\ e^- \rightarrow 2\ H_2O\ (\ell)$

Analyze The solution has a basic pH, so the appropriate half-reactions from Table A6.1 are those that contain OH^-, not H^+, ions. This condition eliminates the first and last half-reactions just listed, leaving the middle two to use in writing the net ionic equation:

$2\ H_2O\ (\ell) + 2\ e^- \rightarrow H_2(g) + 2\ OH^-\ (aq)$

$O_2(g) + 2\ H_2O\ (\ell) + 4\ e^- \rightarrow 4\ OH^-\ (aq)$

Water is a reactant and H_2 is a product in the first of these half-reactions, as in the target electrolysis reaction. However, O_2 is a reactant in the second half-reaction but a product in the target electrolysis reaction. Therefore, the second half-reaction must be reversed and written as an oxidation half-reaction:

$4\ OH^-(aq) \rightarrow O_2(g) + 2\ H_2O(\ell) + 4\ e^-$

The number of electrons gained and lost in the two half-reactions must balance, which means we must multiply the reduction half-reaction by 2, so that both involve 4 moles of electrons.

Solve Multiplying the reduction half-reaction by 2 and adding it to the oxidation half-reaction gives:

Simplifying by eliminating the terms common to both sides of the reaction arrow:

or,

$2\ H_2O(\ell) \rightarrow 2\ H_2(g) + O_2(g)$

Think About It Had the hydrolysis reaction been run under acidic conditions, the other two half-reactions would have been combined but the overall cell reaction would have been the same: multiplying the first half-reaction by 2 before combining it with the reverse of the last half-reaction gives us

The same result is convincing evidence that both are correct.

Practice Exercise Use the appropriate half-reactions from Table A6.1 to write a net ionic equation describing the oxidation of HNO_2 to HNO_3 by O_2 in an acidic solution.

(Answers to Practice Exercises are in the back of the book.)

SAMPLE EXERCISE 18.2 Diagramming an Electrochemical Cell
LO1, LO2

Figure 18.5 depicts an electrochemical cell in which a copper electrode immersed in a 1.00 *M* solution of Cu^{2+} ions is connected to a silver electrode immersed in a 1.00 *M* solution of Ag^{+} ions. Write a balanced chemical equation for this cell reaction and draw a cell diagram for this cell.

Collect and Organize We have a cell reaction in which electrons spontaneously flow from a copper electrode in contact with a solution of Cu^{2+} ions through an external circuit to a silver electrode in contact with a solution of Ag^{+} ions. The half-reactions in Table A6.1 involving these metals and ions are

$Cu^{2+}(aq) + 2\ e^{-} \rightarrow Cu\ (s)$

$Ag^{+}(aq) + e^{-} \rightarrow Ag\ (s)$

In a cell diagram, the anode and the species involved in the oxidation half-reaction are written on the left, whereas the cathode and the species involved in the reduction half-reaction are written on the right. We use single lines to separate phases and a double line to represent the porous bridge separating the two compartments of the cell.

Analyze In an electrochemical cell, electrons flow from the anode through an external circuit to the cathode. In the cell in Figure

18.5, then, copper is the anode and silver is the cathode. This means that the Cu reduction half-reaction must run in reverse as an oxidation half-reaction:

$$\mathrm{Cu}(s) \rightarrow \mathrm{Cu}^{2+}(aq) + 2\,\mathrm{e}^{-}$$

Two moles of electrons are produced in the anode half-reaction, but only 1 mole of electrons is consumed in the cathode half-reaction at the Ag electrode. We therefore need to multiply the silver half-reaction by 2 before combining the two equations so that all the electrons are accounted for.

Solve Multiplying the Ag^{+} half-reaction by 2 and adding it to the Cu half-reaction, we get

The equation is now balanced.

Applying the rules for drawing a cell diagram:

1. Anode on the left, cathode on the right, bridge in the middle:

   $\mathrm{Cu}(s) \parallel \mathrm{Ag}(s)$

2. Adding electrode–solution boundaries and the formulas of the ions produced and consumed in the cell reaction:

   $\mathrm{Cu}(s) \mid \mathrm{Cu}^{2+}(aq) \parallel \mathrm{Ag}^{+}(aq) \mid \mathrm{Ag}(s)$

3. Adding concentration terms:

   $\mathrm{Cu}(s) \mid \mathrm{Cu}^{2+}(1.00\ M) \parallel \mathrm{Ag}^{+}(1.00\ M) \mid \mathrm{Ag}(s)$

Think About It To test the validity of the cell diagram, translate it into a sentence. *A copper anode is oxidized to aqueous* Cu^{2+} *ions, which are separated by a porous bridge from an aqueous solution of* Ag^{+} *ions that are reduced to Ag atoms at a silver cathode*. This description matches the net ionic equation for the reaction and is consistent with the cell layout and flow of electrons in Figure 18.5.

Practice Exercise Write a balanced chemical equation and draw the cell diagram for an electrochemical cell that has a copper cathode immersed in a solution of Cu^{2+} ions and an aluminum anode immersed in a solution of Al^{3+} ions.

Glossary

voltaic cell

an electrochemical cell in which chemical energy is transformed into electrical work by a spontaneous cell reaction.

electrolysis

a process in which electrical energy is used to drive a nonspontaneous chemical reaction.

electrolytic cell

a device in which an external source of electrical energy does work on a chemical system, turning reactant(s) into higher-energy product(s).

cell diagram

symbols that show how the components of an electrochemical cell are connected.

18.3 Standard Potentials

Table A6.1 lists half-reactions in order of their standard reduction potentials (E°). The superscript ($^\circ$) has its usual thermodynamic meaning—namely, all reactants and products are in their standard states, which means the concentrations of all dissolved substances are 1 *M* and the partial pressures of all gases are 1 bar ($<$ 1 atm). The more positive the value of E°, the greater the probability that the reduction half-reaction will couple with an oxidation half-reaction to produce a spontaneous redox reaction. The most positive E° value in Table A6.1 is for the reduction of fluorine:

This means fluorine is the most easily reduced substance in Table A6.1. It also means that F_2 is the strongest oxidizing agent in the table. It can oxidize any of the substances on the product side of the half-reactions lower in the table. Likewise, F^- is the weakest reducing agent.

CONNECTION In a redox reaction, the substance that contains the element being reduced is the oxidizing agent and the substance that contains the element being oxidized is the reducing agent (see Section 4.8).

The half-reaction at the very bottom of the table with the most negative E° value

is least likely to proceed as written because Li^+ is the weakest oxidizing agent in the table. However, that also means that Li is the strongest reducing agent in this table, so the reverse reaction:

$$Li(s) \rightarrow Li^+(aq) + e^-$$

occurs more readily than the reverse of any other half-reaction in Table A6.1. Lithium metal is a very powerful reducing agent that can reduce any of the substances on the reactant side of the half-reactions in Table A6.1.

Substances with very negative E° values at the bottom of Table A6.1

include the major cations in biological systems and environmental waters: Na^+, K^+, Mg^{2+}, and Ca^{2+}. Their negative E° values indicate that these ions are not easily reduced to their free metals in aqueous solutions. They are chemically very stable (which explains the presence of these cations in nature).

CONCEPT TEST

Compare the order of the metals listed in the activity series in Table 4.6 to the order of the metals listed in Table A6.1. Describe the relationship between these two tables.

CONCEPT TEST

Use the order of the half-reactions listed in Table A6.1 to predict which of the following reactions is/are spontaneous under standard conditions:

1. $Cu(s) + 2\ Fe^{3+}(aq) \rightarrow Cu^{2+}(aq) + 2\ Fe^{2+}(aq)$
2. $2\ Ag(s) + Zn^{2+}(aq) \rightarrow 2\ Ag^{+}(aq) + Zn(s)$
3. $Hg(\ell) + 2\ H^{+}(aq) \rightarrow Hg^{2+}(aq) + H_2(g)$

Standard reduction potentials in Table A6.1 can be used to calculate the standard cell potential (E°_{cell}) of an electrochemical cell. Standard cell potential, as the name suggests, is related to the chemical (potential) energy stored in a cell and specifically to how forcefully the cell can pump electrons out from their anodes, through external circuits, and into their cathodes.

Consider the hypothetical case in which two half-reactions both have the same standard reduction potential. That is, there would be no difference between the abilities of their reactants to function as oxidizing agents and no electrons would spontaneously flow. For two half-reactions with different standard reduction potentials, the larger the E°_{cell} difference between those potentials, the larger the E°_{cell} of the electrochemical cell that could be built from them. Therefore, E°_{cell} can be determined by calculating the difference between the standard reduction potentials of a voltaic cell's cathode and anode:

Let's use Equation 18.2 to calculate E°_{cell} for the Zn/Cu^{2+} voltaic cell in Figure 18.2. The standard reduction potential of the cathode half-reaction is

To obtain the standard potential for the oxidation half-reaction at the zinc anode, we find the standard reduction potential of Zn^{2+} ions in Table A6.1:

Now we use Equation 18.2 to calculate E°_{cell}:

$$E^\circ_{\text{cell}} = E^\circ_{\text{cathode}} - E^\circ_{\text{anode}}$$

$$= 0.342 - (-0.762) = 1.104 \text{ V}$$

This is the cell potential we would measure if we connected a device called a voltmeter across the two electrodes (**Figure 18.6**) at 25°C under standard conditions.

To use Equation 18.2, we need to know which half-reaction occurs at the cathode (reduction) and which occurs at the anode (oxidation). In other words, we need to know which component of the spontaneous cell reaction is more likely to be oxidized and which is more likely to be reduced. This decision can be made based on the data in Table A6.1. In our Zn/Cu^{2+} cell, for instance, the value of E° for the reduction of Cu^{2+} ions to Cu metal is 0.342 V, which is greater than the value of E° for reducing Zn^{2+} ions to Zn metal (-0.762 V). In the Zn/Cu^{2+} voltaic cell, therefore, Cu^{2+} ions are reduced, and Zn metal is oxidized. We can generalize this observation to the cell reaction of any voltaic cell: the half-reaction with the more positive value of E° runs as a reduction and the other half-reaction occurs as an oxidation. As a result, E°_{cell} will always be a positive value for a spontaneous cell reaction.

SAMPLE EXERCISE 18.3 Identifying Anode and Cathode Half-Reactions and Calculating the Value of E°_{cell} LO1, LO3

The half-reactions and the standard reduction potentials of typical AA or AAA single-use alkaline batteries are

What is the net ionic equation for the cell reaction and the value of E°_{cell}?

Collect and Organize We can calculate E°_{cell} by using Equation 18.2:

$$E^\circ_{\text{cell}} = E^\circ_{\text{cathode}} - E^\circ_{\text{anode}}$$

However, first we need to decide which half-reaction occurs at the cathode and which at the anode. The equation for a cell reaction is written by combining half-reactions once the loss or gain of electrons in the two half-reactions is balanced.

Analyze The MnO_2 half-reaction has the more positive E° value, making it our reduction half-reaction. We must reverse the $Zn(OH)_2$ half-reaction, turning it into an oxidation half-reaction. The two half-reactions both involve the transfer of 2 moles of electrons, so we may combine them by simply adding them together.

Solve The oxidation half-reaction at the anode is

$$Zn(s) + 2\ OH^-(aq) \rightarrow Zn(OH)_2(s) + 2\ e^-$$

The reduction half-reaction at the cathode is

$$2\ MnO_2(s) + H_2O(\ell) + 2\ e^- \rightarrow Mn_2O_3(s) + 2\ OH^-(aq)$$

Combining these half-reactions to obtain the overall cell reaction, we get

Simplifying gives us the net ionic equation for the cell reaction:

$$2\ MnO_2(s) + H_2O(\ell) + Zn(s) \rightarrow Mn_2O_3(s) + Zn(OH)_2(s)$$

The overall E°_{cell} for this reaction is obtained by using Equation 18.2:

$$E^\circ_{\text{cell}} = E^\circ_{\text{cathode}} - E^\circ_{\text{anode}}$$

$$= 0.15\ \text{V} - (-\ 1.249\ \text{V}) = 1.40\ \text{V}$$

Think About It The E°_{cell} value is reasonable because in our everyday experience the potential of most alkaline batteries is nominally 1.5 V. In this cell reaction, the net ionic equation is also the complete molecular equation.

Practice Exercise The half-reactions in nicad (nickel–cadmium) batteries are

Write the net ionic equation for the cell reaction and calculate the value of E°_{cell}.

Let's now examine what happens when two half-reactions in which different numbers of electrons are gained and lost are combined into an electrochemical cell. This combination occurs in the zinc–air battery (**Figure 18.7**), a type of battery that has a limitless supply of one of its reactants. This battery powers devices in which small battery size and low mass are high priorities, such as hearing aids. Most of the internal volume of one of these batteries is occupied by an anode consisting of a paste of zinc particles packed in an aqueous solution of KOH. As in alkaline batteries (Sample Exercise 18.3), the anode half-reaction is

$$Zn(s) + 2\ OH^-(aq) \rightarrow Zn(OH)_2(s) + 2\ e^-$$

which is the reverse of the reaction in Table A6.1:

The cathode consists of porous carbon supported by a metal screen. Air diffuses through small holes in the battery and across a layer of

Teflon that lets gases pass through but keeps electrolyte from leaking out. As air passes through the cathode, oxygen is reduced to hydroxide ions:

To write the overall cell reaction, we need to multiply the oxidation half-reaction by 2 before combining it with the reduction half-reaction:

This simplifies to

$$2\ \mathrm{Zn}(s) + \mathrm{O_2}(g) + 2\ \mathrm{H_2O}(\ell) \rightarrow 2\ \mathrm{Zn(OH)_2}(s)$$

$$E^\circ_{\mathrm{cell}} = E^\circ_{\mathrm{cathode}} - E^\circ_{\mathrm{anode}}$$

$$= 0.401\ \mathrm{V} - (-\ 1.25\ \mathrm{V}) = 1.65\ \mathrm{V}$$

Note that when we multiply the anode half-reaction by 2 and add it to the cathode half-reaction, *we do not multiply* the E° of the anode half-reaction by 2. E° is an *intensive* property of a half-reaction or a complete cell reaction, so it does *not* change when the quantities of reactants and products change. Thus, a zinc–air battery the size of a pea has the same E° as one the size of a book (such as those being developed for electric vehicles). On the other hand, the amount of electrical work a zinc–air battery can do *does* depend on how much zinc is inside it because, as we explain in Section 18.4, the electrical work that a voltaic cell can do depends on both cell potential *and* the quantity of charge it can deliver at that potential.

Glossary

standard cell potential (E°_{cell})

a measure of how forcefully an electrochemical cell in which all reactants and products in their standard states can pump electrons through an external circuit.

standard reduction potential (E°)

the potential of a reduction half-reaction in which all reactants and products are in their standard states at 25°C.

18.4 Chemical Energy and Electrical Work

When we connect the Zn and Cu electrodes in Figure 18.6 to a digital voltmeter—the Zn electrode to the negative terminal of the meter and the Cu electrode to the positive terminal—the meter reads 1.104 V. These connections indicate that under standard conditions the battery can pump electrons from the Zn electrode through an external circuit to the Cu electrode with a potential of 1.104 V.

Where does the energy come from to pump electrons this forcefully through an external circuit? A hint at the answer comes from the fact that these moving electrons can do electrical work (w_{elec}), such as lighting a lightbulb or turning an electric motor. We saw in Chapter 17 that the ability of a chemical reaction to do work (different from expansion or compression) is expressed by the change in free energy (ΔG_{cell}) that accompanies the cell reaction. When a thermodynamic system does work (w) on its surroundings, w is less than zero. Similarly, the change in free energy of the reaction (system) that did this work is also less than zero. Thus, the two quantities would be identical if this energy conversion process were 100% efficient:

The work done by a voltaic cell (in this case the $\mathrm{Zn/Cu^{2+}}$ cell reaction) on its surroundings is defined as the product of the quantity of electrical charge (C) that the cell pumps through an external circuit times the cell potential:

The negative sign indicates that work done *by* a voltaic cell on its surroundings (the external circuit) corresponds to free energy lost by the cell.

CONNECTION The sign conventions used for work done *on* a thermodynamic system (+) and the work done *by* the system (−) were explained in Section 6.3 (see Figure 6.20).

Quantities of electrical charge are typically expressed in coulombs (C), not in moles. As noted in Section 2.2, the magnitude of the charge on a single electron is 1.602×10^{-19} coulombs (C). (Note, too, the distinction between italic C, the symbol for the variable “charge,” and nonitalic C, the abbreviation for the unit “coulomb.”) The magnitude of electrical charge on 1 mole of electrons is

This quantity of charge, 9.65×10^4 C/mol e^-, is called the Faraday constant (F) after Michael Faraday (1791–1867), the English chemist and physicist who discovered that redox reactions take place when electrons are transferred from one species to another. The quantity of charge (C) flowing through an electrical circuit is the product of the number of moles (n) of electrons times the Faraday constant:

Combining Equations 18.4 and 18.5 gives us an equation relating w_{elec} and E_{cell}:

If we combine Equations 18.3 and 18.6, we connect the quantity of electrical work a voltaic cell can do on its surroundings with the change in free energy in the cell:

How is the product on the right side of Equation 18.7 the equivalent of energy? The units on the right side are

So, the change in free energy term on the left side of Equation 18.7, which is usually expressed in joules (or kilojoules), is equivalent to an electrical energy term on the right expressed in coulomb-volts. This equivalence makes sense because of the following important unit equality:

$$1\text{ joule} = 1\text{ coulomb-volt} \qquad \text{or} \qquad 1\text{ J} = 1\text{ C}\cdot\text{V}$$

The negative sign on the right side of Equation 18.7 indicates that the E_{cell} of any voltaic cell must have a positive value because the sign of ΔG_{cell} for the spontaneous chemical reaction inside the cell must be negative.

Let's calculate the change in standard free energy of the Zn/Cu^{2+} cell reaction. We start with the standard cell potential calculated in Section 18.3:

$$E^{\circ}_{\text{cell(Zn/Cu}^{2+})} = 1.104\text{ V}$$

We can convert this standard cell potential into a change in standard free energy ($\Delta G^{\circ}_{\text{cell}}$) by using Equation 18.7 under standard conditions, so that $\Delta G = \Delta G^{\circ}$ and $E_{\text{cell}} = E^{\circ}_{\text{cell}}$:

To put this value in perspective, the Zn/Cu^{2+} reaction produces nearly as much useful energy as the combustion of 1 mole of hydrogen gas:

CONCEPT TEST

When a rechargeable battery, such as the one used to start a car's engine, is recharged, an external source of electrical power forces the voltaic cell reaction to run in reverse. What are the signs of E°_{cell} and $\Delta G^{\circ}_{\text{cell}}$ during the recharging process?

SAMPLE EXERCISE 18.4 Relating $\Delta G^{\circ}_{\text{cell}}$ and E°_{cell}LO1, LO4

Many of the "button" batteries used in electric watches consist of a Zn anode and a Ag_2O cathode, separated by a membrane soaked in a concentrated solution of KOH (**Figure 18.8**). At the cathode, Ag_2O is reduced to Ag metal; at the anode, Zn is oxidized to solid $Zn(OH)_2$. Write the net ionic equation for the reaction and use the appropriate standard reduction potentials from Table A6.1 to calculate the values of E°_{cell} and $\Delta G^\circ_{\text{cell}}$.

Collect and Organize We know the reactants and products of the anode and cathode reactions and that the reaction occurs in a basic solution. Equations 18.2 and 18.7 should be useful in calculating E°_{cell} and $\Delta G^\circ_{\text{cell}}$ from the appropriate standard potentials:

$$E^\circ_{\text{cell}} = E^\circ_{\text{cathode}} - E^\circ_{\text{anode}}$$

$$\Delta G^\circ_{\text{cell}} = -nFE^\circ_{\text{cell}}$$

Analyze The half-reaction at the cathode is based on the reduction of Ag_2O to Ag. The appropriate half-reaction in Table A6.1 is

The following entry in Table A6.1 has $Zn(OH)_2$ as the reactant and Zn as the product:

We must reverse this half-reaction to represent the oxidation occurring at the anode before combining it with the cathode half-reaction. The two half-reactions involve the transfer of the same number of electrons ($n = 2$), so combining them simply means adding them together. The value of E°_{cell} is about $0.35 - (-1.25) = 1.60$ V. This value is about 50% larger than the E°_{cell} of the Zn/Cu^{2+} cell (which is 1.10 V). Therefore, compared to the Zn/Cu cell in Figure 18.6, the magnitude of its $\Delta G^\circ_{\text{cell}}$ value should be 50% larger than -212 kJ/mol, or about -300 kJ/mol.

Solve Reversing the $Zn(OH)_2$ half-reaction and adding it to the Ag_2O half-reaction, we get

This simplifies to

$$Ag_2O(s) + H_2O(\ell) + Zn(s) \rightarrow 2\ Ag(s) + Zn(OH)_2(s)$$

Calculating E°_{cell}:

$$E^\circ_{\text{cell}} = E^\circ_{\text{cathode}} - E^\circ_{\text{anode}}$$

$$= 0.342\ \text{V} - (-\ 1.249\ \text{V})$$

$$= 1.591\ \text{V}$$

Converting E°_{cell} to $\Delta G^\circ_{\text{cell}}$:

Think About It The positive value of E°_{cell} and negative value of $\Delta G^\circ_{\text{cell}}$ are expected because voltaic cell reactions are spontaneous. The calculated values are close to those we estimated.

Practice Exercise If a single-use alkaline battery (see Sample Exercise 18.3) produces a cell potential of 1.50 V, what is the value of ΔG_{cell}?

The $\Delta G^\circ_{\text{cell}}$ value of $-\ 307$ kJ for the silver oxide battery reaction in Sample Exercise 18.4 is based on the reaction of 1 mole of Ag_2O and 1 mole of Zn, which correspond to 232 g of Ag_2O and 65 g of Zn. The energy stored in a button battery (Figure 18.8), which has a mass of only 1 or 2 g, would be a tiny fraction of this calculated value. Moreover, no ions appear in the net ionic equation. Because all the reactants and products are solids, the net ionic equation and molecular equation are identical.

Glossary

Faraday constant (*F*)
the magnitude of electrical charge in 1 mole of electrons; its value to three significant figures is 9.65×10^4 C/mol e^2.

18.5 A Reference Point: The Standard Hydrogen Electrode

We can measure the value of E_{cell} by using a voltmeter, but can we measure the individual electrode potentials of the cathode and anode? It turns out that we can assign potentials to an individual electrode by arbitrarily assigning a value of zero volts to a half-reaction that serves as a reference point—namely, the standard potential for the reduction of hydrogen ions to hydrogen gas:

An electrode that generates this reference potential, called the standard hydrogen electrode (SHE), consists of a platinum electrode in contact with a solution of a strong acid ($[H^+] = 1.00\ M$) and hydrogen gas at a pressure of 1.00 bar (< 1 atm; **Figure 18.9**). The platinum is not changed by the electrode reaction. Rather, it serves as a chemically inert conveyor of electrons. Electrons are conveyed to the electrode surface when H^+ ions are reduced to hydrogen gas; electrons are conveyed away from the electrode surface when hydrogen gas is oxidized to H^+ ions. The potential of the SHE is the same for both half-reactions: 0.000 V.

To draw the cell diagram for a cell in which the SHE serves as the anode, we represent the SHE half of the cell as follows:

$Pt(s) \mid H_2(g,\ 1.00\ atm) \mid H^+(1.00\ M) \parallel$

This indicates that the anode half-reaction involves the oxidation of H_2 gas to H^+ ions. If the SHE is the cathode, then we diagram its half of the cell this way:

$\parallel H^+\ (1.00\ M) \mid H_2(g,\ 1.00\ atm) \mid Pt(s)$

This indicates that the cathode half-reaction involves the reduction of H^+ ions to H_2 gas.

Because the standard reduction (or oxidation) potential of the SHE is assigned a reference potential of 0.000 V, the measured $E°_{cell}$ of any voltaic cell in which a SHE is one of the two electrodes—either cathode or anode—can be considered the potential produced by the other electrode. This means that if we attach a voltmeter to the cell, the meter reading is the electrode potential of the other electrode. Suppose, for example, that a voltaic cell consists of a strip of zinc metal immersed in a 1.00 *M* solution of Zn^{2+} ions in one compartment and a SHE in the other (**Figure 18.10a**). Also suppose that a voltmeter is connected to the cell so that it measures the potential at which the cell pumps electrons from the zinc electrode to the SHE. This direction of electron flow means that the zinc electrode is the cell's anode and the SHE is the cathode of the cell. At 25°C the meter reads 0.762 V. We know that the value of *E*

$^{\circ}_{\text{cathode}}$ is that of the SHE (0.000 V) and that E°_{anode} is E°_{Zn}.

Inserting these values and symbols into Equation 18.2,

$$E^{\circ}_{\text{cell}} = E^{\circ}_{\text{cathode}} - E^{\circ}_{\text{anode}}$$

$$E^{\circ}_{\text{cell}} = E^{\circ}_{\text{SHE}} - E^{\circ}_{\text{Zn}}$$

$$0.762\text{ V} = 0.000\text{ V} - E^{\circ}_{\text{Zn}}$$

$$E^{\circ}_{\text{Zn}} = -0.762\text{ V}$$

This value is equal to the standard reduction potential of Zn^{2+} in Table A6.1:

In **Figure 18.10b**, the SHE is coupled to a copper electrode immersed in a 1.00 *M* solution of Cu^{2+} ions. In this cell, electrons flow from the SHE through an external circuit to the copper electrode at a cell potential of 0.342 V at 25°C. The direction of current flow means that the electrons are consumed at the copper electrode, making it the cathode. The value of E° for the copper half-reaction is calculated as follows:

$$E^{\circ}_{\text{cell}} = E^{\circ}_{\text{cathode}} - E^{\circ}_{\text{anode}}$$

$$= E^{\circ}_{\text{Cu}} - E^{\circ}_{\text{SHE}}$$

$$0.342\text{ V} = E^{\circ}_{\text{Cu}} - 0.000\text{ V}$$

$$E^{\circ}_{\text{Cu}} = 0.342\text{ V}$$

This half-reaction potential matches the value of E° for the reduction of Cu^{2+} to Cu metal in Table A6.1.

Even though the SHE serves as the reference for all E° values, it is cumbersome to use and maintain. Therefore, scientists have developed other reliable and more convenient reference electrodes for use in electrochemistry. One common choice is the silver–silver chloride electrode (**Figure 18.11**), which is based on the following half-reaction:

The Ag/AgCl electrode consists of a piece of silver wire coated with a thin layer of AgCl and immersed in a solution containing a high concentration (often a saturated solution) of KCl. Typically, the electrode connects with the solution in the cell through an ion-permeable porous ceramic plug like those that connect the two halves of the electrochemical cells in Figure 18.10.

CONNECTION A saturated solution contains the maximum concentration of a solute possible at a given temperature, as discussed in Section 4.7.

What would happen if we replaced the SHE in Figure 18.10 with a Ag/AgCl electrode in which [KCl] = 1.00 *M*? The voltmeter in Figure 18.10a would now read 0.984 V:

The voltmeter in Figure 18.10b would read:

$$E^\circ_{\text{cell}} = E^\circ_{\text{cathode}} - E^\circ_{\text{anode}} = 0.342\ \text{V} - 0.222 = 0.120\ \text{V}$$

The Ag/AgCl reference electrode and others of similar design are so widely used in electrochemistry that the electrode potentials used in many electrochemical experiments are not reported relative to a SHE, but rather to one of these other reference electrodes.

CONCEPT TEST

A cell consists of a SHE in one compartment and a Ni electrode immersed in a 1.00 *M* solution of Ni^{2+} ions in the other. If a voltmeter is connected to the electrodes as shown in **Figure 18.12**, what will be the value on the voltmeter's display? What would the voltmeter read if we replaced the SHE with an Ag/AgCl reference electrode?

Glossary

Multiplate anode (Pb)

FIGURE 18.13 The lead–acid battery that provides power to start most motor vehicles contains six cells. Each has an anode made of lead and a cathode made of PbO_2 immersed in a solution of 4.5 *M* H_2SO_4, which serves as both a reactant and background electrolyte. The electrodes are formed into plates and held in place by grids made of a lead alloy. The grids connect the cells in series so that the operating potential of the battery (12.0 V) is the sum of six E_{cell} values (each 2.0 V).

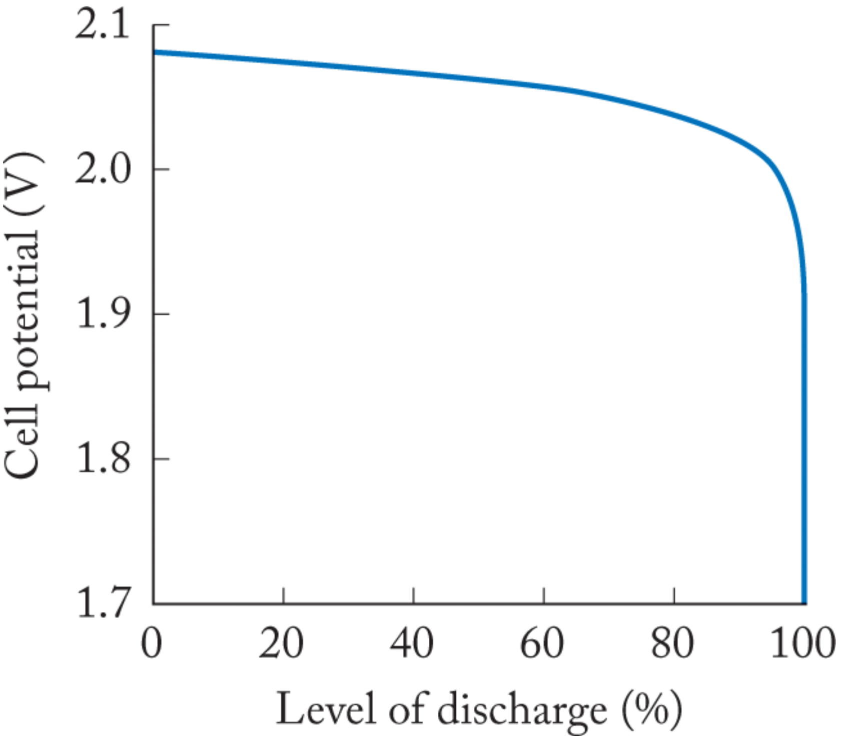

FIGURE 18.14 The potential of a cell in a lead–acid battery decreases as reactants are converted into products, but the change in potential is small until the battery is nearly completely discharged. Although the value of E°_{cell} is 2.041 V, a fully charged commercial battery has a slightly higher potential (shown here as 2.08 V) because the concentration of H_2SO_4 in its cells' electrolytes is greater than 1 *M*.

$$E_{\text{cell}} = 2.041\ \text{V} - \frac{0.0592\ \text{V}}{2} \log \frac{1}{[\text{H}^+]^2\,[\text{HSO}_4{}^-]^2}$$

$$E_{\text{cell}} = 2.041\ \text{V} - \frac{0.0592\ \text{V}}{2} \log \frac{1}{0.100^2 \times 0.100^2} = 1.923\ \text{V}$$

$$E_{\text{cell}} = E^\circ_{\text{cell}} - \frac{0.0592\ \text{V}}{n} \log Q = 1.104\ \text{V} - \frac{0.0592\ \text{V}}{2} \log \frac{1.90}{0.100}$$

$$E_{\text{cell}} = 1.104\ \text{V} - \frac{0.0592\ \text{V}}{2}(1.279) = 1.066\ \text{V}$$

CHEMTOUR

$$0 = E^\circ_{\text{cell}} - \frac{0.0592\ \text{V}}{n}\log K$$

$$\log K = \frac{nE^\circ_{\text{cell}}}{0.0592\ \text{V}} \tag{18.11}$$

$$\log K = \frac{nE^\circ_{\text{rxn}}}{0.0592\ \text{V}} \tag{18.12}$$

$$\text{Hg}^{2+}(aq) + 2\ \text{e}^- \rightarrow \text{Hg}(\ell) \qquad E^\circ = 0.851\ \text{V}$$

$$\text{Sn}^{4+}(aq) + 2\ \text{e}^- \rightarrow \text{Sn}^{2+}(aq) \qquad E^\circ = 0.154\ \text{V}$$

$$\log K = \frac{nE^\circ_{\text{rxn}}}{0.0592\ \text{V}} = \frac{2(0.697\ \cancel{\text{V}})}{0.0592\ \cancel{\text{V}}} = 23.55$$

$$K = 10^{23.55} = 4 \times 10^{23}$$

18.6 The Effect of Concentration on E_{cell}

Reactions stop when one of the reactants is completely consumed. This concept was the basis for our discussion of limiting reactants in Chapter 3. A commercial battery, on the other hand, usually stops operating at its rated cell potential—1.5 V for a flashlight battery—before its reactants are completely consumed. In other words, the battery “goes dead” before all the reactants are consumed. This happens because the cell potential of a voltaic cell depends on the concentrations of the reactants and products.

The Nernst Equation

In 1889, the German chemist Walther Nernst (1864–1941) derived an expression, now called the Nernst equation, that describes how cell potentials depend on reactant and product concentrations. We can reconstruct his derivation starting with Equation 17.14, which relates the change in free energy ΔG of any reaction to its change in free energy under standard conditions ΔG°:

Q represents the reaction quotient, which does not contain terms for pure solids and pure liquids.

CONNECTION In Section 17.7 we introduced the relationship between change in free energy and the reaction quotient Q. Writing expressions for reaction quotients was first explained in Section 14.5.

As a spontaneous reaction proceeds, concentrations of products increase, and concentrations of reactants decrease until the positive value of $RT \ln Q$ offsets the negative value of ΔG°. At that point, $\Delta G = 0$ and the reaction has reached chemical equilibrium.

Now let's write an expression analogous to Equation 17.14 that relates the cell potential under nonstandard conditions (i.e., E_{cell}) to E°_{cell}. We start by substituting $-nFE_{\text{cell}}$ for ΔG_{cell} and $-nFE^\circ_{\text{cell}}$ for $\Delta G^\circ_{\text{cell}}$:

$$-nFE_{\text{cell}} = -nFE^\circ_{\text{cell}} + RT\ln Q$$

Dividing all terms by $-nF$ gives

This is the equation Walther Nernst developed in 1889. We can obtain a very useful form of Equation 18.9 if we insert values for R [8.314 J/(mol · K)] and F (9.65×10^4 C/mol), assume $T = 298$ K, and convert the natural logarithm to a base-10 logarithm: $\ln Q = 2.303 \log Q$. With these changes, the Nernst equation becomes

Equation 18.10 allows us to predict how the potential (E_{cell} in V) of a voltaic cell at 298 K changes as the concentrations of products inside the cell increase and the concentrations of reactants decrease. As they do, Q increases and so does the log term in Equation 18.10. The negative sign in front of this term means that the value of E_{cell} decreases as reactants are converted into products. Eventually, E_{cell}

approaches zero. When it reaches zero, the cell reaction has achieved chemical equilibrium. The cell can no longer pump electrons through an external circuit, because it’s dead.

CONCEPT TEST

We can also use Equation 18.10 to calculate the potential of a single electrode. Consider the half-reaction at the Ag/Ag^+ electrode:

$Ag^+(aq) + e^- \rightarrow Ag(s)$ $E^\circ = 0.800$ V

Is the potential of this half-reaction at 25°C greater than or less than 0.800 V when the concentration of Ag^+ is 0.100 *M*?

Batteries are voltaic cells, so their cell potential should drop with usage. Let’s consider how much a cell potential can drop by focusing on the *lead–acid* battery used to start most car engines. These batteries each contain six electrochemical cells. Their anodes are made of Pb and their cathodes are made of PbO_2. Both electrodes are immersed in 4.5 *M* H_2SO_4 (**Figure 18.13**). The E_{cell} value of a fully charged battery is about 2.0 V. The six cells are connected in series so that the operating potential of the battery is the sum of the six cell potentials, or about 12 V.

As the battery discharges, $PbO_2(s)$ is reduced to $PbSO_4(s)$ at the cathodes:

$PbO_2(s) + 3\ H^+(aq) + HSO_4^-(aq) + 2\ e^- \rightarrow PbSO_4(s) + 2\ H_2O(\ell)$

$E^\circ = 1.685$ V

Also, Pb(*s*) is oxidized to $PbSO_4(s)$ at the anodes:

$Pb(s) + HSO_4^-(aq) \rightarrow PbSO_4(s) + H^+(aq) + 2\ e^-$

The reduction half-reaction consumes 2 moles of electrons, and the oxidation half-reaction involves the loss of 2 moles of electrons for each mole of lead that is oxidized.

The net ionic equation for the overall cell reaction is the sum of the two half-reactions:

$PbO_2(s) + Pb(s) + 2\,H^+(aq) + 2\,HSO_4^-(aq) \rightarrow 2\,PbSO_4(s) + 2\,H_2O(\ell)$

To calculate the value of E°_{cell}, we find the reduction potential for the half-reaction that corresponds to the reverse reaction at the anode in Table A6.1 (Appendix 6):

$PbSO_4(s) + H^+(aq) + 2\,e^- \rightarrow Pb(s) + HSO_4^-(aq) \qquad E^\circ = -0.356\ V$

Therefore,

$E^\circ_{cell} = E^\circ_{cathode} - E^\circ_{anode} = 1.685\ V - (-\,0.356\ V) = 2.041\ V$

As the battery discharges, the concentration of sulfuric acid decreases, and so does the value of E_{cell} calculated from the Nernst equation:

Note that there is no term in the numerator representing the quantity of $PbSO_4$ in the cell, nor are there terms in the denominator for the quantities of PbO_2 and Pb because all three battery components are solids. Assuming all three are present, the voltage produced by the battery depends only on the concentration of sulfuric acid in the solution in which the three solid components are immersed.

The decrease in E_{cell} is very gradual, however, not falling below 2.0 V until the battery is about 97% discharged, as shown in **Figure 18.14**. It decreases gradually because of the logarithmic relationship between Q and E_{cell}. If, for example, the concentration of sulfuric acid decreased by an order of magnitude, say, from 1.00 *M* to 0.100 *M*, then the value of E_{cell} would decrease by less than 6%—from 2.041 V to

As a result, most batteries can deliver current at a cell potential close to their “design” potential until they are almost completely discharged.

SAMPLE EXERCISE 18.5 Calculating E_{cell} from E°_{cell} and the Concentrations of Reactants and Products LO5

The standard potential (E°_{cell}) of a voltaic cell based on the Zn/Cu^{2+} ion reaction:

$Zn(s) + Cu^{2+}(aq) \rightarrow Zn^{2+}(aq) + Cu(s)$

is 1.104 V. What is the value of E_{cell} at 25°C when the concentration of Cu^{2+} is 0.100 *M* and the concentration of Zn^{2+} is 1.90 *M*?

Collect and Organize We are given the standard cell potential and the concentrations of Cu^{2+} and Zn^{2+}, and we are asked to determine the value of E_{cell}. The Nernst equation enables us to calculate E_{cell} values for different concentrations of reactants and products. This equation requires us to work with the reaction quotient Q, which we know from Section 14.5 to be the mass action expression for the reaction. Solid copper and zinc are also part of the reaction system, but no terms for pure solids appear in reaction quotients.

Analyze The only term in the numerator of the Q expression for this cell reaction is $[Zn^{2+}]$, and the only one in the denominator is $[Cu^{2+}]$. The two solids, metallic Cu and Zn, are not included. Each Cu^{2+} ion gains two electrons, and each Zn atom donates two electrons, so the value of n in the Nernst equation is 2. The value of $[Zn^{2+}]$ is greater than $[Cu^{2+}]$, which makes $Q > 1$. The negative sign in front of the $0.0592/n \times \log Q$ term in Equation 18.10 means that the calculated value of E_{cell} should be less than the value of E°_{cell}.

Solve Substituting the values of $[Zn^{2+}]$ and $[Cu^{2+}]$ in the Nernst equation gives

---

Think About It The calculated E_{cell} value is less than E°_{cell} (as predicted), but it is only 0.038 V less because the logarithmic dependence of cell potential on reactant and product concentrations minimizes the impact of changing concentrations.

Practice Exercise The standard cell potential of the zinc–air battery (Figure 18.7) is 1.65 V. If the partial pressure of oxygen in the air at 25°C diffusing through its cathode is 0.21 atm, what is the cell potential? Assume the cell reaction is

$$2\ Zn(s) + O_2(g) + 2\ H_2O(\ell) \rightarrow 2\ Zn(OH)_2(s)$$

E° and *K*

Cell Potential, Equilibrium, and Free Energy

When the cell reaction of a voltaic cell reaches chemical equilibrium, $\Delta G_{cell} = E_{cell} = 0$ and $Q = K$. Equation 18.10 then becomes

Rearranging this equation gives

We can use Equation 18.11 to calculate the equilibrium constant for any redox reaction at 25°C, not just those in electrochemical cells. For the more general case, we substitute E°_{rxn} for E°_{cell}:

SAMPLE EXERCISE 18.6 Calculating *K* for a Redox Reaction from the Standard Potentials of Its Half-Reactions LO6

Many procedures for determining mercury levels in environmental samples involve reducing Hg^{2+} ions to elemental Hg by using Sn^{2+} ions. Use the appropriate E° values from Table A6.1 to calculate the equilibrium constant at 25°C for the reaction

$Sn^{2+}(aq) + Hg^{2+}(aq) \rightarrow Sn^{4+}(aq) + Hg(\ell)$

Collect and Organize Equation 18.12 relates the equilibrium constant for any redox reaction to the standard potential E°_{rxn}. To calculate E°_{rxn}, we need to find the difference between the appropriate standard reduction potentials. Table A6.1 lists two half-reactions involving our reactants and products:

Analyze The problem states that Hg^{2+} ions are reduced by Sn^{2+} ions, so Sn^{2+} is the reducing agent in the reaction, which means that it must be oxidized. As a result, the mercury half-reaction occurs at the cathode and the second reaction occurs at the anode, so we must subtract its standard potential from that of the mercury half-reaction. The difference between the two half-reaction potentials is about $+0.7$ V, so the right side of Equation 18.12 will be about $(2 \times 0.7)/0.06 < 23$, and the value of K should be about 10^{23}.

Solve We obtain the standard potential for the reaction from a modified version of Equation 18.2:

$$E^\circ_{\text{rxn}} = E^\circ_{\text{cathode}} - E^\circ_{\text{anode}} = 0.851 \text{ V} - (-0.154 \text{ V}) = 0.697 \text{ V}$$

Using this value for E°_{rxn} in Equation 18.12 and a value of 2 for n (because there are two moles of electrons), we have

---

Think About It The calculated value is quite close to what we estimated. Note how a E°_{rxn} value of less than 1 V corresponds to a huge equilibrium constant, indicating that the reaction essentially goes to completion. The calculated value of K has only one significant figure, which may seem like too few because the uncertain starting values both had three. However, the value of K was calculated from $10^{23.55}$, and the two digits to the left of the decimal point became the exponent in the final K value. Only the first digit after the decimal was significant (the second “5” was carried through the calculation to avoid rounding error), which left the final K value with only one digit before the exponent.

Practice Exercise Use the appropriate standard reduction potentials from Table A6.1 to calculate the value of K at 25°C for the reaction

$$5\ Fe^{2+}(aq) + MnO_4^{-}(aq) + 8\ H^{+}(aq) \rightarrow 5\ Fe^{3+}(aq) + Mn^{2+}(aq) + 4\ H_2O(\ell)$$

Before ending our discussion of how to derive equilibrium constant values at 25°C from E°_{cell} values, we should note that measuring the potential of an electrochemical reaction allows us to calculate equilibrium constant values that may be too large or too small to determine from the equilibrium concentrations of reactants and products. A value of K as large as that calculated in Sample Exercise 18.6 could not be obtained by analyzing the composition of an equilibrium reaction mixture because the concentrations of the reactants would be too small to be determined accurately. Similarly, a cell potential of about -1 V would correspond to a tiny K value and concentrations of products that are too small to be determined quantitatively.

Table 18.1 summarizes how the values of K and E°_{cell} are related to each other and to the change in free energy ($\Delta G^\circ_{\text{cell}}$) of a cell reaction under standard conditions. If we know any one of the quantities in Table 18.1, we can calculate the other two. Spontaneous electrochemical reactions have $E^\circ_{\text{cell}} > 0$ and $K > 1$. The connection between positive cell potential (E_{cell}) and reaction spontaneity applies even under nonstandard conditions. Keep in mind, too, that even small positive values of E°_{cell} (only a fraction of a volt, for example) correspond to very large K values and to cell reactions that go nearly to completion.

Glossary

Nernst equation	an equation relating the potential of a cell (or half-cell) reaction to its standard potential (E°) and to the concentrations of its reactants and products.
cell potential (E_{cell})	the force with which an electrochemical cell can pump electrons through an external circuit.

propylene carbonate, are among the solvents used for the background electrolytes in lithium-ion batteries.

$$3.4\ \text{W} \cdot \text{h} = 3.4\,\frac{\text{J}}{\text{s}} \cdot \text{h} = 3.4\,\frac{(\text{C} \cdot \text{V})}{\text{s}} \cdot \text{h}$$

$$3.4\,\frac{(\text{C} \cdot \text{V})}{\cancel{\text{s}}} \cdot \cancel{\text{h}} \times \frac{3600\ \cancel{\text{s}}}{\cancel{\text{h}}} = 12{,}240\ \text{C} \cdot \text{V}$$

$$12{,}240\ \text{C} \cdot \cancel{\text{V}} \times \frac{1}{3.6\ \cancel{\text{V}}} = 3400\ \text{C}$$

$$3400\ \cancel{\text{C}} \times \frac{\cancel{1\ \text{mol e}^-}}{9.65 \times 10^4\ \cancel{\text{C}}} \times \frac{\cancel{1\ \text{mol Li}^+}}{\cancel{1\ \text{mol e}^-}} \times \frac{6.94\ \text{g Li}^+}{\cancel{1\ \text{mol Li}^+}} = 0.24\ \text{g Li}^+\ \text{ions}$$

18.7 Relating Battery Capacity to Quantities of Reactants

An important performance characteristic of a battery is its capacity to do electrical work—that is, to deliver electrical charge at the designed cell potential. This capacity—the amount of electrical work done—is defined by Equation 18.4, $w_{\text{elec}} = -CE_{\text{cell}}$, where w_{elec} is the quantity of electrical charge (C) expressed in coulombs (C) delivered at a cell potential (E_{cell}) expressed in volts.

Another important unit in electricity is the *ampere* (A), which is the SI base unit (see Table 1.2) of electrical current and equal to a flow of one coulomb of charge per second. In equation form:

Rearranging the terms in Equation 18.13 gives us

Combining this expression with the link between free energy and electrical energy, 1 J = 1 C · V:

A coulomb (ampere-second) is a small quantity of charge, so the capacities of batteries even as small as those used to power LED flashlights are often expressed in units such as ampere-hours. For example, the rechargeable AA batteries in **Figure 18.15** are rated at about 2.5 Ah or 2500 mAh (milliampere-hours).

The units used to express the energy content of large, fully charged batteries, such as batteries used to power all-electric or hybrid vehicles, incorporate the quantity of electrical charge they can store and the voltage with which that charge is delivered to the vehicle's electric motor. These ratings are based on a unit of electrical *power*, that is, the *rate* at which energy is delivered. The SI unit of power is the *watt* (W), which is equal to one joule of energy produced (or consumed) per second. In other words:

$1\ \text{W} = 1\ \text{J/s}$

Combining this definition with Equation 18.15:

Like a joule of energy, a watt of power is a small quantity, so the power of large electric devices, such as the electric motors in all-electric vehicles, are usually expressed in kilowatts (kW), and the energy capacities of the batteries that power those motors are usually expressed in kilowatt-hours (kWh). To appreciate how much energy this unit represents, let's calculate how many joules there are in one kilowatt-hour:

Nickel–Metal Hydride Batteries

Hybrid vehicles such as the Toyota Prius are powered by combinations of small gasoline engines and electric motors. Electricity for the motors comes from battery packs (**Figure 18.16**) made of dozens of nickel–metal hydride (NiMH) cells. At the cathodes in these cells, NiO(OH) is reduced to $Ni(OH)_2$, and at the anodes, made of one or more transition metals, hydrogen atoms are oxidized to H^+ ions. The electrodes are separated by aqueous KOH.

The cathode half-reaction is

$NiO(OH)(s) + H_2O(\ell) + e^- \rightarrow Ni(OH)_2(s) + OH^-(aq)$

At the anode, hydrogen is present as a metal hydride. To write the anode half-reaction, we use the generic formula MH, where M stands for a transition metal or metallic compound that forms a hydride. In a basic background electrolyte, the anode oxidation half-reaction is

$$MH(s) + OH^-(aq) \rightarrow M(s) + H_2O(\ell) + e^-$$

The standard potential of this half-reaction depends on the chemical properties of MH, but generally the value is near that of the SHE, or about 0.0 V.

The overall cell reaction from these two half-reactions is

$$MH(s) + NiO(OH)(s) \rightarrow M(s) + Ni(OH)_2(s)$$

The value of E°_{cell} for the NiMH battery cannot be calculated precisely because we have only an approximate value of E°_{anode}. Most NiMH cells are rated at about 1.2 V.

Now let's relate the electrical energy stored in a battery (in other words, its capacity) to the quantities of reactants needed to produce that energy. Suppose a rechargeable AA NiMH battery is rated to deliver 2.5 ampere-hours of electrical charge at 1.2 V. How much NiO(OH) must be converted to $Ni(OH)_2$ to deliver this much charge? We need to relate the quantity of charge to a number of moles of electrons, then convert that to an equivalent number of moles of reactant, and finally to a mass of reactant. An ampere is defined as a coulomb per second, so the quantity of electrical charge delivered is

The Faraday constant (9.65×10^4 C/mol e^-) can then be used to convert quantity of electrical charge (in C) to the number of moles of charge, which is equal to the number of moles of electrons that flow from the battery:

According to the stoichiometry of the cathode half-reaction, the mole ratio of NiO(OH) to electrons is 1:1. Therefore, the mass of NiO(OH) consumed is

The mass of an AA battery is about 30 g, so this mass of NiO(OH) is reasonable if we allow for the mass of the anode, background electrolyte, and exterior shell.

Lithium-Ion Batteries

The NiMH batteries used in hybrid vehicles do not have the capacity to power them at highway speeds or for extended distances. Nor do these batteries have the energy capacity to power all-electric vehicles such as the Chevrolet Bolt shown on the opening page of this chapter. The electrical power demands of these vehicles require batteries with much greater ratios of energy capacity to battery size. The current technology of choice in these applications is the lithium-ion battery (**Figure 18.17**), the same kind of battery that powers laptop computers, cell phones, and digital cameras.

CONNECTION Crystal structures and octahedral holes were discussed in Section 12.3.

In a lithium-ion battery, Li^+ ions are stored in a graphite or silicon anode. During discharge, these ions move through a nonaqueous electrolyte to a porous cathode. These cathodes are made of transition metal oxides or phosphates that can form stable complexes with Li^+ ions. One popular cathode material is cobalt(IV) oxide. Lithium-ion batteries with these cathodes have cell potentials of about 3.6 V (three times that of a NiMH battery). The cell reaction for a lithium-ion battery with a cobalt oxide cathode is

In a fully charged cell, $x = 1$, which makes the cathode lithium-free CoO_2. As the cell discharges and Li^+ ions move from the carbon anode to the cobalt oxide cathode, the value of x falls toward zero. To balance this flow of positive charges inside the cell, electrons flow from the anode to the cathode through an external circuit. When fully discharged, the cathode is $LiCoO_2$, and the oxidation number of Co is reduced to $+3$. The electrodes in a lithium-ion battery may react with oxygen and water, so the background electrolytes (e.g., $LiPF_6$) are dissolved in polar organic solvents, such as tetrahydrofuran, ethylene carbonate, or propylene carbonate (**Figure 18.18**).

CONCEPT TEST

Which element is oxidized, and which is reduced in the Li^+ ion cell reaction (Equation 18.16)?

SAMPLE EXERCISE 18.7 Relating Mass of Reactant in an Electrochemical Reaction to Quantity of Electrical Charge LO7

The capacity of the lithium-ion battery in a digital camera is 3.4 W · h at 3.6 V. How many grams of Li^+ ions must move from anode to cathode to produce this much electrical energy?

Collect and Organize We are asked to relate the electrical energy generated by an electrochemical cell to the mass of the ions involved in generating that energy. We know the cell potential and its capacity in the energy unit of watt-hours. Given these starting points and the eventual need to calculate moles and then grams of Li^+ ions, the following equivalencies may be useful:

1 watt = 1 joule/second (1 W = 1 J/s) and 1 joule = 1 coulomb-volt (1 J = 1 C · V)

We may also need to use the Faraday constant, 9.65×10^4 C/mol e^-.

Analyze Combining the two equations above gives us one that relates watts to coulombs, volts, and seconds: 1 W = 1 (C · V)/s. Multiplying a value with the units on the right side of this equation by a time (in seconds) cancels out the denominator and gives us a quantity in (C · V). Dividing this quantity by the voltage (V) of the battery yields coulombs (C) of charge. Faraday's constant relates coulombs of charge to moles of electrons, which are related 1:1 to moles of Li^+ ions, which can be converted into grams of Li^+ ions by multiplying by the molar mass of Li.

The initial value, 3.4 W · h, when multiplied by 3600 s/h and then divided by 3.6 V produces roughly 3000 C of charge. Divided by the Faraday constant (~10^5) gives us about 0.03 mol of electrons = 0.03 mol Li^+ ions, which, when multiplied by a molar mass of about 7 g/mol, should produce a mass of about 0.2 g Li^+ ions.

Solve Using the given energy and cell-potential values in the above unit conversion series, we get

Think About It The calculated mass of migrating Li^+ ions is close to our single-digit estimate and, therefore, reasonable. The battery that is the subject of this exercise has a mass of about 22 g, so the migrating Li^+ ions make up only about $(0.24\ g/22\ g) \times 100\% = 1\%$ of the battery's mass. This small percentage is not surprising given the masses of the other required components of the cell, including an anode in which Li^+ ions are surrounded by hexagons of six carbon atoms and a cathode made of CoO_2, for example, which has 13 times the molar mass of Li.

Practice Exercise Magnesium metal is produced by passing an electrical current through molten $MgCl_2$. The reaction at the cathode is

$$Mg^{2+}(\ell) + 2\ e^- \rightarrow Mg(s)$$

How many grams of magnesium metal are produced if an average current of 63.7 A flows for 4.50 h? Assume all the current is consumed by the half-reaction shown.

Learning Objectives

18.8 Corrosion: Unwanted Electrochemical Reactions

We began this chapter with a Particulate Review question based on the corrosion of the metal surface of a car. We now examine this process and some of the half-reactions that contribute to it in more detail. We have seen how half-reactions are physically separated in electrochemical cells. It turns out they are often separated in corrosion reactions as well; in this respect, the chemistry of corrosion is much like the electrochemical reactions in voltaic cells. Corrosion is the process in which metals are oxidized by substances in the environment, leading to deterioration from spontaneous electrochemical reactions. This definition is reflected in several of the factors that promote corrosion:

1. *The presence of water*. Metals that are left out in the rain and snow rust or corrode more rapidly than those that are under cover. For example, objects made from iron spontaneously rust in moist air, as iron reacts with O_2 from the air in a series of reactions that includes

$$4\ Fe(s) + 3\ O_2(g) + 2\ H_2O(\ell) \rightarrow 4\ FeO(OH)(s)$$

2. *The presence of electrolytes*. Just as electrolytes carry electrical current between anodes and cathodes and facilitate cell reactions, corrosion is much more rapid in seawater, for example, than in freshwater.
3. *Contact between dissimilar metals*. Metals corrode more rapidly when in contact with other metals that are less likely to be oxidized; that is, other metals that have higher reduction potentials.

Let’s explore the impact of these factors using the Statue of Liberty as a model. As the statue was built, its exterior copper sheets were attached to and supported by an interior network of iron beams (**Figure 18.19**). The French designers of the statue knew that these two metals in contact with each other might someday pose a corrosion problem because the two have very different electrochemical properties. The difference is reflected in the standard reduction potentials of these elements when they oxidize under neutral to slightly basic conditions, as occur in marine environments:

As we discussed in Section 18.3, the greater (less negative) E° of $Cu(OH)_2$ means that it is more easily reduced under standard conditions than FeO(OH), and Fe is more easily oxidized than Cu. We can confirm this by reversing the iron half-reaction and combining it with the copper half-reaction. We also need to multiply the iron half-reaction by 2 and the copper half-reaction by 3 to balance the loss and gain of electrons:

or

The resulting equation could be that of an electrochemical cell that has a copper cathode coated in $Cu(OH)_2$ and an iron anode. We obtain the standard potential for the reaction by substituting the reduction potentials for each half-reaction (Appendix A6.1) into Equation 18.2:

$$E^\circ_{\text{rxn}} = E^\circ_{\text{cathode}} - E^\circ_{\text{anode}} = -0.230\text{ V} - (-\ 0.87\text{ V}) = 0.64\text{ V}$$

The reaction has a positive standard cell potential, which means that under standard conditions, iron in contact with copper will spontaneously oxidize to FeO(OH) as $Cu(OH)_2$ is reduced.

To suppress the reaction in Equation 18.17, insulators made of asbestos mats soaked in shellac were used to separate the statue's iron skeleton from its copper exterior. Unfortunately, these insulators did not stand up to the humid, marine environment of New York Harbor. They absorbed water vapor and seawater spray, eventually turning into electrolyte-soaked sponges that promoted rather than retarded iron oxidation.

What are the sources of the $Cu(OH)_2$ that are the oxidizing agents in Equation 18.17? The light green patina of the Statue of Liberty (see Figure 18.19) results from the presence of copper(II) compounds such as $Cu(OH)_2$, formed by the oxidation of Cu metal by atmospheric oxygen:

$$O_2(g) + 2\ H_2O(\ell) + 2\ Cu(s) \rightarrow 2\ Cu(OH)_2(s) \quad (18.18)$$

This reaction occurs on an expansive surface of copper metal, which is also an excellent conductor of electricity. Unfortunately, this copper surface was in contact with the statue's iron skeleton through the water-logged, ion-rich asbestos mats. This connection meant that the reactions in Equations 18.17 and 18.18 were linked together. Equation 18.19 describes the resulting interior and exterior reactions:

---

or

Note how the copper half-reaction has disappeared from the overall reaction. Thus, the statue's copper exterior functions as a giant electron delivery system, allowing electrons to flow from iron atoms —as they oxidize to FeO(OH) inside the statue—to molecules of atmospheric O_2 on the exterior surface. The overall effect was a dramatic increase in the rate of oxidation of the original iron skeleton. The reaction in Equation 18.19 resulted in severe deterioration of the skeletal network that held up the Statue of

Liberty, so much so that in the 1980s the iron skeleton had to be replaced with one made of corrosion-resistant stainless steel.

Deterioration of the Statue of Liberty is not an isolated incident. According to one industrial estimate, the direct and indirect cost of corrosion to the U.S. economy exceeds $1 trillion per year. Worldwide, the cost is over $2 trillion. These figures include the costs to repair or replace corroded equipment and structures and to protect them against corrosion. The latter category includes money spent on protective coatings, including paint and chemical or electrochemical modification of metal surfaces to make them less reactive.

Another widely used method for inhibiting corrosion involves chemically bonding metal oxide coatings to metal surfaces. For example, a method called *bluing* is widely used to protect steel tools, gun barrels, wood-burning stoves, and other steel materials. The name comes from the distinctive very dark blue color of a surface layer of magnetite (Fe_3O_4), which can be reaction-bonded to steel. Formation of a protective oxide layer is also the mechanism that makes stainless steel resistant to corrosion. Although the main ingredient in all forms of stainless steel is iron, chromium is also present. Oxidation of surface Cr atoms forms a durable protective layer of Cr_2O_3. Similarly, objects made of aluminum are protected by a surface layer of Al_2O_3 that strongly adheres to the underlying metal and inhibits further oxidation.

Another way to protect metal structures, especially those in contact with seawater (**Figure 18.20**), involves attaching to them objects made of even more reactive metals. These objects are called *sacrificial* anodes. As their name implies, their role is to form a voltaic cell with the protected structure in which the object is the anode and the structure is the cathode, so that the sacrificial anodes oxidize and the structure does not. This preservation technique is called *cathodic protection*. Many of the sacrificial anodes used in the marine industry are made of zinc or aluminum/magnesium alloys.

$$\mathrm{Zn}(s) + 2\,\mathrm{OH}^-(aq) \rightarrow \mathrm{ZnO}(s) + \mathrm{H_2O}\,(\ell) + 2\,\mathrm{e}^-$$

$$\mathrm{Mg}(s) + 2\,\mathrm{OH}^-(aq) \rightarrow \mathrm{MgO}(s) + 3\,\mathrm{H_2O}\,(\ell) + 2\,\mathrm{e}^-$$

$$2\ \mathrm{Al}(s) + 6\ \mathrm{OH}^-(aq) \rightarrow \mathrm{Al}_2\mathrm{O}_3\ (s) + 3\ \mathrm{H}_2\mathrm{O}\ (\ell) + 6\ \mathrm{e}^-$$

These materials have the benefit of forming oxide coatings as they oxidize, which partially protect them and slow the rate at which they oxidize further, thereby extending their life span.

$$\times \frac{1\ \cancel{\text{A}}\cdot\cancel{\text{s}}}{1\ \cancel{\text{C}}} \times \frac{1}{1.00\ \cancel{\text{A}}} \times \frac{1\text{ min}}{60\ \cancel{\text{s}}} = 11.3\text{ min}$$

FIGURE 18.22 The Oscar statuettes given out at Academy Awards ceremonies are made of an alloy of tin, antimony, and copper that is electroplated with three different materials: copper, nickel silver (a silvery alloy of copper, nickel, and zinc), and a final layer of 24-karat gold.

18.9 Electrolytic Cells and

Rechargeable Batteries

Lead–acid, NiMH, and lithium-ion batteries are rechargeable, which means that their spontaneous ($\Delta G < 0$) cell reactions that convert chemical energy into electrical work can be forced to run in reverse. Recharging happens when external sources of electrical energy are applied to the batteries. This electrical energy is converted into chemical energy as it drives nonspontaneous ($\Delta G > 0$) reverse cell reactions, reforming reactants from products. To make this possible, the products of the original cell reactions must be substances that either adhere to, or are embedded in, the electrodes and are available to react with the electrons supplied to the cathodes and drawn away from the anodes by the external power supply.

When a car's lead–acid battery (**Figure 18.21**) discharges, electrons flow out of the $(-)$ terminal, which is connected to the battery's Pb electrodes, as atoms of Pb are oxidized to Pb^{2+} ions, forming $PbSO_4$ and releasing electrons that flow toward the $(-)$ terminal. At the same time, electrons flow into the positive terminal, which is connected to the battery's PbO_2 electrodes. The incoming electrons are consumed as Pb^{4+} ions in PbO_2 are reduced to Pb^{2+} ions in $PbSO_4$. Thus, the Pb electrodes serve as anodes during discharge and the PbO_2 electrodes serve as cathodes.

To recharge the battery, the flow of electrons is reversed as they are pumped from the $(+)$ electrode and into the $(-)$ electrode by an alternator driven by the car's engine. The alternator creates an opposing electrical potential that is greater than that of the battery, forcing the two half-reactions that occur during the discharge cycle to run in reverse, as shown in Figure 18.22. Any $PbSO_4$ that formed on the Pb electrodes during discharge is reduced back to Pb metal:

$$PbSO_4(s) + H^+(aq) + 2\ e^- \rightarrow Pb(s) + HSO_4{}^-(aq)$$

and any $PbSO_4$ that formed on the PbO_2 electrodes is oxidized back to PbO_2:

$$PbSO_4(s) + 2\ H_2O(\ell) \rightarrow PbO_2(s) + 3\ H^+(aq) + HSO_4{}^-(aq) + 2\ e^-$$

In other words, the roles of the two sets of electrodes have been reversed when the battery is recharged: the Pb electrodes connected to the (−) terminal are the cathodes because they are the electrodes where reduction takes place, and the PbO_2 electrodes connected to the (+) terminal are the anodes because they are the electrodes where oxidation takes place.

SAMPLE EXERCISE 18.8 Calculating the Time Required to Oxidize a Quantity of Reactant LO7

If a battery charger for AA NiMH batteries supplies a charging current of 1.00 A, how many minutes does it take to oxidize 0.649 g of $Ni(OH)_2$ to NiO(OH)?

Collect, Organize, and Analyze During the discharge of a NiMH battery, the spontaneous cathode half-reaction is

$$NiO(OH)(s) + H_2O(\ell) + e^- \rightarrow Ni(OH)_2(s) + OH^-(aq)$$

During recharging, the reverse of this half-reaction takes place:

$$Ni(OH)_2(s) + OH^-(aq) \rightarrow NiO(OH)(s) + H_2O(\ell) + e^-$$

One mole of electrons is produced for each mole of $Ni(OH)_2$ consumed. Our first steps are to convert 0.649 g of $Ni(OH)_2$ into moles of $Ni(OH)_2$ and then into moles of electrons. We can use the Faraday constant to convert moles of electrons to coulombs of charge. A coulomb is the same as an ampere-second (Equation 18.14), so dividing by the charging current gives us seconds of charging current. The unit conversions to minutes of charging time are summarized as follows:

Solve

Think About It A charging time of 11.3 min may seem short, but it is reasonable given the relatively small quantity of $Ni(OH)_2$ to be oxidized (0.649 g), which is much less than the total quantity of $Ni(OH)_2$ in a fully charged AA NiMH battery [8.6 g $Ni(OH)_2$, as calculated in Section 18.7].

Practice Exercise Suppose that a car's starter motor draws 230 A of current for 6.0 s to start the car. What mass of Pb is oxidized in the battery to supply this much electricity?

Electrolysis is used in many other processes besides recharging batteries. Electrolytic cells are used to electroplate thin layers of silver, gold, and other metals onto objects, giving these objects the appearance, resistance to corrosion, and other properties of the electroplated metal, but at a fraction of the cost of fabricating the entire object out of the metal (**Figure 18.22**).

In the chemical industry, electrolysis of molten salts is used to produce highly reactive substances, such as sodium, chlorine, and fluorine; alkali and alkaline earth metals; and aluminum. When NaCl, for instance, is heated to just above its melting point (above 800°C), it becomes an ionic liquid that can conduct electricity. If a sufficiently large potential is applied to carbon electrodes immersed in the molten NaCl, sodium ions are attracted to the negative electrode and are reduced to sodium metal, while chloride ions are attracted to the positive electrode and oxidized to Cl_2 gas:

$$2\ Na^+(\ell) + 2\ Cl^-(\ell) \rightarrow 2\ Na(\ell) + Cl_2(g)$$

A final note about how the anode and cathode vary in voltaic and electrolytic cells is in order. As we saw in Section 18.2, the reactions in voltaic cells are spontaneous. These cells pump electrical current through external circuits and electric devices with a force equal to their cell potentials. The anode in a voltaic cell is negative because an oxidation half-reaction supplies negatively charged electrons to the device powered by the cell. Electrons flow from the device into the positive battery terminal that is connected to the cathode, where these electrons are consumed in a reduction half-reaction.

The reactions in electrolytic cells are nonspontaneous. They require electrical energy from an external power supply. When the negative terminal of such a power supply is connected to the cathode of the battery, the power supply pumps electrons into the cathode, where they are consumed in reduction half-reactions. Electrons are pumped away from the anode, where they were generated in an oxidation half-reaction, toward the positive terminal of the power supply. As a result, the cathode of an electrolytic cell is the negative electrode, but the cathode of a voltaic cell is the positive electrode. Similarly, the anode of an electrolytic cell is the positive electrode, but the anode of a voltaic cell is the negative electrode. These electrode differences between voltaic and electrolytic cells make sense if we keep in mind the fundamental definitions:

- Anodes are electrodes where oxidation takes place.
- Cathodes are electrodes where reduction takes place.

CONCEPT TEST

The electrolysis of molten NaCl produces liquid Na metal at the cathode and Cl_2 gas at the anode. However, the electrolysis of an aqueous solution of NaCl also produces a gas at the cathode. Based on the standard potentials in Table A6.1, predict which gas forms at the cathode.

Learning Objectives

- Use the Faraday constant to relate quantity of charge to changes in the quantities of reactants and products in cell reactions **Return to Sample Exercises 18.7, 18.8**

$$H_2(g) \rightarrow 2\,H^+(aq) + 2\,e^- \qquad E^\circ = 0.000\ V$$

18.10 Fuel Cells and Flow Batteries

Fuel cells are promising energy conversion devices for many applications, from powering office buildings to cruise ships to electric vehicles. Fuel cells are voltaic cells, but they differ from batteries in that their supplies of reactants are constantly renewed. Fuel cells are energy conversion devices that continue to supply electricity as long as fuel and oxygen are delivered to the anode and cathode, respectively. Therefore, they do not “discharge”: they never run down, and they don’t die unless their fuel supply is cut off. From a thermodynamic perspective, most batteries are closed systems, whereas fuel cells are open systems.

In a typical fuel cell, electrons are supplied to an external circuit by the oxidation of H_2 at the anode. Electrons are consumed by the reaction of O_2 with protons migrating through the electrolyte to the cathode. Chemical energy from the reaction of hydrogen with oxygen is converted directly into electrical energy, and the net fuel cell reaction is

$$2\ H_2(g)\ +\ O_2(g) \rightarrow 2\ H_2O(\ell)$$

The fuel cells used to power electric vehicles consist of metallic or graphite electrodes separated by a hydrated polymeric material called a *proton-exchange membrane* (PEM). The PEM serves as both an electrolyte and a barrier that prevents crossover and mixing of the fuel and oxidant (**Figure 18.23**). The electrodes are carbon-supported transition metal catalysts dispersed in a layer upon the PEM. The catalytic layers speed up the electrode half-reactions. Platinum catalysts promote the breaking of H–H bonds during the oxidation of H_2 gas to H^+ ions at the anode:

At the cathode, a platinum–nickel alloy with the nominal composition Pt_3Ni is particularly effective in catalyzing the formation of free O atoms from O_2 molecules that are part of the reduction half-reaction:

Hydrogen ions that form at the anode move through the PEM to the cathode, where they combine with the free O atoms formed on the Pt_3Ni catalyst surface and electrons from the external circuit. This migration of positive charges across the PEM electrolyte is concurrent with the flow of electrons through the device in the external circuit.

A single PEM fuel cell typically delivers useful currents at cell potentials of about 0.8 V. The operating cell voltage is less than the expected E°_{cell} value of 1.23 V because some of the energy of combustion is wasted as heat. When these cells are assembled into fuel cell *stacks*, they can produce 100 kW of electrical power. That is enough to give a midsize car, such as the one in **Figure 18.24**, a top speed of 160 km/h (100 mi/h).

PEM fuel cells are well suited for use in vehicles because they are compact and lightweight, and they operate at moderate temperatures (60°C–80°C). It turns out that the performance of nearly all fuel cells is better at above-ambient temperatures because the rates of the half-reactions increase with temperature, as predicted by the Arrhenius equation. The increase in rate results in higher efficiency and more power.

Some fuel cells use basic electrolytes such as concentrated KOH. Pure O_2 is supplied to a cathode made of porous graphite containing a nickel catalyst, and H_2 gas is supplied to a graphite anode containing nickel(II) oxide. Hydroxide ions formed during O_2 reduction at the cathode,

move through the cell to the anode, where they combine with H_2 as it is oxidized to water:

$$2\ H_2(g) + 4\ OH^-(aq) \rightarrow 4\ H_2O(\ell) + 4\ e^-$$

This oxidation half-reaction is the reverse of the following reduction half-reaction in Table A6.1:

This basic pair of standard electrode potentials yields the same E°_{cell} value,

$$E^\circ_{\text{cell}} = 0.401\text{ V} - (-0.828\text{ V}) = 1.229\text{ V}$$

---

as the acidic pair described previously:

$$E^\circ_{\text{cell}} = 1.229\text{ V} - 0.000\text{ V} = 1.229\text{ V}$$

CONNECTION The temperature dependence of reaction rates (the Arrhenius equation, $k = Ae^{-E_a/RT}$) was first discussed in Section 13.4.

This equality is logical because the energy (ΔG°) released under standard conditions by the oxidation of hydrogen gas to form liquid water should have only one value, which means that E°_{cell} should have only one value, independent of electrolyte pH. What, then, is the advantage of the alkaline fuel cell? Although the *thermodynamics* of the cell are independent of pH, the *kinetics* of oxygen reduction are much better in an alkaline environment.

The same chemical energy that is released in fuel cells could also be obtained by burning hydrogen gas in an internal combustion engine. However, typically only about 20%–25% of the chemical energy in the fuel burned in such an engine is converted into mechanical energy; most is lost to the surroundings as heat instead. In contrast, fuel-cell technologies can convert up to about 80% of the energy released in a fuel-cell redox reaction into electrical energy. The electric motors they power are also about 80% efficient at converting electrical energy into mechanical energy. Thus, the overall conversion efficiency of a fuel-cell–powered car is theoretically as high as (80% × 80%), or 64%. Actually, the measured efficiency of the propulsion system of the car in Figure 18.24 is about 60%, which is still more than twice that of an internal combustion engine. In addition, H_2-fueled vehicles emit only water vapor—they produce no oxides of nitrogen, no carbon monoxide, and no CO_2, hence the name “zero-emission vehicles.”

As fuel cells become even more efficient and less expensive, the principal limit on their use in passenger cars will be the availability and cost of hydrogen fuel. Some people worry about the safety of storing hydrogen in a high-pressure tank in a car, although H_2 has a higher ignition temperature than gasoline and spreads through the air more quickly, reducing the risk of fire. Still, hydrogen in air burns over a much wider range of concentrations than does gasoline, and its flame is almost invisible.

Because of the lack of an extensive hydrogen distribution network, many fuel-cell–powered vehicles are buses and fleet vehicles operating from a central location where hydrogen gas is available. With their very large fuel tanks, buses powered by fuel cells have an operating range of 400 km ($<$ 250 mi). Longer ranges would be possible if better methods for storing hydrogen gas were available.

Hydrogen gas is produced from methane in a two-step process introduced in Chapter 14:

In addition to 4 moles of H_2, the process produces 1 mole of CO_2 per mole of CH_4—the same amount of carbon dioxide as the complete combustion of methane produces. From the perspective of climate change, it is the greater efficiency of fuel cells powering electric motors coupled with the higher fuel value of CH_4 compared to the hydrocarbons that make up gasoline and diesel oil that reduces the impact of fuel-cell–powered cars compared to those that rely on the combustion of liquid fossil fuels.

CONNECTION Processes for producing hydrogen gas by reacting methane and other fuels with high-temperature steam are described in Section 14.1.

Switching to the all-electric vehicles described in Section 18.7 avoids the problems of CO_2 production if alternative sources of electricity can replace power plants that burn fossil fuels. In principle, solar and wind power can meet all our energy needs but these too suffer from certain disadvantages. Among the issues most relevant to the current chapter is that the Sun does not shine all day and the wind does not blow continually. We need ways to store the excess electricity produced on sunny and windy days for use when demand peaks. The lithium-ion and other batteries described in Section 18.7 lack the necessary energy storage capacity, so scientists are exploring redox flow batteries such as the one shown in **Figure 18.25**.

A redox flow battery consists of two large storage tanks containing solutions of electrolytes. The two solutions are pumped through an electrochemical cell resembling the fuel cell, except that a cation-exchange membrane separates the two solutions instead of two gases. The electrons flow through an external circuit and into a device or into a power grid. Pumping in fresh electrolyte keeps the battery charged. Eventually, decreasing reactant concentrations in the holding tanks require that other energy sources, such as solar- or wind-generated electricity, be used to reverse the voltaic reaction and regenerate the reactants. In this way, charging the redox flow battery allows a utility to store excess solar and wind energy by recharging redox flow batteries and then relying on battery power at night or when winds are calm. Commercial installations of redox flow batteries are being built that have energy storage capacities in the 10s to 100s of megawatt hours (MWh); enough to meet peak-hour demands for electricity of a small city.

A popular electrolyte system is based on the different oxidation states of vanadium. At the anode, V^{2+} ions are oxidized to V^{3+}:

while $VO_2{}^+$ ions are reduced to VO^{2+} ions at the cathode:

One electron is produced in the first half-reaction and one is consumed in the second, so we simply combine the two half-reactions to obtain an overall cell reaction:

$$V^{2+}(aq) + VO_2{}^+(aq) + 2\,H^+(aq) \rightarrow V^{3+}(aq) + VO^{2+}(aq) + H_2O(\ell)$$

Using Equation 18.2 to calculate E°_{cell}:

$$E^\circ_{cell} = E^\circ_{cathode} - E^\circ_{anode} = 0.991\text{ V} - (-\,0.255\text{ V}) = 1.246\text{ V}$$

CONCEPT TEST

Why must redox flow batteries be large to be practical as energy storage devices?

SAMPLE EXERCISE 18.9 Integrating Concepts: Corrosion at Sea

In the 18th century, the British Royal Navy began the practice of adding copper sheathing to the bottoms of its sailing vessels to inhibit the growth of barnacles and seaweed that slowed them down. Unfortunately, the first copper sheets they used were fastened with iron nails. (a) Explain why using iron nails was not a good idea. (b) Which metal would corrode?

Modern navies continue to encounter shipboard corrosion problems, sometimes with disastrous results. In 1963, the USS *Thresher*, the lead boat in a new class of nuclear submarines, was conducting deep diving tests about 200 miles off the coast of Cape Cod when it suddenly sank. All 129 sailors and civilians aboard perished. It was later determined that loss of the *Thresher* may have been caused by failure of the silver solder used to connect metal pipes that transported seawater to cool the *Thresher*'s nuclear power plant. Metal pipes that carry seawater are made of copper/nickel alloys. (c) Why might silver solder have been considered a logical choice for connecting them? (d) How is the oxidation of silver in seawater influenced by the presence of chloride ions? (e) Use the appropriate half-reactions and standard reduction potentials from Table A6.1 (see Appendix 6) to calculate the cell potential for the air-oxidation of Ag in pH 8.00 seawater in which $[Cl^-] = 0.56\ M$. Assume $P_{O_2} = 0.21$ atm. Is the reaction spontaneous?

Collect and Organize First we are asked to explain why nailing one metal to another is a bad idea when they will be immersed in seawater and to identify which one will corrode. Then we have another corrosion problem involving Ag and Cu/Ni alloys, where we need to address their electrochemical properties and to explain how the oxidation of Ag in seawater depends on the presence of Cl^- ions. Finally, we are asked to determine whether Ag spontaneously oxidizes in aerated seawater, using half-reactions from Table A6.1 to calculate E_{cell}.

Analyze The problem with nailing copper sheets with iron nails is like that encountered in the Statue of Liberty (see Figure 18.19), in which the iron skeleton of the statue rusted so badly that it had to be replaced. Copper and iron metal in contact with each other and surrounded by a strong electrolyte (seawater) form an electrochemical cell in which copper is the cathode and iron is the anode as shown in Equation 18.17.

The logic behind using silver solder to connect pipes made of another metal (or metal alloy) must have been based on their similar electrochemical properties. To determine similarity, we need to use the appropriate half-reaction for silver. Table A6.1 lists two half-reactions: one that is simply $\text{Ag}^+(aq) + \text{e}^- \rightarrow \text{Ag}(s)$ and the other in which the half-reaction occurs in a solution of chloride ions: $\text{AgCl}(s) + \text{e}^- \rightarrow \text{Ag}(s) + \text{Cl}^-(aq)$. Given the high $[\text{Cl}^-]$ in seawater and the limited solubility of AgCl, we should use the latter to compare electrochemical properties and to determine whether the oxidation of Ag is spontaneous.

Solve

1. Iron and copper should *not* be allowed to contact each other in seawater because they are dissimilar metals, as shown by the standard reduction potentials of the following half-reactions:

$$\begin{aligned} &\text{Fe}^{2+}(aq) + 2\,\text{e}^- \rightarrow \text{Fe}(s) && E^\circ = -0.447\ \text{V} \\ &\text{Cu}^{2+}(aq) + 2\,\text{e}^- \rightarrow \text{Cu}(s) && E^\circ = 0.342\ \text{V} \end{aligned}$$

   Cu^{2+} ions are produced by air oxidation of the Cu metal to Cu(OH)_2. When Cu and Fe are in contact with each other in an electrolytic solution, the two become the cathode and anode, respectively, of a voltaic cell with the cell reaction:

   $\text{Cu}^{2+}(aq) + \text{Fe}(s) \rightarrow \text{Cu}(s) + \text{Fe}^{2+}(aq)$

   This reaction has an $E^\circ_{\text{cell}} = E^\circ_{\text{cathode}} - E^\circ_{\text{anode}} = 0.342\ \text{V} - (-\ 0.447\ \text{V}) = 0.789\ \text{V}$.

2. The spontaneous cell reaction indicates that Fe is the metal

that is oxidized (corrodes).

3. Table A6.1 contains the following half-reactions involving Ag, Cu, and Ni:

$$\begin{aligned} &AgCl(s) + e^- \rightarrow Ag(s) + Cl^-(aq) && E^\circ = 0.222\ V \\ &Cu^{2+}(aq) + 2\,e^- \rightarrow Cu(s) && E^\circ = 0.342\ V \\ &Ni^{2+}(aq) + 2\,e^- \rightarrow Ni(s) && E^\circ = -0.257\ V \end{aligned}$$

The E° value of the Ag reaction is in between the other two values. If the actual electrochemical properties of the alloy are closer to those of Cu than Ni (which, it turns out, they are), then Ag would have been a logical choice to use in connecting pipes made from the alloy.

4. The difference in the potentials of the two silver half-reactions in Table A6.1,

$$\begin{aligned} &AgCl(s) + e^- \rightarrow Ag(s) + Cl^-(aq) && E^\circ = 0.222\ V \\ &Ag^+(aq) + e^- \rightarrow Ag(s) && E^\circ = 0.800\ V \end{aligned}$$

indicates that the presence of Cl^- ions has a significant impact on the electrochemical properties of Ag. As Ag atoms are oxidized, they precipitate as AgCl, which keeps the concentration of $Ag^+(aq)$ low. The Nernst equation for the Ag^+/Ag half-reaction is

$$E = E^\circ - 0.0592\ V \log(1/[Ag^+])$$

A small $[Ag^+]$ value in the denominator means a large value for the log term and an E value for the Ag^+/Ag half-reaction that is much less than its E°. A smaller potential for the reduction half-reaction means a greater potential for the oxidation of Ag. Therefore, Ag is more likely to be oxidized in the presence of Cl^- ions.

5. The appropriate half-reactions for the corrosion of silver in seawater are

$$\begin{aligned} &O_2(g) + 4\,H^+(aq) + 4\,e^- \rightarrow 2\,H_2O(\ell) && E^\circ = 1.229\ V \\ &AgCl(s) + e^- \rightarrow Ag(s) + Cl^-(aq) && E^\circ = 0.222\ V \end{aligned}$$

To assess the spontaneity of the air-oxidation of Ag, we need to reverse the second half-reaction and multiply it by 4 to balance the loss and gain of electrons:

$$\begin{array}{r} O_2(g) + 4\,H^+(aq) + 4\,e^- \rightarrow 2\,H_2O(\ell) \\ 4[Ag(s) + Cl^-(aq) \rightarrow AgCl(s) + e^-] \\ \hline O_2(g) + 4\,H^+(aq) + 4\,Ag(s) + 4\,Cl^-(aq) \rightarrow 4\,AgCl(s) + 2\,H_2O(\ell) \end{array}$$

The silver reaction takes place at the anode and the standard cell potential is

$$E^\circ_{\text{cell}} = E^\circ_{\text{cathode}} - E^\circ_{\text{anode}} = 1.229\text{ V} - 0.222\text{ V} = 1.007\text{ V}$$

Using this E°_{cell} value and setting up the Nernst equation for the reaction gives us

$$E_{\text{cell}} = E^\circ_{\text{cell}} - \left(\frac{0.0592\text{ V}}{4}\right)\log\left[\frac{1}{(P_{O_2})[H^+]^4[Cl^-]^4}\right]$$

We take the antilog of pH = 8.00 and use the $P_{O2}[Cl^-]$ values for aerated seawater:

$$\begin{aligned} E_{\text{cell}} &= 1.007\text{ V} - \left(\frac{0.0592\text{ V}}{4}\right)\log\left[\frac{1}{(0.21)(1.00\times10^{-8})^4(0.56)^4}\right] \\ &= 0.51\text{ V} \end{aligned}$$

The positive cell potential means that the oxidation of silver in seawater should be spontaneous.

Think About It The above analysis makes it clear why using iron nails to fasten copper sheathing to the hulls of wooden sailing ships was a bad idea. However, we were unable to definitively establish the role of the silver solder joints in the sinking of the *Thresher*. According to modern naval engineering references, silver solder and Cu/Ni alloys should have similar electrochemical properties when immersed in seawater.

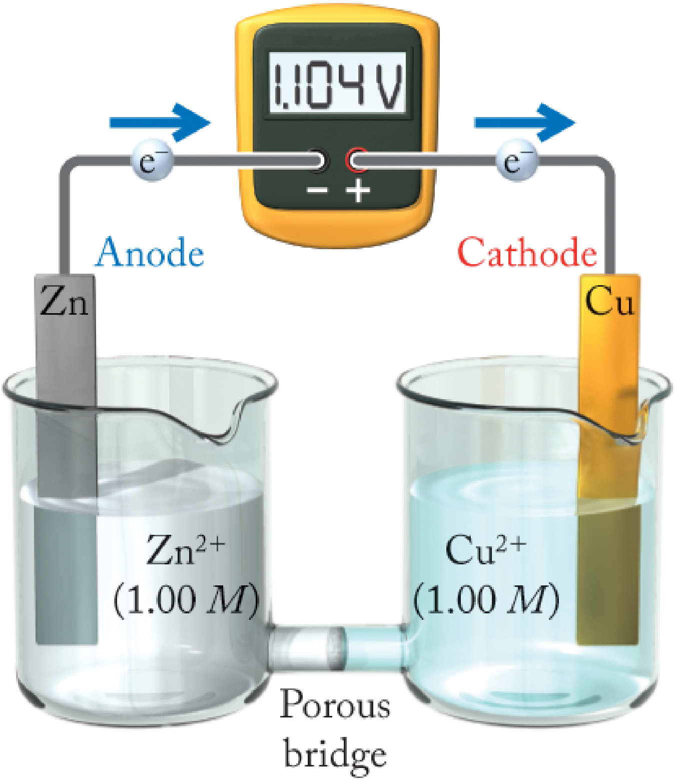
Glossary

fuel cell	a voltaic cell based on the oxidation of a continuously supplied fuel; the reaction is the equivalent of combustion, but chemical energy is converted directly into electrical energy.
redox flow battery	an electrochemical cell consisting of two solutions separated by an ion-exchange membrane.

SUMMARY

- LO1 Electrochemistry is the branch of chemistry that links redox reactions to the production or consumption of electrical energy. Any redox reaction can be broken down into oxidation and reduction half-reactions. (Section 18.1)
- LO2 In an electrochemical cell, the oxidation half-reaction occurs at the anode and the reduction half-reaction occurs at the cathode. Migration of the ions in the cell's electrolyte allows electrical charges to flow between the cathode and anode compartments as electrons flow through an external

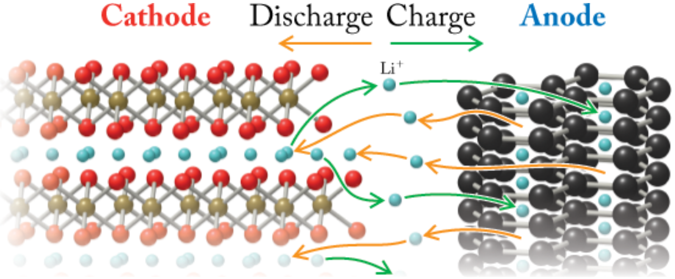
electrical circuit. A cell diagram shows how the components of the cathodic and anodic compartments of the cell are connected. (Sections 18.1 and 18.2)



- LO3 The difference between the standard reduction potentials (E°) of a cell's cathode and anode half-reactions is equal to the standard cell potential (E°_{cell}), with the more positive E° half-reaction occurring at the cathode. The value of E°_{cell} is a measure of how forcefully a voltaic cell, in which all reactants and products are in their standard states, can pump electrons through an external circuit. All standard cell potentials are referenced to the cell potential of the standard hydrogen electrode ($E^\circ_{\text{SHE}} = 0.000$ V). (Sections 18.3, 18.4, 18.5)
- LO4 A voltaic cell has a positive cell potential ($E_{\text{cell}} > 0$) and its cell reaction has a negative change in free energy ($\Delta G_{\text{cell}} < 0$). This decrease in free energy in a voltaic cell is available to do work in an external electrical circuit. The Faraday

constant relates the quantity of electrical charge to the number of moles of electrons and indirectly to the number of moles of reactants. (Section 18.4)

- LO5 The potential of a voltaic cell decreases as reactants turn into products. The Nernst equation describes how cell potential changes with concentration changes. (Section 18.6)
- LO6 The potential of a voltaic cell approaches zero as the cell reaction approaches chemical equilibrium, at which point $E_{\text{cell}} = 0$ and $Q = K$. (Sections 18.6, 18.7, 18.10)



- LO7 The quantities of reactants consumed in a voltaic cell reaction are related by the Faraday constant to the coulombs of electrical charge delivered by the cell. Nickel–metal hydride batteries supply electricity when H atoms are oxidized to H^+ ions at the anodes and NiO(OH) is reduced to $Ni(OH)_2$ at the cathodes. In lithium-ion batteries, electricity is produced when Li^+ ions stored in graphite anodes move toward and are incorporated into transition metal oxide or phosphate cathodes. (Sections 18.7, 18.8, 18.9)
- LO8 Cars and trucks that are propelled by electric motors are considered “zero-emission” vehicles because they efficiently convert the chemical energy in their batteries or fuel cells into mechanical work with no release of pollutants. However, these vehicles still depend on fossil fuels that release fossil CO_2 for some of the electricity needed to charge their batteries and to produce the hydrogen consumed in their fuel cells.

PARTICULATE PREVIEW WRAP-UP

The two half-reactions depict the oxidation of hydrogen and the reduction of oxygen:

$$H_2(g) \rightarrow 2\ H^+(aq) + 2\ e^-$$

$$O_2(g) + 4\ H^+(aq) + 4\ e^- \rightarrow 2\ H_2O(\ell)$$

which sum to a balanced, overall reaction of

$$2\ H_2(g) + O_2(g) \rightarrow 2\ H_2O(\ell)$$

When chemists physically separate two half-reactions, electrons can be forced to flow through an external circuit from one half-cell to the other. This external flow of electrons can be harnessed to do work as electricity. Chemists call hydrogen a “clean” fuel because it emits only water vapor, unlike traditional fuels, which when combusted, produce oxides of nitrogen and carbon that pollute the atmosphere.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts and Equations	Sample Exercises
Writing net ionic equations of cell reactions by combining half-reactions	Combine the reduction and oxidation half-reactions after balancing the gain and loss of electrons.	18.1
Diagramming an electrochemical cell	Use the format: anode | anode solution ‖ cathode solution | cathode Insert solution concentrations if they are known.	18.2
Identifying anode and cathode half-reactions and calculating the value of E_{cell}°	The half-reaction with the more positive standard reduction potential is the cathode half-reaction in a voltaic cell. $E^\circ_{cell} = E^\circ_{cathode} - E^\circ_{anode}$ (18.2)	18.3
Relating ΔG_{cell} and E_{cell}	$\Delta G_{cell} = -nFE_{cell}$ (18.7) where n is the number of moles of electrons transferred in the cell reaction and F is the Faraday constant, 9.65×10^4 C/mol e^-.	18.4
Calculating E_{cell} from E°_{cell} and the concentrations of reactants and products	E_{cell} at 25°C is related to E°_{cell} and the reaction quotient by the Nernst equation: $E_{cell} = E^\circ_{cell} - \frac{0.0592\ V}{n} \log Q$ (18.10)	18.5
Calculating K for a redox reaction from the standard potentials of its half-reactions	E°_{rxn} is related to K at 298 K by $\log K = \frac{nE^\circ_{rxn}}{0.0592\ V}$ (18.12)	18.6

C18.17	**Relating mass of reactant in an electrochemical reaction to quantity of electrical charge**	Determine the number of moles of electrons transferred, use the Faraday constant to relate coulombs of charge to moles of electrons.
C18.18	**Calculating the time required to oxidize a quantity of reactant**	Use the Faraday constant and the relationship between moles of electrons and moles of reactants to describe an electrolytic process.

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

In the voltaic cell shown in Figure P18.1, the greater density of a concentrated solution of $CuSO_4$ allows a less concentrated solution of $ZnSO_4$ solution to be (carefully) layered on top of it. Why is a porous bridge not needed in this cell?

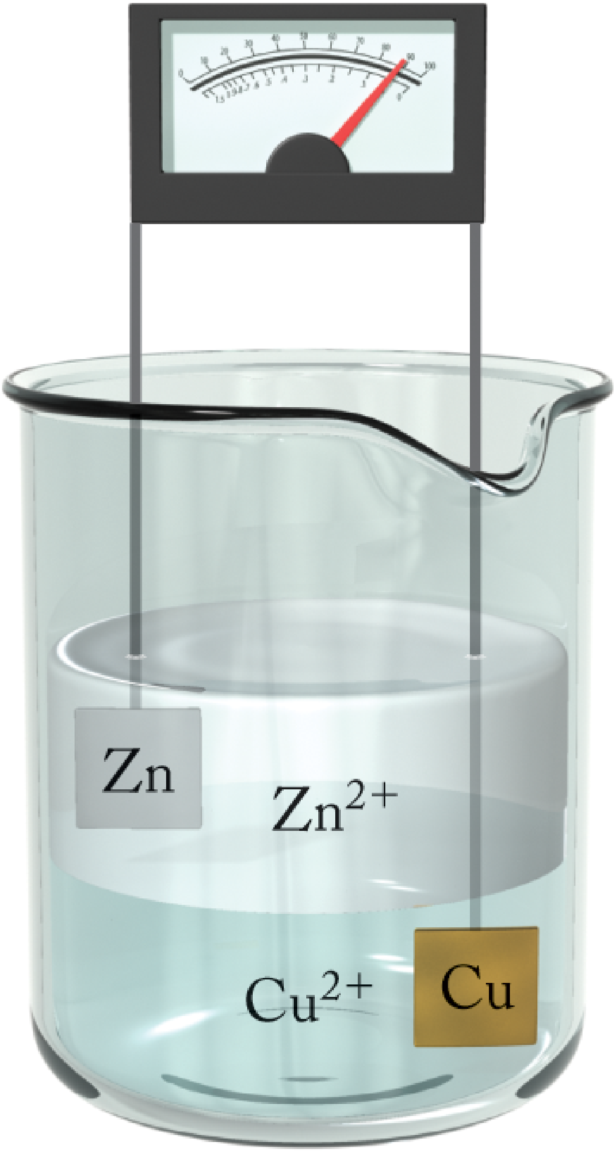


FIGURE P18.1

In the voltaic cell shown in Figure P18.2, the concentrations of Cu^{2+} and Cd^{2+} are 1.00 *M*. Based on the standard potentials in Appendix 6, identify which electrode is the anode and which is the cathode. Indicate the direction of electron flow.

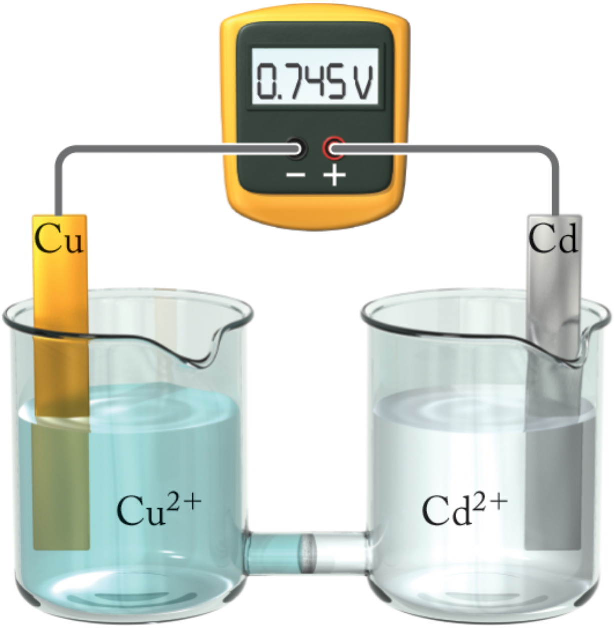

FIGURE P18.2

In the voltaic cell shown in Figure P18.3, $[Ag^+] = [H^+] = 1.00\ M$ and $P_{H2} = 1.00$ atm. From the standard potentials in Table A6.1 (Appendix 6), identify which electrode is the anode and which is the cathode. Indicate the direction of electron flow.

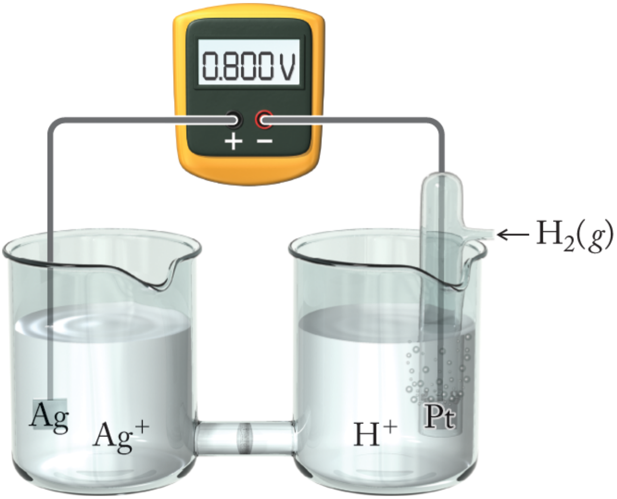

FIGURE P18.3

In many electrochemical cells the electrodes are metals that carry electrons to and from the cell but are not chemically changed by the cell reaction. Each of the highlighted clusters in the periodic table in Figure P18.4 consists of three metals. Which of the highlighted clusters is best suited to form inert electrodes?

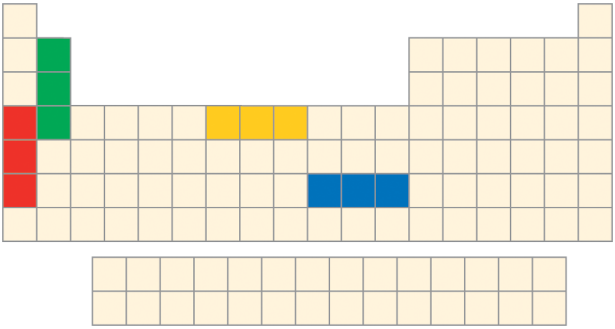

FIGURE P18.4

Which of the four curves in Figure P18.5 best represents the dependence of the potential of a lead–acid battery on the concentration of sulfuric acid? The scale of the *x*-axis is logarithmic.

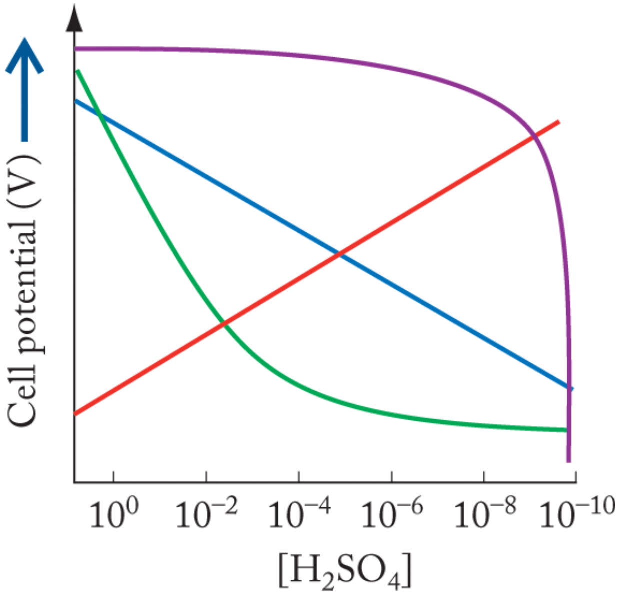

FIGURE P18.5

From top to bottom in Figure P18.6, the sizes of the batteries are D, C, AA, and AAA. The performance of batteries such as these is often expressed in units such as (a) volts, (b) watt-hours, or (c) milliampere-hours. Which of the values differ significantly between the four batteries?

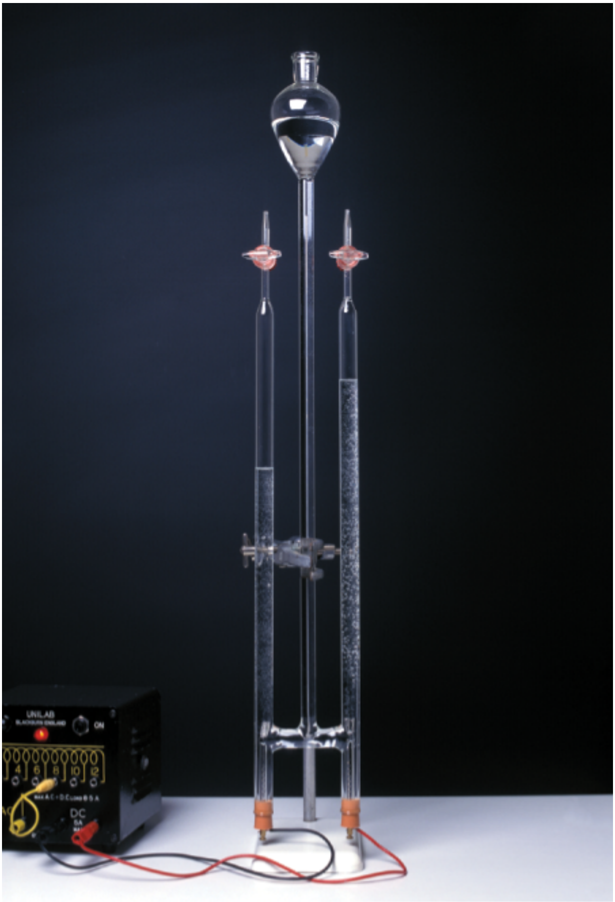
D LR20 AM1 1.5V
Made in Japan Fabriqué au Japon
C LR14 AM2 1.5V
Made in Japan Fabriqué au Japon
AA LR6 AM3 1.5V
AAA LR03 AM4 1.5V
Made in Indonesia Fabriqué en Indonésie

FIGURE P18.6

The apparatus in Figure P18.7 is used for the electrolysis of water. Hydrogen and oxygen gas are collected in the two inverted burets. An inert electrode at the bottom of the left buret is connected to the negative terminal of a 6 V battery, whereas the electrode in the buret on the right is connected to the positive terminal. A small quantity of sulfuric acid is added to speed up the electrolytic reaction.

1. What are the half-reactions at the left and right electrodes and their standard potentials?
2. Why does sulfuric acid make the electrolysis reaction go more

rapidly?



Overall cell reaction

$$H_2O(\ell) \rightarrow H_2(g) + \tfrac{1}{2}\,O_2(g)$$

FIGURE P18.7

An electrolytic apparatus identical to the one shown in Problem 18.7 is used to electrolyze water, but the reaction is speeded up by the addition of sodium carbonate instead of sulfuric acid.

1. What are the half-reactions and the standard potentials for the electrodes on the left and right?
2. Why does sodium carbonate make the electrolysis reaction go more rapidly?

Most classic cars, such as the one shown in Figure P18.9, have chromium-electroplated, or *chrome*, bumpers.

1. Is the bumper the anode or the cathode in the electroplating process?
2. How does the presence of a layer of chromium protect the bumper from corroding?

FIGURE P18.9

Use representations [A] through [I] in Figure P18.10 to answer questions (a)–(f). The photo in image [E] shows silver deposited onto copper. Suppose the materials in [A], [C], [G], and [I] were combined, along with a porous bridge and external circuit, to generate an electrochemical cell that produced [E].

1. Which metal would be the cathode? Which solution would surround it?

2. Which metal would be the anode? Which solution would surround it?
3. When the reaction in [E] is finished, what will happen to the light blue color of the solution?
4. How could [E] be produced without a porous bridge or an external circuit?
5. Of the four particulate images [B], [D], [F], and [H] in Figure P18.10, which two correspond to the solutions [G] and [I]?
6. Which particulate image represents the copper wire with silver deposited onto it? What does the fourth particulate image depict?

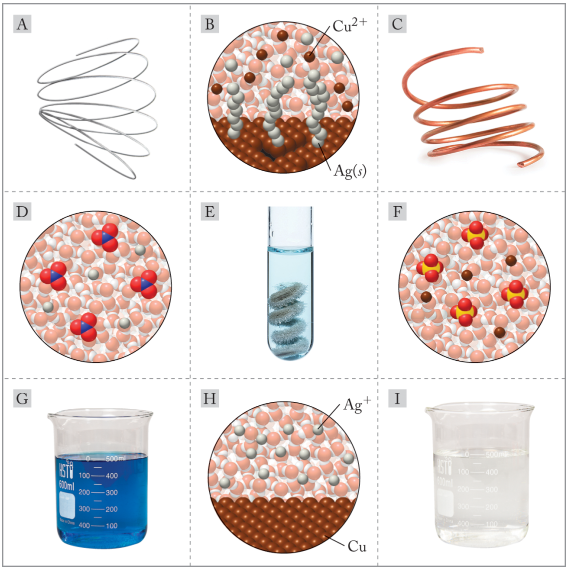


FIGURE P18.10

QUESTIONS AND PROBLEMS

Redox Chemistry Revisited; Electrochemical Cells

Concept Review

An element with a strong tendency to gain electrons is also _______

.

1. easily oxidized
2. a good oxidizing agent
3. a good reducing agent
4. a reactive metal

An element that is a good reducing agent is also _______ .

1. easily oxidized
2. a good oxidizing agent
3. easily reduced
4. a noble gas

Regarding the porous separator between the two halves of an electrochemical cell:

1. Describe how it allows electrical charge to flow between the two half-cells.
2. Explain why a piece of wire could not perform the same function.

The Zn/Cu^{2+} reactions in Figures 18.1 and 18.2 are the same; however, the reaction in the cell in Figure 18.2 generates electricity, whereas the reaction in the beaker in Figure 18.1 does not. Why?

Problems

Complete and balance the following partial chemical equation, using the appropriate half-reactions in Table A6.1 for acidic solutions.

$$Cr_2O_7^{2-}(aq) + Fe^{2+}(aq) \rightarrow Cr^{3+}(aq) + Fe^{3+}(aq)$$

Complete and balance the following partial net ionic equation, using the appropriate half-reactions in Table A6.1 for acidic solutions.

$$MnO_4^{-}(aq) + H_2O_2(aq) \rightarrow MnO_2(s) + O_2(g)$$

An electrochemical cell with an aqueous electrolyte is based on the reaction between Ni^{2+}(*aq*) and Cd(*s*), producing Ni(*s*) and Cd^{2+}(*aq*).

1. Write half-reactions for the anode and cathode.
2. Write a balanced net ionic equation describing the cell reaction.
3. Draw the cell diagram.

A voltaic cell is based on the reaction between Cu^{2+}(*aq*) and Ni(*s*), producing Cu(*s*) and Ni^{2+}(*aq*).

1. Write the anode and cathode half-reactions.
2. Write a balanced cell reaction.
3. Draw the cell diagram.

Lithium–Air Batteries In recent years engineers have been working on a lithium–air battery ($Li–O_2$) as an alternative energy source for electric vehicles.

1. Write the two half-reactions for the battery and diagram the cell in acid solution.
2. Write the two half-reactions for the battery and diagram the cell in basic solution.

Sodium–Sulfur Batteries Less expensive materials make sodium–sulfur batteries attractive for electric vehicles. The balanced chemical equation for this battery is

$$2\ \mathrm{Na}(\ell) + 3\ \mathrm{S}(\ell) \rightarrow \mathrm{Na_2S_3}(s)$$

1. Determine the number of electrons transferred in the cell reaction.
2. Draw the cell diagram.
3. Draw Lewis structures for the product, Na_2S_3.

Refining Gold and Silver One of the ways to extract gold and silver metal from low-grade ores is by treating the ore with an alkaline solution of cyanide (CN^-) ions and dissolved O_2, which produces soluble polyatomic ions with the generic formula $M(CN)_2^-$ (where M = Ag^+ or Au^+) and OH^- ions.

1. Write a net ionic equation describing this reaction.
2. How many moles of electrons are transferred for each mole of silver or gold metal that dissolves?

Pollution Control Removing chromate, CrO_4^{2-}, ions from waste streams is an essential part of pollution control in many industries. One way to remove chromate ions involves reacting them with SO_3^{2-} ions, producing solid $Cr(OH)_3$ and SO_4^{2-} ions under alkaline conditions.

1. Write a net ionic equation describing this reaction.
2. How many moles of electrons are transferred for each mole of chromate that reacts?

Standard Potentials

Concept Review

Is oxygen or chlorine a stronger oxidizing agent under standard conditions? Use the standard reduction potentials in Table A6.1 to support your answer.

Of the group 1 elements Li, K, and Na, which is the strongest reducing agent?

Problems

If a piece of silver is placed in a solution in which $[Ag^+] = [Cu^{2+}] = 1.00\ M$, will the following reaction proceed spontaneously?

$$2\ Ag(g) + Cu^{2+}(aq) \rightarrow 2\ Ag^+(aq) + Cu(s)$$

A piece of cadmium is placed in a solution in which $[Cd^{2+}] = [Sn^{2+}] = 1.00\ M$. Will the following reaction proceed spontaneously?

$$Cd(s) + Sn^{2+}(aq) \rightarrow Cd^{2+}(aq) + Sn(s)$$

Sometimes the anode half-reaction in the zinc–air battery (Figure 18.7) is written with the zincate ion, $Zn(OH)_4{}^{2-}$, as the product. Write a balanced equation for the cell reaction based on this product.

Sometimes the cell reaction of nickel–cadmium batteries is written with Cd metal as the anode and solid NiO_2 as the cathode. If the products of the reactions are a solid hydroxide of cadmium(II) at the anode and a solid hydroxide of nickel(II) at the cathode, write balanced equations for the cathode and anode half-reactions and the overall cell reaction.

In a voltaic cell like the Cu–Zn cell in Figure 18.2, the Cu electrode is replaced with one made of Ni immersed in a solution of $NiSO_4$.

1. Will the standard potential of this Ni/Zn cell be greater than, the same as, or less than 1.10 V?
2. Which electrode would be the anode?

Suppose the copper half of the Cu/Zn cell in Figure 18.2 were replaced with a silver wire in contact with 1 *M* $Ag^{+}(aq)$.

1. What would be the value of E°_{cell}?
2. Which electrode would be the anode?

The half-reactions and standard potentials for a nickel–metal hydride battery with a titanium–zirconium anode are as follows:

$$\text{Cathode:}\quad NiO(OH)(s) + H_2O(\ell) + e^- \rightarrow Ni(OH)_2(s) + OH^-(aq) \qquad E^\circ = 0.52\ V$$

$$\text{Anode:}\quad TiZr_2H(s) + OH^-(aq) \rightarrow TiZr_2(s) + H_2O(\ell) + e^- \qquad E^\circ = -0.80\ V$$

1. Write the overall cell reaction for this battery.
2. Calculate the standard cell potential.

Lithium-Ion Batteries There are lithium-ion batteries that have cathodes composed of $FePO_4$ when fully charged.

1. What is the formula of the cathode when the battery is fully discharged?
2. Is Fe oxidized or reduced as the battery discharges?
3. Is the cell potential of a lithium-ion battery with an iron phosphate cathode likely to differ from one with a cobalt oxide cathode? Explain your answer.

Chemical Energy and Electrical Work

Concept Review

Equation 18.4 tells us that the electrical work done by a voltaic cell on its surroundings (w_{elec}) is equal to the quantity of electrical charge (C) the cell pumps through an external circuit times the cell potential (E_{cell}): $w_{\text{elec}} = -CE_{\text{cell}}$. Why is there a negative sign in the equation?

Some people see an analogy between a battery pumping electrons through a circuit and an actual pump pumping water through a pipe. In this analogy, what electrical quantities correspond to each of the following? (*Hint*: See Table 1.2.)

1. the volume of water flowing through the pipe
2. the pressure forcing the water through the pipe
3. the rate at which a certain volume of water flows through the pipe each second

Problems

The value of E°_{cell} for the following reaction is 0.500 V. What is the value of $\Delta G^\circ_{\text{cell}}$?

$2\ Mn^{3+} + 2\ H_2O \rightarrow Mn^{2+} + MnO_2 + 4\ H^+$

What is the value of ΔG°_{cell} for an electrochemical cell based on a cell reaction described by the following net ionic equation?

$Mg + 2\ Cu^+ \rightarrow Mg^{2+} + 2\ Cu$

For many years the 1.50 V batteries used to power flashlights were based on the following cell reaction:

$Zn(s) + 2\ NH_4Cl(s) + 2\ MnO_2(s) \rightarrow Zn(NH_3)_2Cl_2(s) + Mn_2O_3(s) + H_2O(\ell)$

What is the value of ΔG°_{cell}?

The first generation of laptop computers was powered by nickel–cadmium (nicad) batteries, which generated 1.20 V in accordance with the following cell reaction:

$Cd(s) + 2\ NiO(OH)(s) + 2\ H_2O(\ell) \rightarrow Cd(OH)_2(s) + 2\ Ni(OH)_2(s)$

What is the value of ΔG°_{cell}?

The cells in the nickel–metal hydride battery packs used in many hybrid vehicles produce 1.20 V in accordance with the following cell reaction:

$MH(s) + NiO(OH)(s) \rightarrow M(s) + Ni(OH)_2(s)$

What is the value of ΔG°_{cell}?

A cell in a lead–acid battery delivers exactly 2.00 V of cell potential in accordance with the following cell reaction:

$Pb(s) + PbO_2(s) + 2\ H_2SO_4(aq) \rightarrow 2\ PbSO_4(s) + 2\ H_2O(\ell)$

What is the value of ΔG°_{cell}?

A Reference Point: The Standard Hydrogen Electrode

Concept Review

What is the function of platinum in the standard hydrogen electrode?

Platinum is very expensive, so why is it used in standard hydrogen electrodes where the half-reaction is $2\,H^+(aq) + 2\,e^- \rightarrow H_2(g)$?

The potential of the standard hydrogen electrode (SHE) is the reference against which other half-reaction potentials are expressed. Why, then, is the SHE not widely used as a reference electrode in electrochemical cells?

Suggest a replacement metal for platinum in the standard hydrogen electrode. Explain why you selected the metal you did.

Problems

An electrochemical cell consists of a standard hydrogen electrode and a second half-cell in which a magnesium electrode is immersed in a 1.00 *M* solution of Mg^{2+} ions.

1. What is the value of E_{cell}?
2. Which electrode is the anode?
3. Which is a product of the cell reaction: H^+ ions or H_2 gas?

An electrochemical cell consists of a standard hydrogen electrode and a second half-cell in which a cadmium electrode is immersed in a 1.00 *M* solution of Cd^{2+} ions.

1. What is the value of E_{cell}?
2. Which electrode is the anode?
3. Which is a product of the cell reaction: Cd^{2+} ions or Cd metal?

The Effect of Concentration on E_{cell}

Concept Review

Why does the operating cell potential of most batteries change little until the battery is nearly discharged?

Does the potential of the standard hydrogen electrode increase, decrease, or stay the same if it contains 1.0 *M* HBr instead of 1.0 *M* HCl?

Problems

Glucose Metabolism Muscle cells convert glucose to pyruvate through a multistep process called *glycolysis*. During periods of strenuous exercise, when cellular oxygen levels are low, pyruvate is converted to lactate using the reduced form of nicotinamide adenine dinucleotide (NAD^{H}) in a redox reaction (Figure P18.49). The standard potentials for the reduction of the oxidized form of nicotinamide adenine dinucleotide (NAD$^+$) and pyruvate are as follows:

$\mathrm{NAD^+}(aq) + 2\,\mathrm{H^+}(aq) + 2\,\mathrm{e^-} \rightarrow \mathrm{NADH}(aq) \qquad E° = -0.320\ \mathrm{V}$

$\mathrm{pyruvate}(aq) + 2\,\mathrm{H^+}(aq) + 2\,\mathrm{e^-} \rightarrow \mathrm{lactate}(aq) \qquad E° = -0.190\ \mathrm{V}$

1. Calculate the standard potential for the reaction in Figure P18.49.
2. Calculate the equilibrium constant for the reaction at 25°C.

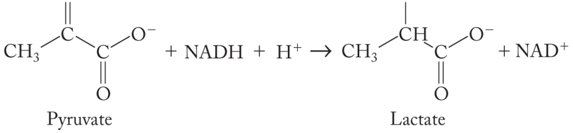

FIGURE P18.49

Citric Acid Cycle Pyruvate can also enter the multistep citric acid cycle (also called the *Krebs cycle*), which is a pathway for oxidizing pyruvate to CO_2 and H_2O. One of the first steps in the citric acid cycle is the redox reaction shown in Figure P18.50 that converts pyruvate to acetyl-CoA using the biological reducing agent nicotinamide adenine dinucleotide (NADH) and the coenzyme CoA–SH.

1. Calculate the standard potential for the reaction in Figure P18.50 given that $\Delta G^\circ = -33.4$ kJ/mol for the reaction.
2. Given the reduction potential for NAD^+,

$$NAD^+(aq) + 2\,H^+(aq) + 2\,e^- \rightarrow NADH(aq) \qquad E^\circ = -0.320\text{ V}$$

calculate the reduction potential for acetyl-CoA:

$$\text{acetyl-CoA} + CO_2 + 2\,e^- \rightarrow \text{pyruvate}(aq) \qquad E^\circ = ?\text{ V}$$

3. Calculate the equilibrium constant for the reaction at 25°C.

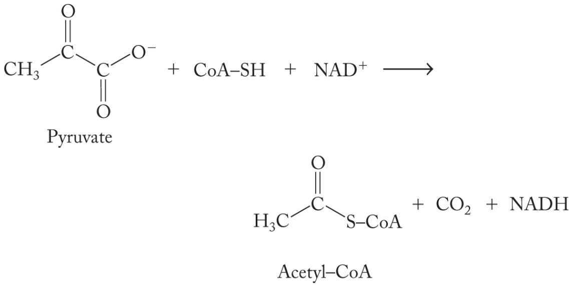

FIGURE P18.50

Permanganate ion oxidizes sulfite to sulfate in basic solution as follows:

$$2\,MnO_4^-(aq) + 3\,SO_3^{2-}(aq) + H_2O(\ell) \rightarrow 2\,MnO_2(s) + 3\,SO_4^{2-}(aq) + 2\,OH^-(aq)$$

Determine the potential for the reaction (E_{rxn}) at 25°C when the concentrations of the reactants and products are as follows: $[\mathrm{MnO_4}^-] = 0.250\ M$, $[\mathrm{SO_3}^{2-}] = 0.425\ M$, $[\mathrm{SO_4}^{2-}] = 0.075\ M$, and $[\mathrm{OH}^-] = 0.0200\ M$. Will the value of E_{rxn} increase or decrease as the reaction proceeds?

A *concentration cell* can be constructed by using the same half-reaction for both the cathode and anode. What is the value of E_{cell} for a concentration cell that combines copper electrodes in contact with 0.35 *M* copper(II) nitrate and 0.00075 *M* copper(II) nitrate solutions?

California Condors The continued recovery of endangered California condors is threatened by lead poisoning. Hunters still use ammunition containing lead and some of their kills are eaten by the condors. Condor stomach acid can have a pH as low as 0.80. Will Pb metal react spontaneously with the acid, forming H_2 gas and Pb^{2+} ions that reach a concentration of $1.0 \times 10^{-6} M$?

Chlorine dioxide (ClO_2) is produced by the following reaction of chlorate (ClO_3^-) with Cl^- in acid solution:

$$2\ \mathrm{ClO_3}^-(aq) + 2\ \mathrm{Cl}^-(aq) + 4\ \mathrm{H}^+(aq) \rightarrow 2\ \mathrm{ClO_2}(g) + \mathrm{Cl_2}(g) + 2\ \mathrm{H_2O}(\ell)$$

1. Determine $E°$ for the reaction.
2. The reaction produces a mixture of gases in the reaction vessel in which $P_{\mathrm{ClO2}} = 2.0$ atm; $P_{\mathrm{Cl2}} = 1.00$ atm. Calculate $[\mathrm{ClO_3}^-]$ if, at equilibrium ($T = 25°\mathrm{C}$), $[\mathrm{H}^+] = [\mathrm{Cl}^-] = 10.0\ M$.

Relating Battery Capacity to Quantities of Reactants

Concept Review

One 12 V lead–acid battery has a higher ampere-hour rating than another. Which of the following parameters are likely to be different for the two batteries?

1. individual cell potentials
2. anode half-reactions
3. total masses of electrode materials
4. number of cells
5. electrolyte composition
6. combined surface areas of their electrodes

Suppose a voltaic cell based on the Cu/Zn cell reaction

$$\mathrm{Zn}(s) + \mathrm{Cu}^{2+}(aq) \rightarrow \mathrm{Cu}(s) + \mathrm{Zn}^{2+}(aq)$$

contains exactly 1 mole of each reactant and product and a second cell based on the Cd/Cu cell reaction

$$\mathrm{Cd}(s) + \mathrm{Cu}^{2+}(aq) \rightarrow \mathrm{Cu}(s) + \mathrm{Cd}^{2+}(aq)$$

also has exactly 1 mole of each reactant and product. Which of the following statements about these two cells is true?

1. Their cell potentials are the same.
2. The masses of their electrodes are the same.
3. The quantities of electrical charge that they can produce are the same.
4. The quantities of electrical energy that they can produce are the same.

Problems

Which of the following voltaic cells will produce the greater quantity of electrical charge per gram of anode material?

$$\mathrm{Cd}(s) + 2\ \mathrm{NiO(OH)}(s) + 2\ \mathrm{H_2O}(\ell) \rightarrow 2\ \mathrm{Ni(OH)_2}(s) + \mathrm{Cd(OH)_2}(s)$$

or

$$4\ \mathrm{Al}(s) + 3\ \mathrm{O_2}(g) + 6\ \mathrm{H_2O}(\ell) + 4\ \mathrm{OH^-}(aq) \rightarrow 4\ \mathrm{Al(OH)_4{}^-}(aq)$$

Which of the following voltaic cells will produce the greater quantity of electrical charge per gram of anode material?

$Zn(s) + MnO_2(s) + 2\ H_2O(\ell) \rightarrow Zn(OH)_2(s) + Mn(OH)_2(s)$

or

$Li(s) + MnO_2(s) \rightarrow LiMnO_2(s)$

Which of the following voltaic cells delivers more electrical energy per gram of anode material at 25°C?

$$Zn(s) + 2\ NiO(OH)(s) + 2\ H_2O(\ell) \rightarrow 2\ Ni(OH)_2(s) + Zn(OH)_2(s) \qquad E^\circ_{cell} = 1.20\ V$$

or

$$Li(s) + MnO_2(s) \rightarrow LiMnO_2(s) \qquad E^\circ_{cell} = 3.15\ V$$

Which of the following voltaic cell reactions delivers more electrical energy per gram of anode material at 25°C?

$$Zn(s) + Ni(OH)_2(s) \rightarrow Zn(OH)_2(s) + Ni(s) \qquad E^\circ_{cell} = 1.50\ V$$

or

$$2\ Zn(s) + O_2(g) + H_2O(\ell) \rightarrow 2\ Zn(OH)_2(s) \qquad E^\circ_{cell} = 2.08\ V$$

Corrosion: Unwanted Electrochemical Reactions

Concept Review

When the iron skeleton of the Statue of Liberty was replaced with stainless steel, the asbestos mats that had separated the skeleton from the copper exterior were replaced with Teflon spacers. Why was Teflon a good choice?

What does a sacrificial anode do to protect a metal structure, and why is the process called *cathodic* protection?

Aquarium Windows The windows of the giant ocean tank at the

New England Aquarium (Figure P18.63) are held in place with aluminum frames. What would be a good material to use to make sacrificial anodes for the frames?

FIGURE P18.63

Corrosion of Copper Pipes The copper pipes frequently used in household plumbing may corrode and eventually leak. The corrosion reaction is believed to involve the formation of copper(I) chloride:

$$2\ \mathrm{Cu}(s) + \mathrm{Cl_2}(aq) \rightarrow 2\ \mathrm{CuCl}(s)$$

1. Write balanced equations for the half-reactions in this redox reaction.
2. Calculate E°_{rxn} and $\Delta G^\circ_{\mathrm{rxn}}$ for the reaction.

Electrolytic Cells and Rechargeable Batteries

Concept Review

The positive terminal of a voltaic cell is the cathode. However, the cathode of an electrolytic cell is connected to the negative terminal of a power supply. Explain this difference in polarity.

The anode in an electrochemical cell is defined as the electrode where oxidation takes place. Why is the anode in an electrolytic cell connected to the positive (+) terminal of an external supply, whereas the anode in a voltaic cell battery is connected to the negative (−) terminal?

The salts obtained from the evaporation of seawater can be a source of halogens, principally Cl_2 and Br_2, through the electrolysis of the molten alkali metal halides. As the potential of the anode in an electrolytic cell is increased, which of these two halogens forms first?

Quantitative Analysis Electrolysis can be used to determine the concentration of Cu^{2+} in a given volume of solution by electrolyzing the solution in a cell equipped with a platinum cathode. If all the Cu^{2+} is reduced to Cu metal at the cathode, the increase in mass of the electrode provides a measure of the concentration of Cu^{2+} in the original solution. To ensure the complete (99.99%) removal of the Cu^{2+} from a solution in which $[Cu^{2+}]$ is initially about 1.0 *M,* will the potential of the cathode (vs. SHE) have to be more or less negative than 0.34 V (the standard potential for $Cu^{2+} + 2\ e^- \rightarrow Cu$)?

Problems

A high school chemistry student wants to demonstrate how water can be separated into hydrogen and oxygen by electrolysis. She knows that the reaction will proceed more rapidly if an electrolyte is added to the water. She has access to 2.00 *M* solutions of H_2SO_4, HBr, NaI, Na_2SO_4, and Na_2CO_3. Which one(s) should she use? Explain your selection(s).

A battery charger used to recharge the NiMH batteries used in a digital camera can deliver as much as 0.75 A of current to each battery. If it takes 100 min to recharge one battery, how many grams of $Ni(OH)_2$ are oxidized to $NiO(OH)$?

A NiMH battery containing 4.10 g of $NiO(OH)$ was 75% discharged when it was connected to a charger with an output of 2.00 A at 1.3 V. How long does it take to recharge the battery?

How long does it take to deposit a coating of gold 1.00 μm thick on a disk-shaped medallion 2.0 cm in diameter and 3.0 mm thick at a constant current of 45 A? The density of gold is 18.3 g/cm^3. The gold solution contains gold(III).

Oxygen Supply in Submarines Nuclear submarines can stay under water nearly indefinitely because they can produce their own oxygen by the electrolysis of water.

1. How many liters of O_2 at 25°C and 1.00 bar are produced in 1 hour in an electrolytic cell operating at a current of 0.025 A?
2. Could seawater be used as the source of oxygen in this electrolysis? Explain why or why not.

In the electrolysis of water, how long will it take to produce 1.00×10^2 L of H_2 at STP (273 K and 1.00 atm) by using an electrolytic cell through which the current is 52 mA?

Calculate the minimum (least negative) cathode potential (versus SHE) needed to begin electroplating nickel from 0.35 M Ni^{2+} onto a piece of iron.

What is the minimum (least negative) cathode potential (versus SHE) needed to electroplate silver onto cutlery in a solution of Ag^+ and NH_3 in which most of the silver ions are present as the complex, $Ag(NH_3)_2^+$, and the concentration of $Ag^+(aq)$ is only $2.50 \times 10^{-4} M$?

Fuel Cells and Flow Batteries

Concept Review

Describe two advantages of hybrid (gasoline engine–electric motor) power systems over all-electric systems based on fuel cells. Describe two disadvantages.

Describe three factors limiting widespread use of cars powered by fuel cells.

Methane can serve as the fuel for electric cars powered by fuel cells. Carbon dioxide is a product of the fuel cell reaction. All cars powered by internal combustion engines burning natural gas (mostly methane) produce CO_2. Why are electric vehicles powered by fuel cells likely to produce less CO_2 per mile?

To make the refueling of fuel cells easier, several manufacturers offer converters that turn readily available fuels—such as natural gas, propane, and methanol—into H_2 for the fuel cells and CO_2. Although vehicles with such power systems are not truly "zero emission," they still offer significant environmental benefits over vehicles powered by internal combustion engines. Describe a few of those benefits.

Problems

Fuel cells with molten alkali metal carbonates as electrolytes can use methane as a fuel. The methane is first converted into hydrogen in a two-step process:

$$CH_4(g) + H_2O(g) \rightarrow CO(g) + 3\ H_2(g)$$

$$CO(g) + H_2O(g) \rightarrow H_2(g) + CO_2(g)$$

1. Assign oxidation numbers to carbon and hydrogen in the reactants and products.
2. Using the standard free energy of formation values in Table A4.3 (Appendix 4), calculate the standard free-energy changes in the two reactions and the overall ΔG° for the formation of $H_2 + CO_2$ from methane and steam.

A direct methanol fuel cell uses the oxidation of methanol by oxygen to generate electrical energy. The overall reaction, $CH_3OH(\ell) + \frac{3}{2} O_2(g) \rightarrow CO_2(g) + 2\ H_2O(\ell)$

has a ΔG° value of $-$ 702.4 kJ/mol of methanol oxidized. What is the standard cell potential for this fuel cell?

There is interest in developing redox flow batteries based on the reduction of $VO_2{}^+$ to VO^{2+}:

$$VO_2{}^+(aq) + 2\ H^+(aq) + e^- \rightarrow VO^{2+}(aq) + H_2O(l) \qquad E^\circ = 0.991\ V$$

Which combination of this half-reaction with another involving the oxidation of Cr^{3+}, Sn^{2+}, or V^{2+} ions will produce the largest electrochemical potential, E°_{cell}?

Which combination of anode reactions from Problem 18.83 and the following cathode reactions in a redox flow battery would lead to the largest electrochemical potential, E°_{cell}?

1. reduction of oxygen in alkaline solution
2. reduction of bromine
3. reduction of Ce^{4+} to Ce^{3+}

Additional Problems

Calculate the E_{cell} value at 298 K for the cell based on the reaction,

$Fe^{3+}(aq) + Cu^+(aq) \rightarrow Fe^{2+}(aq) + Cu^{2+}(aq)$

when $[Fe^{3+}] = [Cu^+] = 1.50 \times 10^{-3} M$ and $[Fe^{2+}] = [Cu^{2+}] = 2.5 \times 10^{-4} M$.

Calculate the E_{cell} value at 298 K for the cell based on the reaction,

$Cu(s) + 2\ Ag^+(aq) \rightarrow Cu^{2+}(aq) + 2\ Ag(s)$

when $[Ag^+] = 2.56 \times 10^{-3} M$ and $[Cu^{2+}] = 8.25 \times 10^{-4} M$.

Using the appropriate standard potentials in Appendix 6, determine the equilibrium constant for the following reaction at 298 K:

$$Fe^{3+}(aq) + Cr^{2+}(aq) \rightarrow Fe^{2+}(aq) + Cr^{3+}(aq)$$

Using the appropriate standard potentials in Appendix 6, determine the equilibrium constant at 298 K for the following reaction between MnO_2 and Fe^{2+} in acid solution:

$$4\ H^{+}(aq) + MnO_2(s) + 2\ Fe^{2+}(aq) \rightarrow Mn^{2+}(aq) + 2\ Fe^{3+}(aq) + 2\ H_2O(\ell)$$

Electrolysis of Seawater Magnesium metal is obtained by the electrolysis of molten Mg^{2+} salts from evaporated seawater.

1. Would elemental Mg form at the cathode or anode?
2. Do you think the principal ingredient in sea salt (NaCl) would need to be separated from the Mg^{2+} salts before electrolysis? Explain your answer.
3. Would electrolysis of an aqueous solution of $MgCl_2$ also produce elemental Mg?
4. If your answer to part (c) was no, what would be the products of electrolysis?

Silverware Tarnish Low concentrations of hydrogen sulfide in air react with silver to form Ag_2S, more familiar to us as tarnish. Silver polish contains aluminum metal powder in a basic suspension.

1. Write a balanced net ionic equation for the redox reaction between Ag_2S and Al metal that produces Ag metal and $Al(OH)_3$.
2. Calculate $E°$ for the reaction.

A magnesium battery can be constructed from an anode of magnesium metal and a cathode of molybdenum sulfide, Mo_3S_4. The standard reduction potentials of the electrode half-reactions are

$Mg^{2+}(aq) + 2\ e^- \rightarrow Mg(s) \qquad E^\circ = -2.37\ V$

$Mg^{2+}(aq) + Mo_3S_4(s) + 2\ e^- \rightarrow MgMo_3S_4(s) \qquad E^\circ = ?$

1. If the standard cell potential for the battery is 1.50 V, what is the value of E° for the reduction of Mo_3S_4?
2. What are the apparent oxidation states of Mo in Mo_3S_4 and in $MgMo_3S_4$?
3. The electrolyte in the battery contains a complex magnesium salt, $Mg(AlCl_3CH_3)_2$. Why is it necessary to include Mg^{2+} ions in the electrolyte?

Suppose there were a scale for expressing electrode potentials in which the standard potential for the reduction of water in base,

$$2\ H_2O(\ell) + 2\ e^- \rightarrow H_2(g) + 2\ OH^-(aq)$$

is assigned an E° value of 0.000 V. How would the standard potential values on this new scale differ from those in Appendix 6?

Clinical Chemistry The concentrations of Na^+ ions in red blood cells (11 m*M*) and in the surrounding plasma (140 m*M*) are quite different. Calculate the potential difference across the cell membrane because of this concentration gradient at 37°C.

Waterline Corrosion The photo in Figure P18.94 shows a phenomenon known as waterline corrosion. Assuming the oxidizing agent in the corrosion process is O_2, propose a reason why metal pilings such as these tend to corrode the most at the waterline and corrode less at heights above and below the waterline.

FIGURE P18.94

The Particulate Review exercise at the beginning of this chapter includes a photograph of a rusting automobile. Our daily experience with rust tells us that wet iron surfaces are more likely to rust. The following equations describe the rusting of iron:

(i) $4\ \mathrm{Fe}(s) + 3\ \mathrm{O_2}(g) + 6\ \mathrm{H_2O}(\ell) \rightarrow 4\ \mathrm{Fe(OH)_3}(s)$

(ii) $2\ \mathrm{Fe(OH)_3}(s) \rightarrow \mathrm{Fe_2O_3}(s) + 3\ \mathrm{H_2O}(\ell)$

1. Identify the half-reactions for the overall process in equation (i).
2. Calculate E° for reaction (i) given $E^\circ = -0.775$ V for the reduction of $\mathrm{Fe(OH)_3}(s)$ to iron metal.
3. Calculate ΔG and E° for the process in the Particulate Review

exercise:

$4\ Fe(s) + 3\ O_2(g) \rightarrow 2\ Fe_2O_3(s)$

Rusting Shipwreck The *Titanic* sank in the waters of the North Atlantic on its maiden voyage in 1912. When the wreck was finally located in 1985, much of the vessel was covered by *rusticles*, which have the formula FeO(OH) (Figure P18.96). Reactions responsible for the formation of FeO(OH) include:

(i) $2\ Fe(s) + O_2(g) + 2\ H_2O(\ell) \rightarrow 2\ Fe(OH)_2(s)$

(ii) $4\ Fe(OH)_2(s) + O_2(g) + 2\ H_2O(\ell) \rightarrow 4\ Fe(OH)_3(s)$

(iii) $Fe(OH)_3(s) \rightarrow FeO(OH)(s) + H_2O(\ell)$

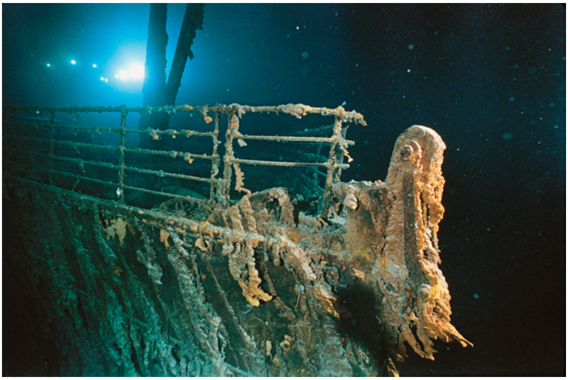

FIGURE P18.96

---

1. Which of these are redox reactions?
2. Use the following half-reaction and $E°$ value to calculate $E°_{cell}$ for reaction (ii): $Fe(OH)_3(s) + e^- \rightarrow Fe(OH)_2(s) + OH^-(aq)$ $E° = -0.56\ V$

Olympic Games The diving competition at the 2016 Olympic Games in Rio de Janeiro was plagued by green, turbid, and odorous water in the diving pool (Figure P18.97). Chlorine was used as a disinfectant in the pool water. One hypothesis for the green color is that 160 L of a 30% hydrogen peroxide solution (9.8 *M* H_2O_2) was added to the pool by mistake, deactivating the chlorine disinfectant and allowing green algae to grow.

1. When chlorine dissolves in slightly alkaline pool water, it hydrolyzes, forming hypochlorite and chloride ions:

$$Cl_2(g) + 2\ OH^-(aq) \rightarrow OCl^-(aq) + Cl^-(aq) + H_2O(\ell)$$

Use the appropriate half-reactions in Appendix 6 to calculate $E°_{rxn}$ for the reaction between OCl^- ions and H_2O_2.

2. Calculate the value of *K* for the reaction between OCl^- ions and H_2O_2.
3. If the swimming pool had dimensions of 25.0 m × 25.0 m × 10.0 m and contained 2.0 mg/L of OCl^- ions before H_2O_2 was added, what was the concentration of OCl^- ions after the reaction with H_2O_2?

FIGURE P18.97

Flint, Michigan, Water Supply Flint, Michigan, made headlines in

2017 when the municipal water supply was found to contain dangerous levels of dissolved lead(II) ion. The problem arose when the city began using water from the Flint River in its treatment plant and made changes in the purification process. The source of the lead turned out to be the lead and iron in the pipes.

1. One source of $Pb^{2+}(aq)$ is the reaction between dissolved oxygen and Pb in pipes. Write a balanced redox equation for this reaction in acidic solution.
2. Calculate E°_{cell} for the reaction in part (a) and determine whether it is spontaneous at 298 K.
3. Is the reaction more or less favorable in basic solution?
4. The pH of the water in Flint decreased from 8.0 in December 2014 to 7.3 in August 2015. How does this affect the cell potential if the $[Pb^{2+}(aq)] = 2000$ ppb and $P_{O2} = 0.21$ atm at 298 K? (*Hint*: Use Henry's law to calculate $[O_2]$.)
5. In principle, adding Cl^- to the water would precipitate any Pb^{2+} as $PbCl_2$ ($K_{sp} = 1.7 \times 10^{-5}$). What is the concentration of chloride in a saturated solution of $PbCl_2$? At what chloride concentration would $[Pb^{2+}]$ drop below 10 ppb?

Glossary

electrochemistry

the branch of chemistry that examines the transformations between chemical and electrical energy.

electrochemical cell

an apparatus that can either generate electrical energy from a chemical reaction or use electrical energy to produce a chemical reaction.

anode

an electrode at which an oxidation half-reaction (loss of electrons) takes place.

cathode

an electrode at which a reduction half-reaction (gain of electrons) takes place.

cell diagram	symbols that show how the components of an electrochemical cell are connected.
standard hydrogen electrode (SHE)	a reference electrode based on the half-reaction 2 $H^{1(aq)}$ + 2 e2S $H_{2(g)}$ that produces a standard electrode potential of 0.000 V.
Nernst equation	an equation relating the potential of a cell (or half-cell) reaction to its standard potential ($E°$) and to the concentrations of its reactants and products.
standard reduction potential ($E°$)	the potential of a reduction half-reaction in which all reactants and products are in their standard states at 25°C.
standard cell potential ($E°_{cell}$)	a measure of how forcefully an electrochemical cell in which all reactants and products in their standard states can pump electrons through an external circuit.
Faraday constant (F)	the magnitude of electrical charge in 1 mole of electrons; its value to three significant figures is 9.65×10^4 C/mol e^2.

THE DEAD SEA SCROLLS These artifacts were discovered in the late 1940s and early 1950s in caves near the northwest coast of the Dead Sea. Made of parchment and papyrus, many contained passages from the Hebrew Bible, including one with the entire Book of Isaiah, a portion of which is shown. By measuring the natural radioactivity of the scrolls due to the presence of carbon-14, scientists were able to determine that the scrolls were written between 200 bce and 100 ce.

Nuclear Chemistry Applications in Science and Medicine

PARTICULATE REVIEW

Isotopes Revisited

In Chapter 19 we investigate the stability and properties of radioactive nuclei. Three atomic nuclei are depicted here; each is drawn so that all the subatomic particles in the nucleus are visible.

- How many protons and how many neutrons does each nuclide contain?
- What is the mass number of each nuclide?
- Which two are isotopes of each other?

(Review Sections 2.2 and 2.3 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Unstable and Stable Nuclides

Radiocarbon dating measures the amount of carbon-14, the nuclide depicted here, in carbon-containing artifacts such as the Dead Sea Scrolls to determine the age of artifacts. Accurate measurements depend upon knowing how this unstable nuclide decays. As you read Chapter 19, look for ideas that will help you answer these questions.

- Does carbon-14 have more neutrons or protons?
- How might the ratio of neutrons to protons affect the decay of an unstable nuclide?
- What nuclide is produced when carbon-14 undergoes decay? What is the neutron-to-proton ratio of this nuclide?

Learning Outcomes

- LO1 Relate the binding energy of atomic nuclei to their composition and stability
- LO2 Predict the decay modes of radionuclides and the products they form

  Sample Exercise 19.1

- LO3 Compare the radioactivity of a sample of a radionuclide to the quantity of the nuclide in the sample

  Sample Exercise 19.2

- LO4 Compare the quantity of a radionuclide remaining after a defined decay time to the initial quantity and the half-life of the nuclide

Sample Exercise 19.3

- LO5 Determine the age of a sample by radiometric dating

  Sample Exercise 19.4

- LO6 Describe the dangers of exposure to nuclear radiation and calculate effective radiation doses

  Sample Exercise 19.5

- LO7 Relate the energy change in a nuclear reaction to the masses of the products and reactants

  Sample Exercise 19.6

$$\begin{aligned} \text{mass of 2 neutrons} &= 2(1.67493 \times 10^{-27}\ \text{kg}) \\ \text{mass of 2 protons} &= 2(1.67262 \times 10^{-27}\ \text{kg}) \\ \hline \text{total mass} &= 6.69510 \times 10^{-27}\ \text{kg} \end{aligned}$$

$$\begin{array}{l} 6.69510 \times 10^{-27}\ \text{kg} \\ -\ 6.64465 \times 10^{-27}\ \text{kg} \\ \hline 0.05045 \times 10^{-27}\ \text{kg} = 5.045 \times 10^{-29}\ \text{kg} \end{array}$$

$$\begin{aligned} \text{BE} &= (\Delta m)c^2 \\ &= 5.045 \times 10^{-29}\ \text{kg} \times (2.998 \times 10^{8}\ \text{m/s})^2 \\ &= 4.534 \times 10^{-12}\ \text{kg} \cdot (\text{m/s})^2 = 4.534 \times 10^{-12}\ \text{J} \end{aligned}$$

$$\frac{4.534 \times 10^{-12}\ \cancel{\text{J}}}{\cancel{\text{atom}}} \times \frac{6.022 \times 10^{23}\ \cancel{\text{atoms}}}{\text{mol}} \times \frac{1\ \text{kJ}}{\cancel{1000\ \text{J}}} = 2.730 \times 10^{9}\ \text{kJ/mol}$$

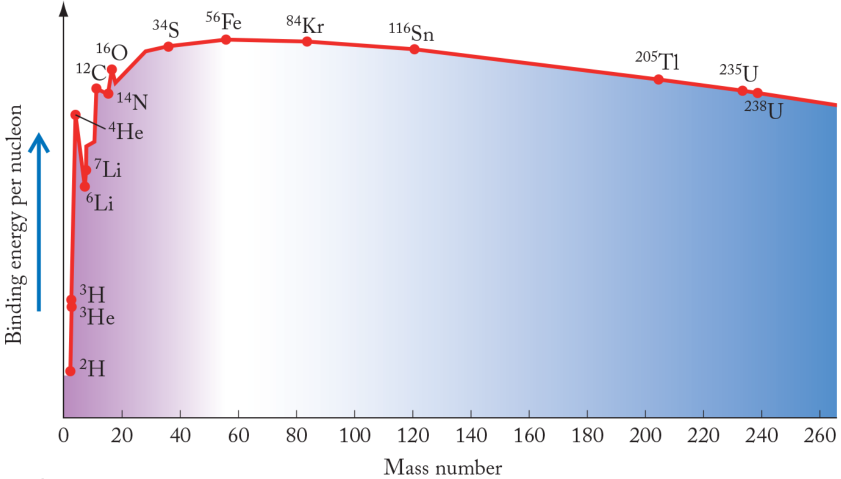

FIGURE 19.1 Trends in the binding energy per nucleon of atomic nuclei. For all nuclides up to ^{56}Fe, fusion reactions lead to products that have greater binding energies per nucleon than do the reactants. Therefore, these fusion reactions release energy. However, fusion of nuclei with atomic numbers greater than 26 produces nuclei that have less binding energy per nucleon than do

the reactants, and thus consumes energy.

19.1 Energy and Nuclear Stability

In 1898 Marie Curie separated and purified two new radioactive elements from uranium—polonium and radium—helping launch a new branch of chemistry now known as nuclear chemistry. Interest in the applications of radium grew rapidly. Paint containing radium was used to create luminous dials for watches and gauges. Ointments containing radium were prescribed as treatments for skin lesions. People were encouraged to visit health spas such as those in Saratoga Springs, New York, where the waters contained low concentrations of dissolved radium salts.

The proliferation of radium-containing products led to the discovery that nuclear radiation is dangerous. In one tragic example, young women hired to paint the dials of watches during World War I were instructed to "point" the tips of their brushes by licking them, inadvertently introducing radium into their bodies, where it concentrated in their teeth and bones. Within a few years, many of these young women developed bone cancer and died. Marie Curie herself succumbed to aplastic anemia caused by years of research with radioactive materials.

CONNECTION In Section 2.2 we described Henri Becquerel's discovery of radioactive uranium, and we saw how Ernest Rutherford's experiment, using α particles from the radioactive decay of uranium, led to the model of a dense atomic nucleus composed of protons and neutrons.

In recent years a better understanding of the biological impacts of radiation has led to the development of nuclear methods for diagnosing and treating disease that minimize the hazards of radiation to patients and those who treat them. Nuclear reactors provide doctors and scientists with radioactive atoms that decay over minutes to hours by predictable pathways. Selective uptake of these nuclides by different organs in the body allows doctors to evaluate organ function and prescribe treatment when function is impaired. Radiation from other nuclides that concentrate in cancerous tissues can be used, often in conjunction with other therapies, to destroy malignant tumors.

CONNECTION In Section 1.7 we described the rapid transformation of energy into matter that followed the Big Bang. The relationship between the energy and matter involved is described by Einstein's equation, $E = mc^2$.

Nuclear radiation results from reactions that take place in the unstable nuclei of some atoms. The energy released by these reactions can be used to help meet the world's need for electrical power and to diagnose and treat disease. However, these radioactive substances also pose a threat to human health, so shielding ourselves from them is essential. We begin by looking at the energy associated with nuclear transformations.

CONNECTION In Section 2.9 we explored the nucleosynthesis responsible for the formation of our early universe, including how early elements such as hydrogen and helium were transformed into more massive nuclei in the cores of the giant stars that populated the first generation of galaxies.

We first explored nuclear transformations in Section 2.9, focusing on the reactions that take place in stars. Beginning with the lightest elements, hydrogen and helium, stars ultimately produce nuclei as heavy as iron atoms, which contain 26 protons. Why does stellar nucleosynthesis end with the formation of iron nuclei? The answer has to do with the energy that binds the neutrons and protons together in atomic nuclei. This form of energy was discovered in the 1930s when scientists determined that the masses of stable nuclei are always less than the sum of the free masses of their nucleons. (The masses and symbols of subatomic particles are listed in **Table 19.1**.) For example, the total mass of the free nucleons in one ^{4}He nucleus—that is, 2 neutrons and 2 protons—is

The difference between this value and the mass of a ^{4}He nucleus (from Table 19.1) is

This difference is called the mass defect (Δm) of the nucleus. The energy equivalent to the mass defect of a nucleus is called its binding energy (BE) and can be calculated using Einstein's equation:

This value may seem very small, but it is the binding energy of a single nucleus. Its value per mole of ^{4}He is equivalent to billions of kilojoules:

For comparison, the bond energy of the H—H bond in H_2 is only 436 kJ/mol, which means the binding energy in a mole of He atoms is more than 6,000,000 times greater!

TABLE 19.1 Symbols and Masses of Subatomic Particles and Small Nuclei

Name	Symbol	Mass (kg)
neutron	$^{1}_{0}n$	1.67493×10^{-27}
proton	$^{1}_{1}p$ or $^{1}_{1}H$	1.67262×10^{-27}
electron (beta particle)	$^{0}_{-1}\beta$ or $^{0}_{-1}e$	9.10939×10^{-31}
deuteron	$^{2}_{1}D$ or $^{2}_{1}H$	3.34358×10^{-27}
alpha particle	$^{4}_{2}\alpha$ or $^{4}_{2}He$	6.64466×10^{-27}
positron	$^{0}_{1}\beta$	9.10939×10^{-31}

Most of the stable nuclei with more nucleons than helium-4 have even larger binding energies. This makes sense because a nucleus with many protons in proximity must be held together by an enormous energy to overcome the coulombic repulsion these positively charged particles exert on one another. When close together, nucleons come under the influence of a fundamental force of nature known as the strong nuclear force. It operates only over very small distances, such as the diameters of atomic nuclei, but it is many times stronger than the repulsions the protons experience.

Despite the enormous difference in the magnitudes of the forces involved, binding energies and bond energies are similar in that their zero reference points are free nucleons and free atoms, respectively. When these particles come together, forming nuclei or molecules, they are attracted to each other by the strong nuclear force in nuclei or by the electrostatic attractions between negatively charged electrons and the positively charged nuclei of other atoms that are the source of covalent bond energies. To separate nuclei or molecules into their component nucleons or atoms requires adding energy to overcome these forces and return the particles to their free, zero-energy states. Thus, both binding energies and bond energies have positive values.

To identify trends in the stabilities of different nuclei, their binding energies are usually divided by the number of nucleons in each nucleus. A graph of binding energy per nucleon plotted against mass number is shown in **Figure 19.1**. These energy values reach a maximum with ^{56}Fe. This pattern means that ^{56}Fe is the most stable nuclide in the universe, which fits what we know about stellar nucleosynthesis. The nuclear furnaces of giant stars are fueled by the energy released when lighter nuclei fuse to form heavier nuclei, but only when the heavier ones that form are more stable than the lighter ones. Energy is not released if one of the reacting particles is ^{56}Fe or a heavier nuclide because, according to Figure 19.1, these heavier fusion products are *less stable*, not more stable. Their formation consumes energy instead of producing it. Thus, an aged giant star whose core has turned into iron as a result of multiple nuclear fusion processes has essentially run out of fuel. Without heating from its nuclear furnace, the star's fusion reactions cease and its enormous gravity forces it to collapse into itself. The result is rapid heating as the star's mass is compressed, which causes the star to explode, releasing elements from $Z = 1$ to $Z = 26$. In rare cases stars explode with so much energy that they synthesize and release elements with atomic numbers greater than 26. Such an event is called a supernova, such as "Tycho's supernova" shown in Figure 2.26.

CONCEPT TEST

Why does a negative change in mass when nucleons combine to form a nucleus produce a positive binding energy?

(Answers to Concept Tests are in the back of the book.)

Glossary

nuclear chemistry	a subdiscipline of chemistry that explores the properties and reactivity of atomic nuclei.
mass defect (Δm)	the difference between the mass of a nucleus and the masses of the individual nucleons that make it up.
binding energy (BE)	the energy that would be released when free nucleons combine to form the nucleus of an atom; it is also the energy needed to split the nucleus into free nucleons.
strong nuclear force	the fundamental force of nature that keeps nucleons together in atomic nuclei.

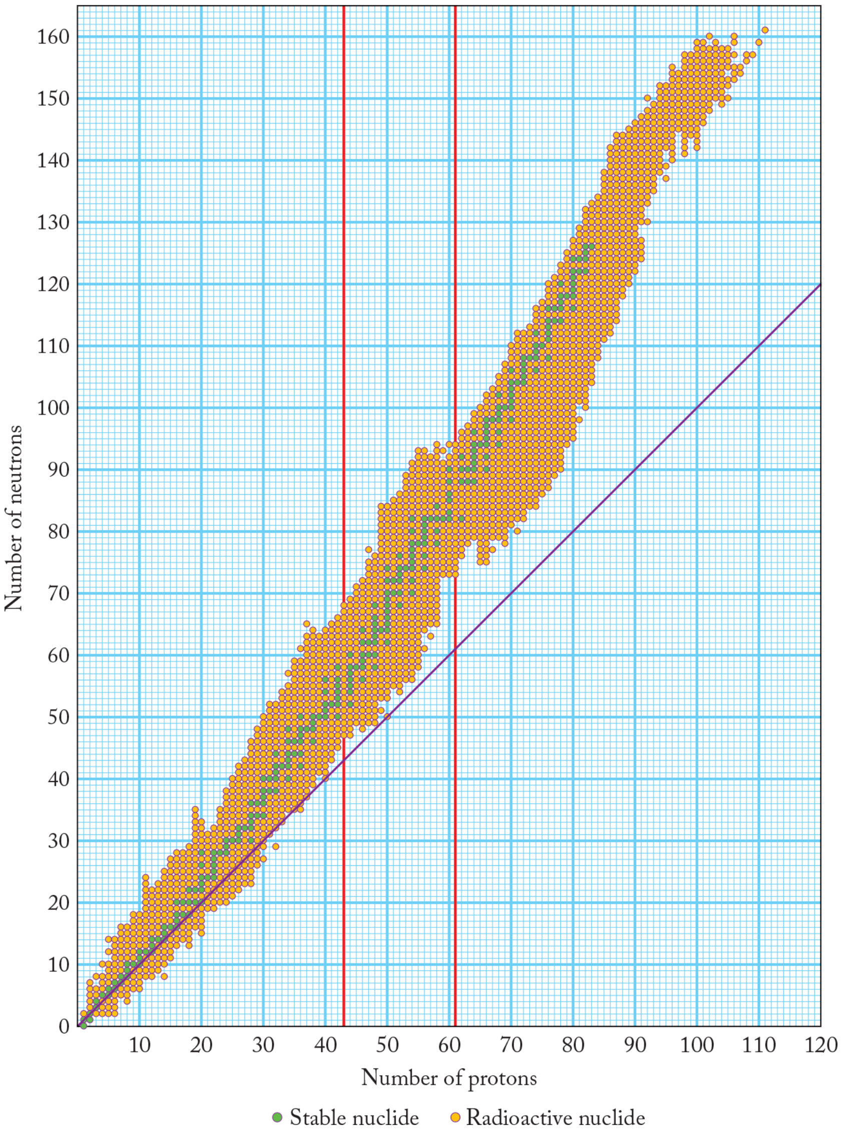

FIGURE 19.2 The belt of stability. Green dots represent stable combinations of protons and neutrons. Orange dots represent known radioactive (unstable) nuclides. Nuclides that fall along the purple line have equal numbers of neutrons and protons. There are no stable nuclides (no green dots) for $Z = 43$ (technetium) and $Z = 61$ (promethium), as indicated by the two vertical red lines.

FIGURE 19.4 Radioactive decay results in predictable changes in the number of protons and neutrons in a nucleus. In α decay, the nucleus loses 2 neutrons and 2 protons, resulting in a decrease of 2 in atomic number and 4 in mass number. Beta decay leads to an increase of 1 proton at the expense of 1 neutron, so the atomic number increases by 1, but the mass number is unchanged. In positron emission and electron capture, the number of protons decreases by 1 and the number of neutrons increases by 1, so the atomic number decreases by 1, but the mass number remains the same.

The dashed arrows are alternative pathways representing less than 1% of the decay events in this series. Whether decay proceeds by the solid-line pathways or the dashed-line pathways, the end product is always stable lead-206.

19.2 Unstable Nuclei and

Radioactive Decay

The values of the atomic masses and mass numbers of the elements in the periodic table indicate the ratios of neutrons to protons in the nuclei of their stable isotopes. The lighter elements have atomic masses that are about twice their atomic numbers and have neutron-to-proton ratios close to unity. For example, ^{12}C has 6 neutrons and 6 protons, and most oxygen atoms have 8 neutrons and 8 protons.

With increasing values of Z, however, the ratio of neutrons to protons increases. This trend is illustrated in **Figure 19.2**, where the green dots represent combinations of neutrons and protons that form stable nuclides. The band of green dots runs diagonally through the graph, defining the belt of stability. Notice how the belt curves upward away from the purple straight line, which represents a neutron-to-proton ratio of 1. Based on this curvature, the neutron:proton ratio increases from about 1:1 for the lightest stable nuclides to about 1.5:1 for the most massive ones.

The nuclides represented by orange dots in Figure 19.2 are radionuclides. They are not stable but instead undergo radioactive decay, which is the spontaneous disintegration of radioactive nuclei, accompanied by the release of nuclear radiation. Modes of radioactive decay depend on whether a nuclide is above or below the belt of stability. Those above, such as carbon-14, are *neutron rich* and tend to undergo *beta* (*β*) *decay*: a nuclear reaction in which a neutron disintegrates, producing a proton that remains in the nucleus and a high-speed, high-energy electron, called a β particle, that is emitted from the atom.

CONNECTION We encountered beta (β) decay, the spontaneous ejection of a β particle by a neutron-rich nucleus, in Section 2.9.

For example, a ^{14}C nucleus contains 6 protons and 8 neutrons, which means its neutron-to-proton ratio is 1.333—a large value for a small nucleus. This neutron-rich nucleus undergoes β decay as one of its 8 neutrons disintegrates into a proton, leaving it with $(8 - 1 = 7)$ neutrons and $(6 + 1 = 7)$ protons. These values mean that the product of the decay process is a nucleus of nitrogen-14. The following radiochemical equation describes the reaction:

The shimmering red shadow around the carbon nucleus in the drawing indicates that the carbon-14 nucleus is unstable and releases energy as it decays.

CONNECTION Section 2.9 explains how to write and balance nuclear equations.

Balancing Nuclear Equations

Nuclides below the belt of stability are *neutron poor* and undergo decay processes that *increase* their neutron-to-proton ratio. In one of these processes, the radioactive nucleus emits a high-velocity particle that has the same mass as an electron but that has a positive charge. It is called a positron $({}^{0}_{1}\beta)$, and its ejection from a neutron-poor nucleus is called positron emission. The net effect of positron emission is the production of a nuclide of a nucleus with one fewer proton and one more neutron, as illustrated in the decay of carbon-11:

Positrons belong to a group of subatomic particles that have the opposite charge but the same mass as particles typically found in atoms. In addition to positrons there are also protons with negative charges, called *antiprotons*. These charge opposites are particles of antimatter.

Particles of matter and their antimatter opposites are like mortal enemies. If they collide, they instantly annihilate each other. In their mutual destruction, they cease to exist as matter, and all of their mass is converted to energy in the form of two or more gamma (γ) rays:

The yellow “sunburst” here symbolizes the energy released in the process depicted.

Emission of γ rays accompanies all nuclear reactions, not just positron emission. The γ rays represent quantities of energy that are equivalent to the loss in mass that occurs when reactants form products in nuclear reactions. They are generated by the nuclear furnaces of stars and permeate outer space. Those that reach Earth are absorbed by the gases in our atmosphere. In the process, molecular gases are broken up into their component atoms, and atomic nuclei may be broken up into subatomic particles.

CONNECTION Figure 7.7 reveals that γ rays are the highest energy (shortest wavelength) form of electromagnetic radiation.

There is another way to increase the neutron-to-proton ratio of a neutron-poor nucleus: it can capture one of the inner-shell electrons of its atom. When it does, the negatively charged electron combines with a positively charged proton. The product of this combination reaction is a neutron. The effect of this electron capture process on the nucleus is the same as positron emission: the number of protons *decreases* by one and the number of neutrons *increases* by one. When a nucleus of carbon-11 undergoes electron capture, the product is boron-11, the same nuclide formed in positron emission:

Table 19.2 summarizes the effects of being neutron rich, neutron poor, or neither on isotopes of carbon. Carbon has two stable isotopes: ^{12}C and ^{13}C. The isotopes with mass numbers *greater* than 13 are neutron rich and undergo beta decay, whereas those with mass numbers *less* than 12 are neutron poor and undergo either positron emission or electron capture.

SAMPLE EXERCISE 19.1 Predicting the Modes and Products of Radioactive Decay LO2

Predict the mode of radioactive decay of ^{32}P, which is one of the most widely used radionuclides in biomedical research and treatment. Identify the nuclide that is produced in the decay process.

Collect, Organize, and Analyze We are asked to predict the mode of decay of a radionuclide, which depends on whether it is neutron rich or neutron poor. The mass number of ^{32}P is greater than the average atomic mass of all phosphorus atoms (30.974 u), which indicates that ^{32}P is neutron rich. Neutron-rich radioisotopes of lighter elements tend to undergo β decay in their nuclei to decrease the number of neutrons and increase the number of protons. Alternatively, we can consult the graph in **Figure 19.3**, which is a close up of the relevant portion of the belt of stability first shown in Figure 19.2. In Figure 19.3, ^{32}P (17 neutrons + 15 protons) is represented by the orange dot directly above the green dot for ^{31}P (the one and only stable phosphorus nuclide), which means that ^{32}P is radioactive and neutron rich.

Solve A β particle must be one product of the decay reaction, giving the incomplete nuclear equation:

The missing product must have an atomic number of 16 (so that the subscripts on the right side add up to 15), which makes it an isotope of S. Its mass number must be 32, so the product is sulfur-32:

Think About It By emitting a β particle, the ^{32}P nucleus increased its number of protons by one and decreased its number of neutrons by one, thereby reducing its neutron "richness" and forming a stable isotope of sulfur. (Locate the green dot in Figure 19.3 that represents ^{32}S to confirm that it is stable.)

Practice Exercise What is the mode of radioactive decay of ^{28}Al? Identify the nuclide produced by the decay process.

(Answers to Practice Exercises are in the back of the book.)

All known nuclides with more than 83 protons are radioactive. Because there is no stable reference point in the pattern of green dots in Figure 19.2, it is hard to say whether any given nuclide with $Z > 83$ is neutron rich or neutron poor. We can make one general statement though: these most massive nuclides tend to undergo either β decay or alpha (α) decay. In α decay they produce a nuclide with two fewer protons and two fewer neutrons, as shown here for uranium-238:

Figure 19.4 illustrates the changes in atomic number and mass number caused by the various modes of decay.

Among the most massive radionuclides, one radioactive decay process often leads to another in what is referred to as a *radioactive decay series*. Consider, for example, the decay series that begins with the α decay of ^{238}U to ^{234}Th (**Figure 19.5**). Thorium has no stable isotopes and undergoes two β decay steps to produce ^{234}U. In a series of subsequent α decay steps, ^{234}U turns into thorium-230, radium-226, radon-222, polonium-218, and finally lead-214. Although some isotopes of lead ($Z = 82$) are stable, ^{214}Pb is not one of them. Therefore, the radioactive decay series continues, as shown at the bottom left of Figure 19.5, and does not end until the stable nuclide ^{206}Pb is produced.

CONCEPT TEST

In the ^{238}U radioactive decay series, five α decay steps in a row transform ^{234}U into ^{214}Pb. Given the shape of the belt of stability, why does it make sense that the product of these α decay steps would be a neutron-rich nuclide that undergoes β decay?

Glossary

belt of stability

the region on a graph of number of neutrons versus number of protons that includes all stable nuclei.

radionuclide

an unstable nuclide that undergoes radioactive decay.

radioactive decay

the spontaneous disintegration of unstable particles accompanied by the release of radiation.

nuclear reaction

a process that changes the number of neutrons or protons in the nucleus of an atom.

positron $({}^{0}_{1}\beta)$

a particle with the mass of an electron but with a positive charge.

positron emission

the spontaneous emission of a positron from a neutron-poor nucleus.

antimatter

particles that are the charge opposites of normal subatomic particles.

electron capture

a nuclear reaction in which a neutron-poor nucleus draws in one of its surrounding electrons, which transforms a proton in the nucleus into a neutron.

alpha (α) decay

a nuclear reaction in which an unstable nuclide spontaneously emits an alpha particle.

FIGURE 19.6 In a Geiger counter, a particle produced by radioactive decay passes through a thin window, usually made of beryllium or a plastic film. Inside the tube, the particle ionizes atoms of argon gas. The resulting argon cations migrate toward the negatively charged tube housing, and the electrons migrate toward a positive electrode, creating a pulse of current through the tube. The current pulses are amplified and recorded via a meter and a speaker that produces an audible “click” for each pulse.

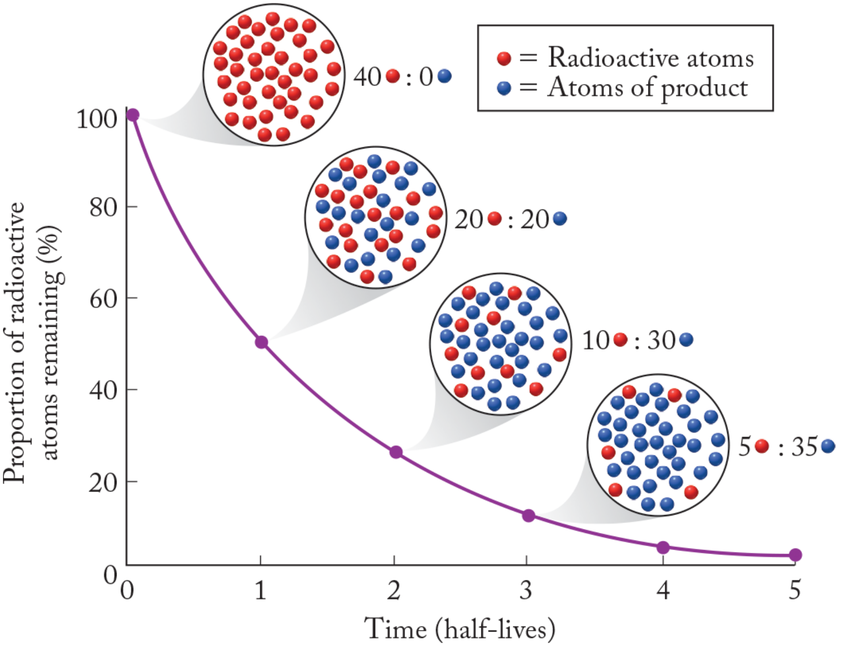

FIGURE 19.7 Radioactive decay follows first-order kinetics, which means, for example, that if a sample initially contains 40 radioactive atoms, it will contain only one-half that number after an interval equal to one half-life. Half of the remaining half, or 10 radioactive atoms, remain after two half-lives, and so on.

$$A = kN \tag{19.1}$$

$$t_{1/2} = \frac{0.693}{k} \tag{13.19}$$

19.3 Measuring and Expressing Radioactivity

Henri Becquerel discovered radioactivity in 1896 when he observed that uranium and other substances produced radiation that fogged photographic film. Photographic film is still used to detect radioactivity in the film dosimeter badges worn by people working with radioactive materials to record their exposure to radiation. Detectors called scintillation counters use materials called *phosphors* to absorb energy released during radioactive decay. The phosphors then release the absorbed energy as visible light, the intensity of which is a measure of the amount of radiation initially emitted.

Radioactivity can also be measured with many types of Geiger counters, which detect the common products of radioactivity—namely, α particles, β particles, and γ rays—on the basis of their abilities to ionize atoms (**Figure 19.6**). A sealed metal cylinder, filled with gas (usually argon) and a positively charged electrode, has a window that allows α particles, β particles, and γ rays to enter. Once they do, they ionize argon atoms into Ar^+ ions and free electrons. Free electrons migrate toward the positive electrode and Ar^+ ions migrate toward the negatively charged detector shell. This ion migration produces a pulse of electrical current whenever radiation enters the cylinder. The current is amplified and read out to a meter and a microphone that makes a clicking sound.

One measure of radioactivity in a sample is the number of nuclei that decay per unit time. This parameter is called the radioactivity (A) of the sample. The SI unit of radioactivity is the becquerel (Bq), named in honor of Henri Becquerel and equal to the decay of one radioactive atom per second. An older and much larger unit of radioactivity is the curie (Ci), named in honor of Marie and Pierre Curie, where

$$1\ \text{Ci} = 3.70 \times 10^{10}\ \text{Bq} = 3.70 \times 10^{10}\ \text{atoms s}^{-1}$$

Both the becquerel and the curie quantify the *rate* at which a radioactive substance decays, which provides a measure of how radioactive a sample is. All radioactive decay processes follow first-order kinetics, in which the reaction rate is equal to the rate constant (k) times the concentration of a reactant (R):

$$\text{Rate} = k[\text{R}]$$

We refer to radioactivity (A) instead of reaction rate when describing radioactive decay, and to the number of atoms (N) of a radionuclide in a sample instead of their concentration:

Because radioactivity (A) represents the number of radioactive atoms that decay per second, the units of the *decay rate constant* (k) are per second, which means radioactivity itself has units of atoms (that decay) per second, or atoms s^{-1}.

CONNECTION The *half-life* ($t_{1/2}$) is the time in the course of a chemical reaction during which the concentration of a reactant decreases by half (see Section 13.3). For a first-order reaction, $t_{1/2}$ is inversely proportional to the rate constant (k).

Because radioactive decay is a first-order reaction, the decay rate constant is related to the radionuclide's half-life (**Figure 19.7**) by Equation 13.19:

Glossary

scintillation counter

an instrument that determines the level of radioactivity in samples by measuring the intensity of light emitted by phosphors in contact with the samples.

Geiger counter

a portable device for determining nuclear radiation levels by measuring how much the radiation ionizes the gas in a sealed detector.

becquerel (Bq)

the SI unit of radioactivity equal to the decay of one radioactive atom per second.

curie (Ci)

a non-SI unit of radioactivity in which 3.70 × 10
10 radioactive atoms decay per second.

$$t_{1/2} = \frac{0.693}{k}$$

$$11.4\ \cancel{\mathrm{d}} \times \frac{24\ \cancel{\mathrm{h}}}{1\ \cancel{\mathrm{d}}} \times \frac{60\ \cancel{\mathrm{min}}}{1\ \cancel{\mathrm{h}}} \times \frac{60\ \mathrm{s}}{1\ \cancel{\mathrm{min}}} = 9.85 \times 10^{5}\ \mathrm{s}$$

$$k = \frac{0.693}{9.85 \times 10^{5}\ \mathrm{s}} = 7.04 \times 10^{-7}\ \mathrm{s}^{-1}$$

$$N = 1.00\ \cancel{\mu\mathrm{g}} \times \frac{1\ \cancel{\mathrm{g}}}{10^{6}\ \cancel{\mu\mathrm{g}}} \times \frac{1\ \cancel{\mathrm{mol}}}{223\ \cancel{\mathrm{g}}} \times \frac{6.022 \times 10^{23}\ \mathrm{atoms}}{1\ \cancel{\mathrm{mol}}} = 2.70 \times 10^{15}\ \mathrm{atoms}$$

$$\frac{1.90 \times 10^{9}\ \cancel{\mathrm{atoms}}}{\cancel{\mathrm{s}}} \times \frac{1\ \mathrm{Ci}}{3.70 \times 10^{10}\ \cancel{\mathrm{atoms/s}}} = 0.0514\ \mathrm{Ci}$$

$$\ln[\mathrm{X}] = -kt + \ln[\mathrm{X}]_0 \qquad (13.18)$$

$$\ln N_t = -kt + \ln N_0 \qquad (19.2)$$

$$\ln N_t = -0.693\,\frac{t}{t_{1/2}} + \ln N_0 \qquad (19.3)$$

$$\ln N_t = -0.693\,\frac{t}{t_{1/2}} + \ln N_0 = -0.693\,\frac{6.67\ \cancel{\mathrm{min}}}{10.25\ \cancel{\mathrm{min}}} + \ln(7.25 \times 10^{5}) = 13.043$$

$$N_t = e^{13.043} = 4.62 \times 10^{5}\ \mathrm{neutrons}$$

19.4 Calculations Involving Half-Lives of Radionuclides

In Section 19.4 we use first-order reaction kinetics to *calculate* the level of radioactivity in a sample initially and after it has decayed for a specified time and to calculate how long it takes for a sample to decay to a target percentage of its initial radioactivity. We start by calculating the radioactivity of a sample based on the quantity and half-life of a radionuclide in the sample.

SAMPLE EXERCISE 19.2 Calculating the Radioactivity of a Sample
LO3

Radium-223 undergoes decay with a half-life of 11.4 days. What is the radioactivity of a sample that contains 1.00 μg of ^{223}Ra? Express your answer in becquerels and in curies.

Collect and Organize We are given the half-life and quantity of a radioactive substance and are asked to determine its radioactivity—that is, its rate of decay. The decay rate constant (k) is related to half-life by Equation 13.19:

According to Equation 19.1 ($A = kN$), radioactivity (A) is the product of the rate constant and the number of atoms of radionuclide (N) in the sample.

Analyze Before using Equation 13.19, we must convert the half-life into seconds because both of the radioactivity units we need to calculate are based on the number of atoms that decay per second. To calculate radioactivity, we must determine the number of radioactive atoms in 1.00 μg of radium. This will probably be a very large number, which, coupled with the relatively short half-life of ^{223}Ra, means that many nuclei should undergo radioactive decay each second.

Solve The half-life of ^{223}Ra in seconds is

Using this value in Equation 13.19 and solving for k:

The number of atoms (N) of ^{223}Ra is

Inserting these values of k and N into Equation 19.1 gives us

$A = kN = 7.04 \times 10^{-7}\ \text{s}^{-1} \times 2.70 \times 10^{15}$ atoms $= 1.90 \times 10^{9}$ atoms/s

Because 1 Bq = 1 atom/s, the radioactivity of the sample is 1.90×10^{9} Bq. Expressing radioactivity in curies:

Think About It The large number of atoms that decay each second meets our expectation of a high level of radioactivity.

Practice Exercise In March 2011 an earthquake and tsunami off the coast of northeast Japan crippled nuclear reactors at a power station in Fukushima, Japan. The resulting explosions and fires released ^{133}Xe into the atmosphere. Determine the radioactivity of 1.00 μg of this radionuclide ($t_{1/2} = 5.25$ days) in becquerels and in millicuries.

In Section 13.3 we used the integrated rate law for first-order reactions to develop Equation 13.18, which relates the concentration of reactant X, $[X]$, at any time t during the course of a first-order reaction to its initial concentration, $[X]_0$, and the rate constant (k) of the reaction:

To apply this relationship to radioactive decay reactions, we replace the concentration terms with numbers of radioactive atoms at time 0 (N_0) and at any later time t (N_t):

Frequently the kinetics of radioactive decay processes are expressed using their half-lives rather than rate constants, so we use Equation 13.19 to substitute $t_{1/2}$ for k in Equation 19.2:

The fraction $t/t_{1/2}$ represents the number of half-lives (including fractions of half-lives) that have passed since the sample contained N_0 atoms of the radionuclide. Sample Exercise 19.3 illustrates how useful Equation 19.3 can be.

SAMPLE EXERCISE 19.3 Calculating the Quantity of a Radionuclide Remaining in a Sample LO4

Free neutrons are radioactive, undergoing β decay with a half-life of 10.25 min. Starting with a population of 7.25×10^5 free neutrons, how many are left after 6.67 min?

Collect, Organize, and Analyze Equation 19.3 relates quantities of radioactive particles to decay times. In this problem the initial number of neutrons (N_0) is 7.25×10^5, $t = 6.67$ min, and $t_{1/2} = 10.25$ min. We need to solve for N_t. The value of t is less than $t_{1/2}$, so fewer than half of the initial number of neutrons will have decayed after 6.67 min. In other words, more than half of the neutrons will still be present.

Solve Substituting the data into Equation 19.3 and solving for N_t:

Think About It The value of N_t is reasonable because, as predicted, less than half of the initial quantity of free neutrons decayed in a time (6.67 min) that was less than the half-life.

Practice Exercise Cesium-131 is a short-lived radionuclide ($t_{1/2} = 9.7$ d) used to treat prostate cancer. If the therapeutic strength of the radionuclide is directly proportional to the number of nuclei present, how much therapeutic strength does a cesium-131 source lose over exactly 60 days? Express your answer as a percentage of the strength the source had at the beginning of the first day.

Learning Objectives

- Compare the radioactivity of a sample of a radionuclide to the quantity of the nuclide in the sample **Return to Sample Exercise 19.2**
- Compare the quantity of a radionuclide remaining after a defined decay time to the initial quantity and the half-life of the nuclide **Return to Sample Exercise 19.3**

$$^{14}_{7}\mathrm{N} + {}^{1}_{0}\mathrm{n} \rightarrow {}^{14}_{6}\mathrm{C} + {}^{1}_{1}\mathrm{p}$$

$$^{14}_{6}\mathrm{C} \rightarrow {}^{14}_{7}\mathrm{N} + {}^{0}_{-1}\beta$$

$$\ln \frac{N_t}{N_0} = -0.693 \frac{t}{t_{1/2}}$$

$$t = -\frac{t_{1/2}}{0.693} \ln \frac{N_t}{N_0} \tag{19.4}$$

$$\begin{aligned} t &= -\frac{t_{1/2}}{0.693} \ln \frac{N_t}{N_0} \\ &= -\frac{5730 \text{ yr}}{0.693} \ln(0.619) \\ &= 3966 \text{ yr} = 3.97 \times 10^3 \text{ yr} \end{aligned}$$

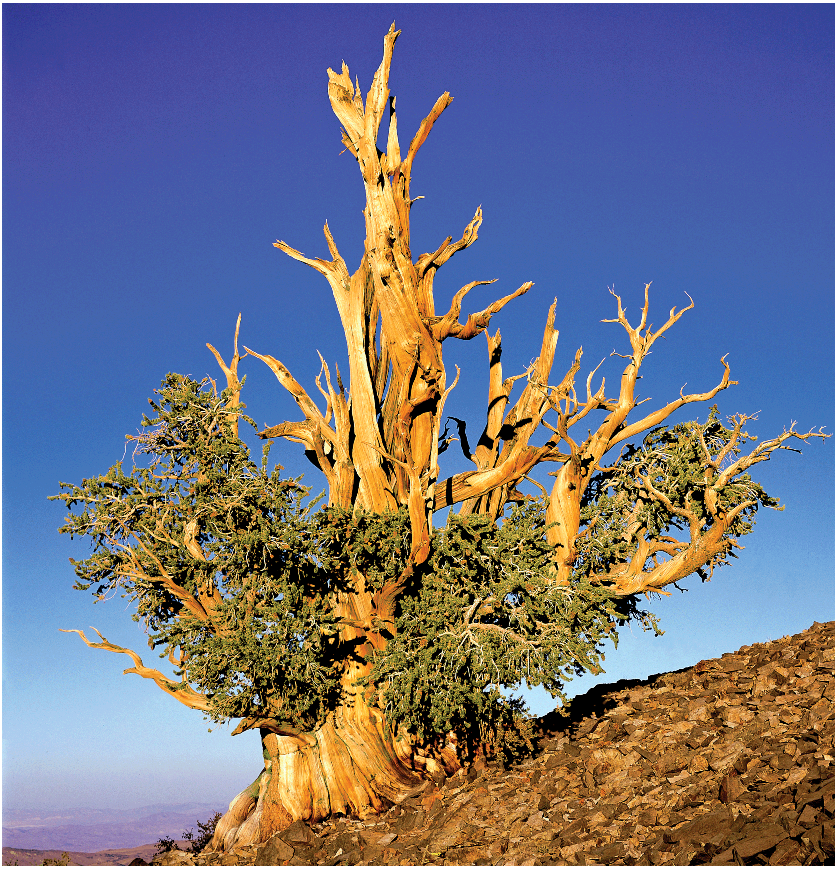

FIGURE 19.8 Radiocarbon dating relies on knowing the atmospheric concentration of carbon-14 over time. Annual growth rings in the trunks of ancient living trees, such as the bristlecone pines in the American Southwest, act as a check of the atmospheric carbon-14 levels over thousands of years. The ages of the rings can be determined by counting them, and their carbon-14 content can be determined by mass spectrometry.

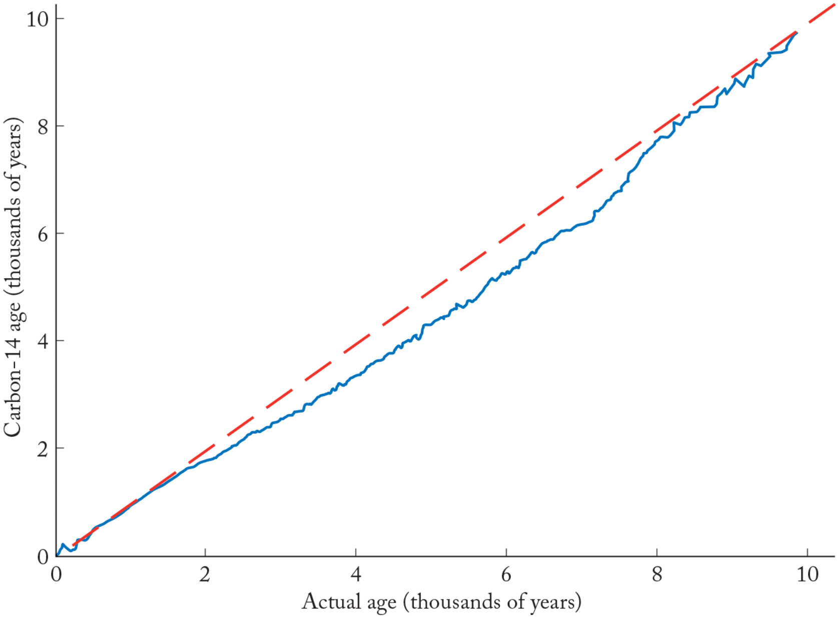

FIGURE 19.9 Calibration curves for radiocarbon dating allow scientists to accurately calculate the ages of archeological objects. If the rate of ^{14}C production in the upper atmosphere were constant, then the age of objects on the basis of their ^{14}C content would match their actual age—a condition represented by the red dashed line. However, analyses of tree rings, corals, and lake sediments indicate that the rate of ^{14}C production in the upper atmosphere is variable, so a real plot of ^{14}C age versus actual age produces the jagged blue line. This plot allows scientists to convert ^{14}C ages into actual ages.

19.5 Radiometric Dating

Radiometric dating refers to methods for determining the age of objects on the basis of the tiny concentrations of radionuclides that occur naturally in them and the rates of radioactive decay of these nuclides. The concept originated in the early 1900s with the work of Ernest Rutherford, who recognized that radioactive decay processes have characteristic half-lives. Rutherford proposed to use this concept to determine the age of rocks and even the age of Earth itself. The basis for his initial attempt was the emission of α particles from uranium ore. He correctly suspected that α particles were part of helium atoms, and he proposed to determine the age of uranium ore samples by determining the concentration of helium gas trapped inside them.

Rutherford's helium method did not yield accurate results, but it did inspire a young American chemist, Bertram Boltwood (1870–1927), who had determined that the decay of radioactive uranium involves a series of decay events ending with the formation of stable lead (see Figure 19.5). In 1907 Boltwood published the results of dating 43 samples of uranium-containing minerals on the basis of the ratio of lead to uranium in them. The ages he reported spanned hundreds of millions to over a billion years and probably represented the first successful attempt at radiometric dating.

The development of the mass spectrometer for accurately determining the abundances of individual isotopes of elements, coupled with more accurate half-life values for decay events such as those in Figure 19.5, has allowed scientists to use the ratio of ^{206}Pb to ^{238}U in geological samples to determine their ages with a precision of about $\pm 1\%$. Other methods, including one based on the decay of ^{235}U to ^{207}Pb ($t_{1/2} = 7.0 \times 10^6$ yr), may be used to analyze the same samples, providing independent determinations that mutually ensure more accurate results. In 1956 American geochemist Claire Patterson (1922-1995) showed that the oldest rocks on Earth are more than 4.0 billion years old and that meteorites formed as the solar system formed are 4.5 billion years old.

CONNECTION In Section 2.3 we saw that mass spectrometry (i.e., Francis W. Aston's positive-ray analyzer, Figure 2.10) can be used to determine the abundances of the isotopes of elements in a sample. Mass spectrometry is discussed in greater detail in Section 3.8.

These radiometric methods for dating geological samples yield reliable results only when the sample is a closed system, which means that the only loss of the radionuclide is through radioactive decay and that all of the nuclides produced by the decay processes remain in the sample. In addition, those decay processes must be the only source of the product nuclides. For these reasons, scientists must exercise care in selecting the types of samples they subject to radiometric dating analysis. For example, the presence of the mineral zircon ($ZrSiO_4$) in a geological sample is good news for scientists interested in using radiometric dating because U^{4+} ions readily substitute for Zr^{4+} ions as crystals of $ZrSiO_4$ solidify from the molten state, but Pb^{2+} ions do not. Therefore, the only source of ^{206}Pb and ^{207}Pb in a zircon sample should be the decay of ^{238}U and ^{235}U, respectively.

In 1947 American chemist Willard Libby (1908–1980) developed a radiometric dating technique, called radiocarbon dating, for determining the age of artifacts from prehistory and early civilizations. The method is based on determining the carbon-14 content of samples derived from plants or the animals that consumed them. Carbon-14 originates in the upper atmosphere, where cosmic rays break apart the nuclei of atoms, forming free protons and neutrons. When one of these neutrons collides with a nitrogen-14 atom, it forms an atom of radioactive carbon-14 and a proton:

Atmospheric carbon-14 combines with oxygen, forming $^{14}CO_2$. The atmospheric concentration of $^{14}CO_2$ amounts to only about 10^{-12} of all the molecules of CO_2 in the air. These traces of radioactive CO_2, along with the stable forms, $^{12}CO_2$ and $^{13}CO_2$, are incorporated into the structures of green plants during photosynthesis. The tiny fraction of the plant's mass that is ^{14}C gets even tinier after a plant dies, or after a part of it stops growing and photosynthesizing, because ^{14}C undergoes β decay, as we described in Section 19.2:

The half-life of this decay process is 5730 years.

The dating process starts by determining the ^{14}C content (N_t) of an object of historical interest, such as a piece of wood from an ancient building, charcoal from a prehistoric campfire, or the parchment used in the Dead Sea Scroll shown in the opening photo of this chapter. The analyst also needs to know (or be able to predict) the object's ^{14}C content when the material in it was alive (N_0). This information can be used in an equation based on Equation 19.3 in which the N terms are combined in the ln term:

Next, the terms are rearranged to solve for *t*:

SAMPLE EXERCISE 19.4 Radiocarbon Dating LO5

The ^{14}C content of a wooden harpoon handle found in the remains of an Inuit encampment in western Alaska is 61.9% of the ^{14}C content of the same type of wood from a recently cut tree. How old is the harpoon?

Collect, Organize, and Analyze The half-life of carbon-14 is 5730 years. Equation 19.4 provides the age *t* of the artifact if we know the ratio of the ^{14}C in it today to its initial ^{14}C content. The ^{14}C content of the modern sample can be used as a surrogate for the initial ^{14}C content of the artifact. Therefore, 61.9% (or 0.619) represents the ratio N_t/N_0. This value is greater than 0.5, which means that the age of the sample is less than one half-life (5730 yr).

Solve Substituting into Equation 19.4:

Think About It The resulting age is less than one half-life, which is reasonable because it contained more than half the original carbon-14 content. The result is expressed with three significant figures to match that of the starting composition (61.9%).

Practice Exercise The carbon-14:carbon-12 ratio in papyrus growing along the Nile River today is 1.8 times greater than in a papyrus scroll found near the Great Pyramid at Giza. How old is the scroll?

The accuracy of radiocarbon dating can be checked by determining the ^{14}C content of the annual growth rings of very old trees, such as the bristlecone pines that grow in the American Southwest (**Figure 19.8**). When scientists plot the radiocarbon ages of these rings against their actual ages obtained by counting rings starting from the outer growth layer of the tree (representing $t = 0$), they find that the two sets of ages do not agree exactly, as shown in **Figure 19.9**. There are several reasons for this lack of agreement, including variability in the rate of ^{14}C production because of changing intensity of the cosmic rays striking Earth's upper atmosphere. To ensure accurate ^{14}C results, scientists must correct for these and other variations, and they must be careful to avoid contaminating ancient samples with modern carbonaceous material. With proper analytical technique, modern radiocarbon dating results are generally accurate to within 40 years for samples that are 500–50,000 years old.

CONCEPT TEST

How might the increased consumption of fossil fuels over the last century affect the ^{14}C content of growing plant tissues?

Glossary

radiometric dating	a method for determining the age of an object on the basis of the quantity of a radioactive nuclide, the products of its decay that the object contains, or both.
radiocarbon dating	a method for establishing the age of a carbon-containing object by measuring the amount of radioactive carbon-14 remaining in the object.

Learning Objectives

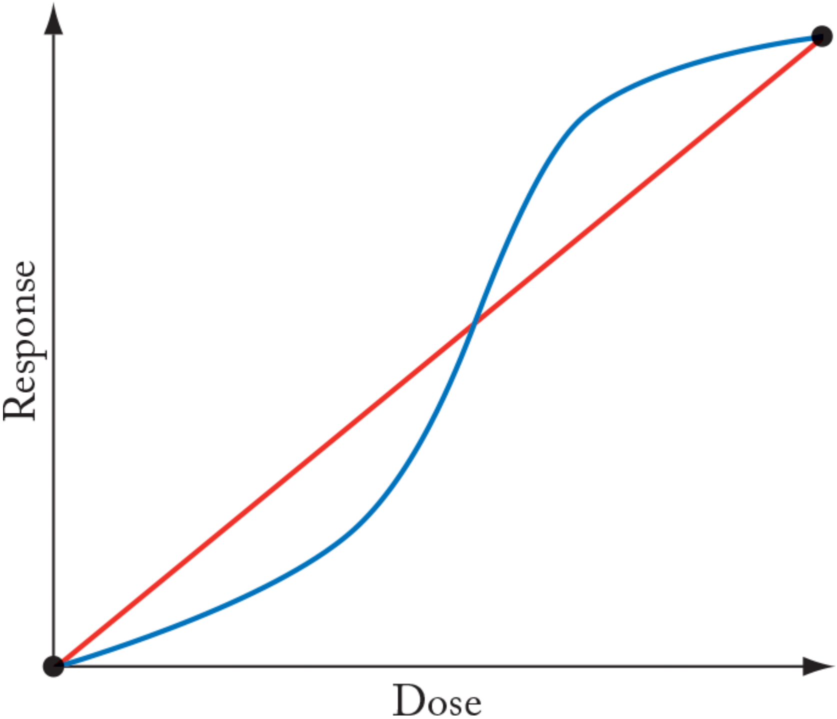

FIGURE 19.16 The risk of death from radiation-induced cancer may follow one of two models. In the linear response model (red line), risk is directly proportional to the radiation exposure. In the S-shaped model (blue line), risk remains low below a critical threshold and then increases rapidly as the exposure increases. In

the S-shaped model, the risk is less than for the linear model at low doses but is higher at higher doses.

19.6 Biological Effects of Radioactivity

The γ rays and most of the α and β particles produced by nuclear reactions have more than enough energy to tear chemical bonds apart, producing odd-electron radicals or free electrons and cations. Consequently, these rays and particles are classified as ionizing radiation. Other examples include X-rays and short-wavelength ultraviolet rays. The ionization of atoms and molecules in living tissue can lead to radiation sickness, cancer, birth defects, and death. The scientists who first worked with radioactive materials were unaware of these hazards, and some of them suffered for it. Marie Curie died from radiation exposure, and so did her daughter Irène Joliot-Curie, who continued the research started by her parents.

In medicine, the term *ionizing radiation* is limited to photons and particles that have sufficient energy to remove an electron from water[1]:

The logic behind this definition is that the human body is composed largely of water. Therefore, water molecules are the most abundant ionizable targets when we are exposed to nuclear radiation. The cation H_2O^+ reacts with another water molecule in the body to form a hydronium ion and a hydroxyl free radical:

$$H_2O^+(aq) + H_2O(\ell) \rightarrow H_3O^+(aq) + OH$$

The rapid reactions of free radicals with biomolecules can disrupt cell function, sometimes with life-threatening consequences.

Radiation-induced alterations to the biochemical machinery that controls cell growth are most likely to occur in tissues in which cells grow and divide rapidly. One such tissue is bone marrow, where billions of white blood cells are produced each day to fortify the body’s immune system. Molecular damage to bone marrow can lead to leukemia—the uncontrolled production of nonfunctioning white blood cells that spread throughout the body, crowding out healthy cells. Ionizing radiation can also cause molecular alterations in the genes and chromosomes of sperm and egg cells, increasing the chances of birth defects.

Radiation Dosage

The biological impact of ionizing radiation depends on how much of it is absorbed by an organism. If the radiation is coming from one radioactive source, then the amount absorbed depends on the radioactivity of the source and the energy of the radiation that is produced per decay event. Tables of radioactive isotopes often include information about their modes of decay and the energies of the particles and γ rays they emit.

Absorbed dose is the quantity of ionizing radiation absorbed by a unit mass of living tissue. The SI unit of absorbed dose is the gray (Gy). One gray is equal to the absorption of 1 J of radiation energy per kilogram of body mass:

$$1\ \text{Gy} = 1\ \text{J/kg}$$

TABLE 19.3 RBE Values of Nuclear Radiation

Radiation	RBE
γ Rays	1.0
β Particles	1.0–1.5
Neutrons	3–5
Protons	10
α Particles	20

Grays express dosage, but they do not indicate the amount of *tissue damage* caused by that dosage. Different products of nuclear reactions affect living tissue differently. Exposure to 1 Gy of γ rays produces about the same amount of tissue damage as exposure to 1 Gy of β particles. However, 1 Gy of α particles, which move about 100 times slower than β particles but have nearly 10^4 times the mass, causes up to 20 times as much damage as 1 Gy of γ rays.

Neutrons cause 3 to 5 times as much damage. To account for these differences, values of relative biological effectiveness (RBE) have been established for the various forms of ionizing radiation (**Table 19.3**). When an absorbed dose in grays is multiplied by an RBE factor, the product is called the *effective* dose, a measure of tissue damage. The SI unit of effective dose is the sievert (Sv).

Table 19.4 summarizes the various units used to express quantities of radiation and their biological impact. Two non-SI units are listed that predate their SI counterparts but are still often used. They are *radiation absorbed dose* (*rad*), which is equivalent to 0.01 Gy, and *roentgen equivalent man* (*rem*) for tissue damage. One rem is the product of one rad of ionization times the appropriate RBE factor. There are 100 rems in 1 Sv.

The RBE of 20 for α particles may lead you to believe that these particles pose the greatest health threat from radioactivity. Not exactly. Because they are so big, α particles have little penetrating power; they are stopped by a sheet of paper, clothing, or even a layer of dead skin (**Figure 19.10**). If you ingest or inhale an α emitter, however, then the relatively massive α particles cause severe damage to the small number of cells each of them can penetrate. In contrast, γ rays emanating from sources outside the body are dangerous because they have the greatest penetrating power.

TABLE 19.4 Units for Expressing Quantities of Ionizing Radiation

[illegible] Common Unit
[illegible] decay events/s
[illegible] absorbed
[illegible] tissue damage

The effects of exposure to different single effective doses of radiation are summarized in **Table 19.5**. To put these data in perspective, the effective dose from a typical dental X-ray is about 5 μSv, or about 2000 times less than the lowest exposure level cited in the table.

Widespread exposure to very high levels of radiation occurred after the 1986 explosion at the Chernobyl nuclear reactor in what is now Ukraine (**Figure 19.11**). Many plant workers and first responders were exposed to more than 1.0 Sv of radiation. At least 30 of them died in the weeks after the accident. Many of the more than 300,000 workers who cleaned up the area around the reactor exhibited symptoms of radiation sickness, and at least 5 million people in Ukraine, Belarus, and Russia were exposed to fallout in the days following the accident. Studies conducted in the early 1990s uncovered high incidences of thyroid cancer in children in southern Belarus as a result of ^{131}I released in the Chernobyl accident, and children born in the region nearly a decade after the accident had unusually high rates of mutations in their DNA because of their parents’ exposure to ionizing radiation. Genetic damage was also widespread among plants and animals living in the region.

Radiation exposure was not confined to Ukraine and Belarus. After the accident, a cloud of radioactive material spread across northern Europe. (Its detection came as a surprise because news of the incident had been covered up by the leaders of what was then the Soviet Union.) Within two weeks increased levels of radioactivity were detected throughout the Northern Hemisphere (**Figure 19.12**). The accident produced a global increase in human exposure to ionizing radiation estimated to be equivalent to 50 μSv per year, which is comparable to ten dental X-rays.

TABLE 19.5 Acute Effects of Single Whole-Body Effective Doses of Ionizing Radiation

Effective Dose (Sv)	Effect
0.05–0.25	No acute effect, possible carcinogenic or mutagenic damage to DNA
0.25–1.0	Temporary reduction in white blood cell count
1.0–2.0	Radiation sickness: fatigue, vomiting, diarrhea, impaired immune system
2.0–4.0	Severe radiation sickness: intestinal bleeding, bone marrow destruction
4.0–10.0	Death, usually through infection, within weeks
>10.0	Death within hours

As a result of an earthquake and tsunami in March 2011, nuclear reactors at a power station in Fukushima, Japan, released between 340 and 780 PBq (i.e., 340×10^{15} to 780×10^{15} Bq) of radiation into the environment (**Figure 19.13**), with an estimated 80% landing in the Pacific Ocean. This represents a slightly smaller release of radiation than the Chernobyl disaster, estimated at 5200 PBq.

Evaluating the Risks of Radiation

To put global radiation exposure from Chernobyl in perspective, we need to consider typical annual exposure levels. For many people, the principal source of radiation is radon gas in indoor air and in well water (**Figure 19.14**). Like all noble gases, radon ($Z = 86$) is chemically inert. Unlike the others, all of its isotopes are radioactive (as are all known nuclides with $Z > 83$—see Section 19.2). The most common isotope, radon-222, is produced when uranium-238 in rocks and soil decays to lead-206 (see Figure 19.5). The radon gas formed in this decay series percolates upward and can enter a building through cracks and pores in its foundation.

If you breathe air contaminated with radon and then exhale before it decays, no harm is done. If radon-222 decays inside the lungs, however, then it emits an α particle that can attack lung tissue. The nuclide produced by the α decay of ^{222}Rn is radioactive polonium-218, which may become attached to tissue in the respiratory system and undergo a second α decay, forming lead-214:

As we have seen, α particles are the most damaging product of nuclear decay when formed *inside the body.* How big of a threat does radon pose to human health? Concentrations of indoor radon depend on local geology (**Figure 19.15**) and on how gastight building foundations are. The air in many buildings contains concentrations of radon with radioactivity levels in the range of 1 pCi per liter of air. How hazardous are such tiny concentrations? There appears to be no simple answer. The U.S. Environmental

Protection Agency has established 4 pCi/L as an "action level," meaning that people occupying houses with higher concentrations should take measures to minimize their exposure.

CONCEPT TEST

The Environment Canada guideline for radon in indoor air is 200 Bq/m^3. Is this value more or less than the American action level?

This action level is based on studies of the incidence of lung cancer in workers in uranium mines. These workers are exposed to radon concentrations (and concentrations of other radionuclides) that are much higher than the concentrations in homes and other buildings. However, many scientists believe that people exposed to very low levels of radon for many years are as much at risk as miners exposed to high levels of radiation for shorter periods. Some researchers use a model that assumes a linear relation between radon exposure and incidence of lung cancer. This model is represented by the red line in **Figure 19.16**, which graphs the risk of cancer deaths as a function of radiation absorbed. On the basis of this dose–response model, an estimated 15,000 Americans die of lung cancer each year because of exposure to indoor radon. This number comprises 10% of all lung-cancer fatalities and 30% of those among nonsmokers.

Is this linear model valid? Perhaps—but some scientists believe that there may be a threshold of exposure below which radon poses no significant threat to public health. They advocate an S-shaped dose–response curve, shown by the blue line in Figure 19.16. The risk of death from cancer in the S-shaped curve is much lower than in the linear response model at low radiation exposure but rises rapidly above a critical value.

SAMPLE EXERCISE 19.5 Calculating Effective Dose LO6

It has been estimated that a person living in a home where the air radon concentration is 4.0 pCi/L receives an annual absorbed dose of ionizing radiation equivalent to 0.40 mGy increasing the risk of dying from lung cancer by 1%. What is the person's annual effective dose, in millisieverts (mSv), from this radon? Use information from Figure 19.14 to compare this annual effective dose from radon with the average annual effective dose from radon estimated for persons living in the United States.

Collect, Organize, and Analyze We are given an absorbed radiation dose of 0.40 mGy. Radon isotopes emit α particles, which we know from Table 19.3 have a relative biological effectiveness of 20. The effective dose caused by an absorbed dose of ionizing radiation is the absorbed dose multiplied by the RBE of the radiation.

Solve

$$0.40\ \text{mGy} \times 20 = 8.0\ \text{mSv}$$

According to the caption to Figure 19.14, the average American is exposed to 3.6 mSv of radiation per year, and the graph indicates that 54% of that amount, or 1.9 mSv, comes from radon. A person living in the home described in this problem has an effective dose from radon that is slightly more than four times the average value.

Think About It The calculated value is more than twice the average annual effective dose of 3.6 mSv from all sources of radiation. This is why public health officials are concerned about radon exposure.

Practice Exercise Imaging the lower gastrointestinal tract involves the administration of a barium salt followed by radiation with X-rays. A typical effective dose in these studies is 8 μSv. If an X-ray machine emits X-rays with an energy of 6.0×10^{-17} J each, how many of these X-rays must be absorbed per kilogram of tissue to produce an effective dose of 8 μSv? Assume the RBE of these X-rays is 1.2.

Glossary

ionizing radiation

high-energy products of radioactive decay that can ionize molecules.

gray (Gy)

the SI unit of absorbed radiation; 1 Gy = 1 J/kg of tissue.

relative biological effectiveness (RBE)

a factor that accounts for the differences in physical damage caused by different types of radiation.

sievert (Sv)

the SI unit used to express the amount of biological damage caused by ionizing radiation.

Endnotes

- Even relatively low-energy γ rays have 10^4 times the energy needed to ionize water. Return to reference 1
- RBE = relative biological effectiveness.Return to reference a
- RBE = relative biological effectiveness.Return to reference a

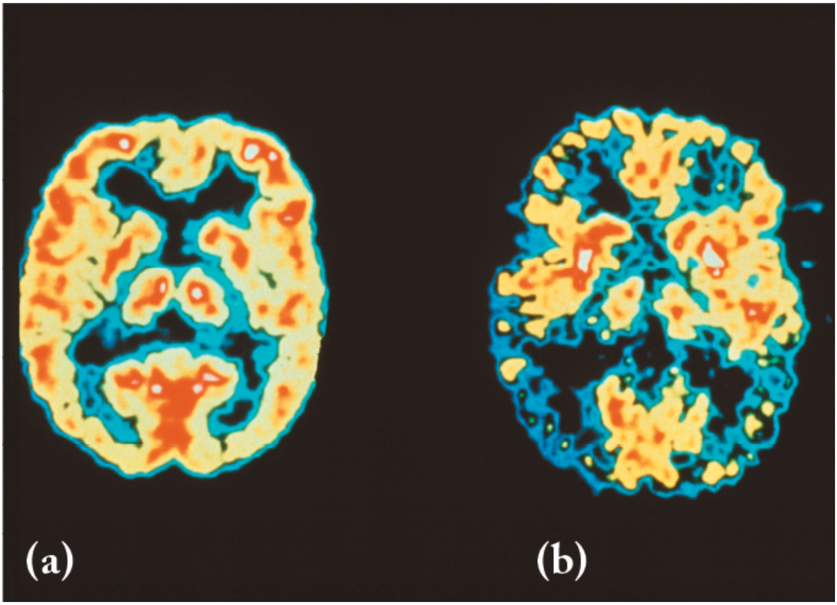

FIGURE 19.17 Positron emission tomography (PET) is used to monitor cell activity in organs such as the brain. (a) Brain function in a healthy person. The red and yellow regions indicate high brain activity; blue and black indicate low activity. (b) Brain function in a patient with Alzheimer's disease.

19.7 Medical Applications of Radionuclides

Radionuclides are used in both the detection and the treatment of diseases: they are key agents in the respective medical fields of *diagnostic radiology* and *therapeutic radiology*. In diagnostic radiology, radionuclides are used alongside magnetic resonance imaging (MRI) and other imaging systems that involve only nonionizing radiation. Therapeutic radiology, however, is based almost entirely on the ionizing radiation that comes from nuclear processes.

Therapeutic Radiology

Because ionizing radiation causes the most damage to cells that grow and divide rapidly, it is a powerful tool in the fight *against* cancer. Radiation therapy consists of exposing cancerous tissue to γ radiation.

Surgically inaccessible tumors can be treated with beams of γ rays from a radiation source outside the body. Unfortunately, γ radiation destroys both cancer cells and healthy ones. Thus, patients receiving radiation therapy frequently suffer symptoms of radiation sickness, including nausea, vomiting (the tissues that make up intestinal walls are especially susceptible to radiation-induced damage), and hair loss. To reduce the severity of these side effects, radiologists must carefully control the dosage a patient receives.

Often the radiation source is external to the patient, but sometimes it is encased in a platinum capsule and surgically implanted in a cancerous tumor. The platinum provides a chemically inert outer layer and acts as a filter, absorbing α and β particles emitted by the radionuclide but allowing γ rays to pass into the tumor.

A nuclide’s chemical properties can sometimes be exploited to direct it to a tumor site. For example, most iodine in the body is concentrated in the thyroid gland, so an effective therapy against thyroid cancer starts with ingestion of potassium iodide containing radioactive iodine-131. Some radionuclides used in cancer therapy are listed in **Table 19.6**.

TABLE 19.6 Some Radionuclides Used in Radiation Therapy

Nuclide	**Half-Life**	**Radiation**	**Treatment**
^{32}P	14.3 d	β	leukemia therapy
^{60}Co	5.27 yr	β, γ	cancer therapy
^{131}I	8.1 d	β	thyroid therapy
^{131}Cs	9.7 d	γ	prostate cancer therapy
^{192}Ir	74 d	β, γ	coronary disease

TABLE 19.7 Selected Radionuclides Used for Medical Imaging

Nuclide	**Half-Life (h)**	**Radiation**	**Site Studied**
^{99m}Tc	6.01	γ	bones, circulatory system, various organs
^{123}I	13.2	γ	thyroxine production in thyroid gland

^{201}Tl	Coronary arteries, heart muscle
^{67}Ga	Tumors in the brain and other organs

Diagnostic Radiology

The transport of radionuclides in the body and their accumulation in certain organs also provide ways to assess organ function. In some applications, a tiny quantity of a radioactive isotope is used, together with a much larger amount of a stable isotope of the same element. The radioactive isotope is called a *tracer*, and the stable isotope is the *carrier*. For example, the circulatory system can be imaged by injecting into the blood a solution of sodium chloride containing a trace amount of ^{24}NaCl. Circulation is monitored by measuring the γ rays emitted by ^{24}Na as it decays.

The ideal isotope for medical imaging is one that has a half-life about equal to the length of time required to perform the imaging measurements. It should emit moderate-energy γ rays or β particles but no α particles that might cause tissue damage. Sodium-24 (a β emitter with a half-life of 15 h) meets both these criteria. **Table 19.7** lists several other radionuclides that are used in medical imaging.

Positron emission tomography (PET) is a powerful tool for diagnosing organ and cell function. PET uses short-lived, neutron-poor, positron-emitting radionuclides such as carbon-11, oxygen-15, and fluorine-18. A patient might be administered a solution of glucose in which some of the sugar molecules contain atoms of ^{11}C, ^{15}O, or an atom of ^{18}F in place of a hydrogen atom. The rate at which glucose is metabolized in various regions of the brain is monitored by detecting the γ rays produced by positron–electron annihilations. Unusual patterns in PET images of brains (**Figure 19.17**) can indicate schizophrenia, bipolar disorder, Alzheimer's disease, damage from strokes, and even nicotine addiction in tobacco smokers.

FIGURE 19.18 Each fission event in the chain reaction of a

uranium-235 nucleus begins when the nucleus captures a neutron, forming an unstable uranium-236 nucleus that then splits apart (fissions) in one of several ways. In the first process shown here, the uranium-236 nucleus splits into krypton-92, barium-141, and three neutrons. If, on average, at least one of the three neutrons from each fission event causes the fission of another uranium-235 nucleus, then the process is sustained in a chain reaction.

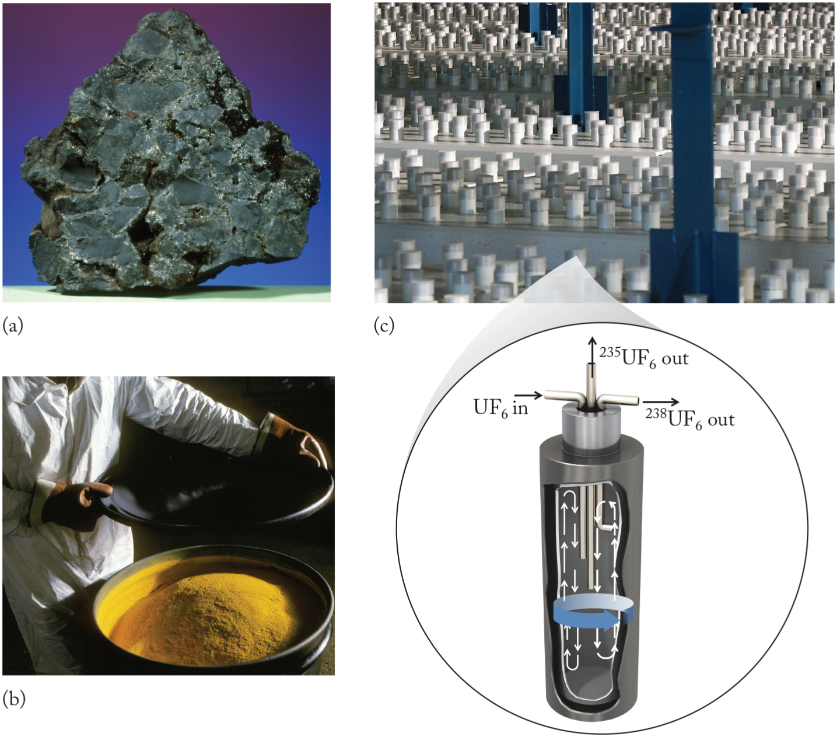

FIGURE 19.19 Preparing uranium fuel. (a) A piece of pitchblende, source of the uranium fuel for nuclear reactors. Pitchblende ore is ground up and extracted with strong acid. (b) The uranium compounds (mostly U_3O_8) obtained from the extract are called yellowcake. (c) Uranium oxides are converted to volatile UF_6, which is centrifuged at very high speed to separate $^{235}UF_6$ from $^{238}UF_6$. The less dense and less abundant $^{235}UF_6$ is enriched near the center of the centrifuge cylinder and separated from the heavier $^{238}UF_6$.

FIGURE 19.21 A pressurized, water-cooled nuclear power plant uses fuel rods containing uranium enriched to about 4% uranium-235. The fission chain reaction is regulated with control rods and a moderator that is either water or liquid sodium. The moderator slows down the neutrons released by fission so that they can be captured more efficiently by other uranium-235 nuclei. It also transfers the heat produced by the fission reaction to a steam generator. The steam generated by this heat drives a turbine that generates electricity. Nuclear power plants are usually situated near coasts or large rivers, where large amounts of coolant water are readily available.

19.8 Nuclear Fission

The energy stored in atomic nuclei can also be put to practical use for electrical power generation. When an atom of uranium-235 captures a neutron, the nucleus of the unstable product, uranium-236, splits into two lighter nuclei in a process called nuclear fission. Several uranium-235 fission reactions can occur, including these three:

In all of these reactions, the sums of the masses of the products are slightly less than the sums of the masses of the reactants. As we observed for nucleosynthesis in Section 19.1, this difference in mass is converted to energy in accordance with Einstein's equation ($E = mc^2$).

These reactions also produce additional neutrons, which can be absorbed by other uranium-235 nuclei and initiate more fission events in a chain reaction (**Figure 19.18**). The reaction proceeds as long as there are enough uranium-235 nuclei present to absorb the neutrons being produced. On average, at least one neutron from each fission event must cause another nucleus to split apart for the chain reaction to be self-sustaining. The quantity of fissionable material needed to ensure that every fission event produces another is called the critical mass. For uranium-235, the critical mass is about 52 kg for a sphere of the pure isotope. The critical mass decreases to 15 kg if surrounded by a substance that reflects neutrons back toward the ^{235}U.

Uranium-235 is the most abundant fissionable isotope, but it makes up only 0.72% of the uranium in the principal uranium ore, pitchblende (**Figure 19.19a**). The uranium in nuclear reactors must be at least 3% to 4% uranium-235, and enrichment to about 85% is needed for nuclear weapons. The most common method for enriching uranium ore involves extracting the uranium in a process that yields a material called yellowcake, which is mostly U_3O_8 (**Figure 19.19b**). This oxide is then converted to UF_6, which, despite a molar mass of more than 300 g per mole, is a volatile solid that sublimes at 56°C. The volatility of this nonpolar molecular compound can be explained by the relatively weak London dispersion forces experienced by its compact, symmetrical molecules (**Figure 19.20**). Fissionable $^{235}UF_6$ is separated from $^{238}UF_6$ on the basis of their slightly different densities. Elaborate centrifuge systems are used to exploit this difference (**Figure 19.19c**).

Harnessing the energy released by nuclear fission to generate electricity began in the middle of the 20th century. In a typical nuclear power plant (**Figure 19.21**), fuel rods containing 3% to 4% uranium-235 are interspersed with rods of boron or cadmium that control the rate of the chain reaction by absorbing some of the neutrons produced during fission. Pressurized water flows around the fuel and control rods, removing the heat created during fission and transferring it to a steam generator. The water also acts as a moderator, slowing down the neutrons and thereby allowing for their more efficient capture by ^{235}U atoms.

In 1952 the first breeder reactor was built, so called because in addition to producing energy to make electricity, a breeder reactor makes (“breeds”) its own fuel. The reactor starts out with a mixture of plutonium-239 and uranium-238. As the plutonium fissions and the energy from those reactions is collected to produce electricity, some of the neutrons that are produced sustain the fission chain reaction just as in the reactor shown in Figure 19.21, while others convert the uranium into more plutonium fuel:

In less than 10 years of operation, a breeder reactor can make enough plutonium-239 to refuel itself *and* another reactor. Unfortunately, plutonium-239 is a carcinogen and one of the most toxic substances known. Only about 1–2 kg are needed to make an atomic bomb, and it has a long half-life: 2.4×10^4 years. Understandably, extreme caution and tight security surround the handling of plutonium fuel and the transportation and storage of nuclear wastes containing even small amounts of plutonium. Health and safety matters related to reactor operation and spent-fuel disposal are the principal reasons there are no breeder power stations in the United States, although they have been built in at least seven other countries.

Glossary

nuclear fission

a nuclear reaction in which the nucleus of an element splits into two lighter nuclei; the process is usually accompanied by the release of one or more neutrons and energy.

chain reaction

a self-sustaining series of fission reactions in which the neutrons released when nuclei split apart initiate additional fission events and sustain the reaction.

critical mass

the minimum quantity of fissionable material needed to sustain a chain reaction.

breeder reactor

a nuclear reactor in which fissionable material is produced during normal reactor operation.

19.9 Nuclear Fusion and the Quest for Clean Energy

The energy of the Sun is derived from the high-speed collision and reaction of hydrogen nuclei to form helium. This nuclear fusion process involves more steps than the process that probably took place during primordial nucleosynthesis (see Chapter 2), when protons (hydrogen nuclei) and neutrons fused to form deuterons (nuclei of the hydrogen isotope deuterium, D):

Once deuterons formed, they also collided with each other and fused, forming α particles, which are the nuclei of helium-4 atoms:

Recall from Chapter 2 that each subscript in a nuclear equation represents the atomic number (Z) of an atom or the electrical charge of a subatomic particle and each superscript represents the atom or particle’s mass number (A).

Hydrogen fusion in our Sun follows a different path because free neutron concentrations are far lower there than they were in the primordial universe. In the Sun, colliding protons may fuse to form a deuteron and a positron:

In the second stage of solar fusion, protons fuse with deuterons to form helium-3 nuclei:

Finally, fusion of two helium-3 nuclei produces a helium-4 nucleus and two protons:

Deuterium and ^{3}He nuclei are intermediates in the hydrogen-fusion process because they are made in one step but then consumed in another. To write an overall equation for solar fusion, we combine Equations 19.7, 19.8, and 19.9, multiplying Equations 19.7 and 19.8 by 2 to balance the production and consumption of the intermediate particles:

This equation reduces to:

Annihilation reactions between the positrons produced in Equation 19.10 and electrons in the matter surrounding the reactants release considerable energy, but most of the energy from hydrogen fusion comes from the loss in mass as four protons are transformed into an α particle (i.e., a helium-4 nucleus) and two positrons (see Table 19.1). In Sample Exercise 19.6 we use Einstein's equation, $E = mc^2$, to calculate how much energy this is.

For decades scientists and engineers have sought to harness the enormous energy released during hydrogen fusion for peaceful purposes. In 2010 construction began on ITER (originally an acronym for International Thermonuclear Experimental Reactor), a project to build the world's largest nuclear fusion reactor. Located at the Cadarache facility in southern France, the project is funded and run by the European Union, India, Japan, China, Russia, South Korea, and the United States. When it is operational, ITER will use a device called a *tokamak* (**Figure 19.22**) to heat a mixture of deuterium $({}^{2}_{1}\text{H})$ and tritium $\left({}^{3}_{1}\text{H}\right)$ to temperatures near 1.5×10^8 K. At such temperatures, all these atoms are ionized, forming an incandescent plasma that is confined by the tokamak's powerful magnets to the center of a donut-shaped tunnel. High-speed collisions between deuterium and tritium nuclei in the plasma produce nuclei of helium-4:

The neutrons produced in the reaction collide with the nuclei of Li atoms in "breeder" blankets surrounding the hydrogen plasma. Two nuclear reactions are initiated by these collisions, depending on which isotope of Li is involved:

The reactions in Equations 19.12 and 19.13 produce tritium nuclei.

In this way the reactions supply more fuel for the primary fusion reaction. The world's supply of deuterium, the other fuel, is enormous (seawater contains about 15 mg of deuterium per kilogram). On the other hand, tritium is not abundant in nature because it is radioactive, with a half-life of only 12.3 years. One disadvantage of these reactions is their reliance on lithium during a time when expanding production of lithium-ion batteries (see Section 18.7) is increasing global demand for the element. The National Ignition Facility located at the Lawrence Livermore National Laboratory in California has taken a different approach to initiating fusion reactions. Powerful lasers are focused on a small sample containing deuterium and tritium to start the fusion reaction.

CONCEPT TEST

Nuclear reactors powered by the energy released by the fission of uranium-235 have been operating since the 1950s, but a reactor powered by the energy released by the fusion of hydrogen has yet to be built. Why is it taking so long to build a fusion reactor?

SAMPLE EXERCISE 19.6 Calculating the Energy Released in a Nuclear Reaction LO7

How much energy in joules is released by the overall fusion process in which four protons undergo nuclear fusion, producing an α particle and two positrons (Equation 19.10)?

Collect and Organize We are asked to calculate the energy released in the nuclear reaction:

The energies associated with nuclear reactions are related to differences in the masses of the reactant and product particles and Einstein's equation, $E = mc^2$. The masses of the particles in Table 19.1 are given in kilograms, which is convenient because the relationship between energy and mass is linked to the unit conversion

$1 J = 1 \text{ kg} \cdot (\text{m/s})^2$

Analyze Given the value of the masses in Table 19.1, the difference in mass will probably be less than 10^{-27} kg. When multiplied by the square of the speed of light, $(2.998 \times 10^8 \text{ m/s})^2 \approx 10^{17}$, the calculated value of E should be less than 10^{-10} J.

Solve First we calculate the change in mass:

The energy corresponding to this loss in mass is calculated using Einstein's equation where $m = -4.40081 \times 10^{-29}$ kg:

Think About It The decrease in mass translates into energy lost by the reaction system to its surroundings. As we predicted, the absolute value of this energy is less (actually much less) than 10^{-10} J, which seems like an awfully small value compared with the world's energy needs. However, this value applies to the formation of a single α particle. If we multiply it by Avogadro's number and convert it into a value in kilojoules per mole, a unit we typically use in thermochemistry, we get

---

To put this value in perspective, it is about 10^7 times the change in free energy from the combustion of 1 mole of hydrogen gas.

Practice Exercise How much energy is released in the nuclear reaction described by Equation 19.11? Express your answer in kilojoules per mole. (*Note*: The mass of a tritium nucleus is 5.00736×10^{-27} kg.)

SAMPLE EXERCISE 19.7 Integrating Concepts: Radium Girls and Safety in the Workplace

Radium was discovered by Pierre and Marie Curie in 1898. By 1902, the new element had its first practical use: radium compounds were mixed with zinc sulfide (ZnS) to make paint that glowed in the dark as α particles emitted by the decay of ^{226}Ra ($t_{1/2} = 1.6 \times 10^3$ yr) caused ZnS crystals to emit a greenish fluorescence (**Figure 19.23**). The paint was used to make dials for watches, clocks, and instruments used on naval vessels and, a few years later, in military and civilian airplanes.

By 1914, U.S. companies were making radium-painted dials and employing young women in their late teens and early 20s as dial painters. Soon after their employment, many of the women became very sick, suffering from anemia and other symptoms we now associate with exposure to nuclear radiation. Some developed bone cancer and more than 100 of them, who became known around the world as the Radium Girls, died. Their deaths were linked to the practice of “pointing” the fine paint brushes they used, which meant using their lips to make fine points on the brushes to help them paint the tiny numerals and hands on watch faces (**Figure 19.24**). In the process, they ingested some of the radioactive paint. Tests later determined that about 20% of the radium ingested was incorporated into their bones, where it attacked bone marrow and caused malignancies known as osteosarcomas.

---

1. Suggest a reason why radium was concentrated in the victims’ bones.
2. Studies of radiation levels and incidence of cancer in more than 1000 female dial painters yielded the results in the table presented here. Which of the two dose–response curves in Figure 19.16 best fits these results?

Radium Exposure (mg ingested)	Occurrence of Malignancy (% of workers exposed)
1	0
3	0
10	0
30	0
100	5
300	50
1000	85

3. The green luminescence of radium watch dials began to fade after a few years. Did this loss in luminosity result from

decreased radioactivity in the paint? Explain why or why not.

4. In one study, the levels of radioactivity in pocket watches with radium-painted dials were found to be between 0.6 and 1.39 μCi per watch. How many micrograms of ^{226}Ra produce 1.39 μCi of radioactivity?

Collect and Organize We are asked (a) why ingested ^{226}Ra concentrates in bones; (b) whether malignancy in dial painters was proportional to their exposure to ^{226}Ra radiation or followed an S-shaped dose–response curve; (c) why the luminosity of radium-activated paint fades after a few years; and (d) how many micrograms of ^{226}Ra are needed to produce 1.39 mCi of radiation. One curie (Ci) is equal to 3.70×10^{10} decay events/s. The half-life ($t_{1/2}$) of ^{226}Ra is 1600 years and is related to the first-order rate constant (k) of the decay reaction by the equation $t_{1/2} = 0.693/k$. The level of radioactivity (A) in a sample of radium is equal to the product of the rate constant and the number (N) of ^{226}Ra atoms: $A = kN$.

Analyze Radium is a group 2 element and should have chemical and biochemical properties that are similar to those of the other elements in that group, including its association with biological tissues. High concentrations of another group 2 element, calcium, occur in teeth and bones. Worker exposure levels in the data table cover a wide range, but exposure up to nearly 100 mg ^{226}Ra caused few malignancies, whereas concentrations above 100 mg caused many. The half-life of ^{226}Ra is 1600 years, so the radioactivity of a sample decreases little over a few years or even over many decades. Relating a half-life expressed in years to a level of radioactivity expressed in a multiple of decay events per second requires converting units of time and then quantities of radioactive atoms to moles and then micrograms.

Solve

1. Radium probably accumulates in bones because its chemistry is similar to that of calcium, which means that $^{226}\text{Ra}^{2+}$ ions are likely to take the place of Ca^{2+} ions in bone.
2. Malignancies did not occur among the dial painters who ingested less than 100 mg of ^{226}Ra; however, the percentage of the women who suffered malignancies increased sharply

with exposure between 100 and 1000 mg. This pattern is described by the S-shaped (blue) curve in Figure 19.16.

3. Given the 1600-year half-life of ^{226}Ra, the loss of watch dial luminescence was not the result of depleted radioactivity. Rather, it must have resulted from less efficient conversion of the energy of radioactive decay into visible light by ZnS crystals.
4. Let's first convert the half-life of ^{226}Ra into a decay rate constant in units of s^{-1}:

$$k = \frac{0.693}{t_{1/2}} = \frac{0.693}{1.6 \times 10^3\ \cancel{\text{yr}}} \times \frac{1\ \cancel{\text{yr}}}{365.25\ \cancel{\text{d}}} \times \frac{1\ \cancel{\text{d}}}{24\ \cancel{\text{h}}} \times \frac{1\ \cancel{\text{h}}}{3600\ \text{s}}$$
$$= 1.372 \times 10^{-11}\ \text{s}^{-1}$$

Next, we solve the equation $A = kN$ for N, and we use the rate constant just calculated and the radioactivity of the watch to calculate the number of ^{226}Ra atoms in the dial:

$$N = \frac{A}{k} = \frac{1.39\ \cancel{\mu\text{Ci}}}{1.372 \times 10^{-11}\ \cancel{\text{s}}^{-1}} \times \frac{1\ \cancel{\text{Ci}}}{10^6\ \cancel{\mu\text{Ci}}}$$
$$\times \frac{3.70 \times 10^{10}\ \text{atoms Ra}\ \cancel{\text{s}}^{-1}}{\cancel{\text{Ci}}} = 3.75 \times 10^{15}\ \text{atoms of Ra}$$

The corresponding mass in micrograms is

$$3.75 \times 10^{15}\ \cancel{\text{atoms Ra}} \times \frac{1\ \cancel{\text{mol Ra}}}{6.022 \times 10^{23}\ \cancel{\text{atoms Ra}}}$$
$$\times \frac{226\ \text{g Ra}}{1\ \cancel{\text{mol Ra}}} \times \frac{10^6\ \mu\text{g}}{1\ \text{g}} = 1.4\ \mu\text{g of Ra}$$

Think About It The similarity in the level of radioactivity (1.39 μCi) in the watch dial and the mass of radium (1.41 μg) producing it is not a coincidence. When the curie was adopted as the standard unit of radioactivity in the early 20th century, it was chosen to honor the pioneering work of Marie and Pierre Curie, and it was based on what was then believed to be the level of radioactivity in 1 g of radium. Newspaper articles published in the 1920s made clear that Marie Curie was deeply troubled by the tragedy of the

Radium Girls. Sadly, in 1934 she herself died from aplastic anemia—a disease caused by the inability of bone marrow to produce red blood cells.

Glossary

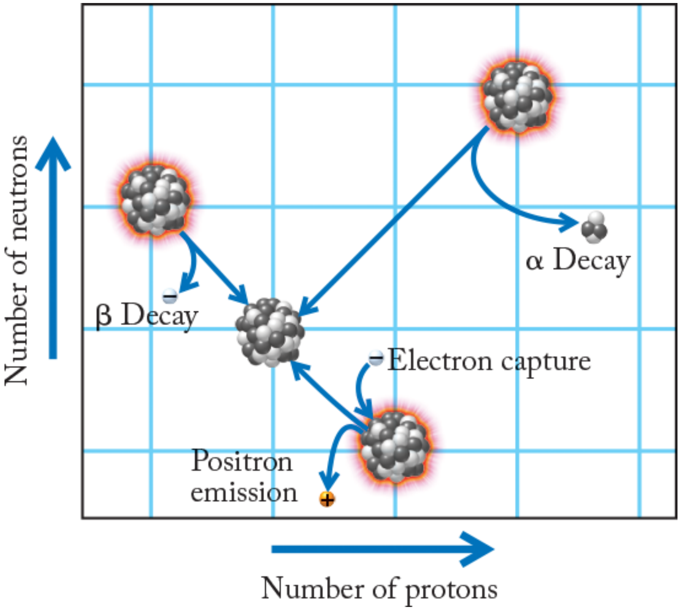
nuclear fusion
: a nuclear reaction in which subatomic particles or atomic nuclei collide with each other at very high speeds and fuse, forming more massive nuclei and releasing energy.

Learning Objectives

- Relate the energy change in a nuclear reaction to the masses of the products and reactants **Return to Sample Exercise 19.6**

SUMMARY

LO1 Nuclear chemistry is the study and application of reactions that involve changes in atomic nuclei. The mass defect (Δm) of a nucleus is the difference between its mass and the sum of the masses of its nucleons. Binding energy (BE) is the energy needed to separate a nucleus into its component nucleons. Binding energy per nucleon is a measure of the relative stability of a nucleus compared to others of similar atomic number. When a particle of matter encounters a particle of antimatter, both are converted into energy (they annihilate one another), yielding γ rays. (Section 19.1)

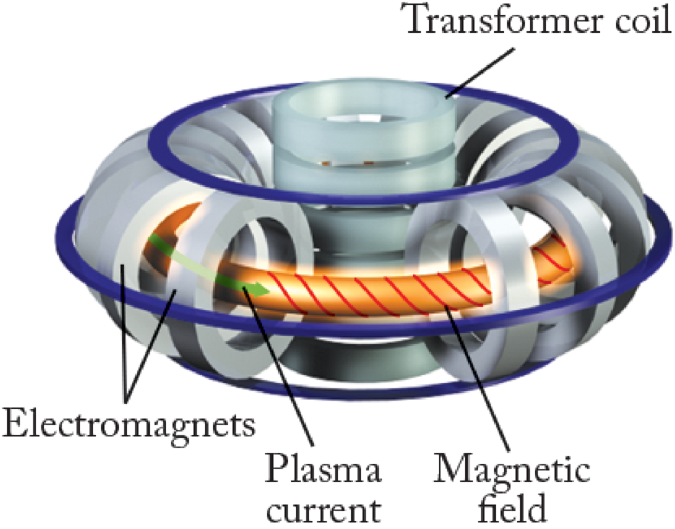


- LO2 Stable nuclei have neutron-to-proton ratios that fall within a range of values called the belt of stability. Unstable nuclides undergo radioactive decay. Neutron-rich nuclides (mass number greater than the average atomic mass) undergo β decay, whereas neutron-poor nuclides undergo positron emission or electron capture. Very heavy nuclides ($Z > 83$) may undergo β decay or α decay. (Section 19.2)

- LO3 Scintillation counters and Geiger counters are used to measure levels of nuclear radiation. Radioactivity is the number of decay events per unit time and is related to the radionuclide's half-life. Common units are the becquerel (Bq; 1 decay event/s) and the curie (Ci; 1 Ci $= 3.70 \times 10^{10}$ Bq). (Section 19.3)
- LO4 Radioactive decay follows first-order kinetics, so the half-life ($t_{1/2}$) of a radionuclide is a characteristic value of the decay process. (Section 19.4)

- LO5 Radiometric dating is used to determine the age of an object from its content of a radionuclide or its decay product, or both. Radiocarbon dating involves measuring the amount of radioactive carbon-14 that remains in an object derived from plant or animal tissue to calculate the age of the object. The accuracy of the technique relies on calibration of the data with results of radiometric analyses of samples of known age, such as the trunks of trees that have lived for thousands of years and whose age can be confirmed by their growth rings. (Section 19.5)

- LO6 The products of radioactive decay, α particles, β particles, and γ rays, have enough energy to break up molecules into electrons and cations and are examples of ionizing radiation, which can damage body tissue and DNA. The quantity of ionizing radiation energy absorbed per kilogram of body mass is called the *absorbed dose* and is expressed in grays (Gy; 1 Gy = 1.00 J/kg). The effective dose of any type of ionizing radiation is the product of the absorbed dose in grays and the relative biological effectiveness (RBE) of the radiation; the unit of effective dose is the sievert (Sv). Alpha particles have a larger RBE than do β particles and γ rays but have the least penetrating power of these three types of ionizing radiation. Selected radioactive isotopes are useful as tracers in the human body to map biological activity and diagnose diseases. Other radioactive isotopes are used to treat cancers. (Sections 19.6, 19.7)



- LO7 Neutron absorption by uranium-235 and a few other massive isotopes may lead to nuclear fission, creating lighter nuclei, accompanied by the release of energy that can be harnessed to generate electricity. A chain reaction happens when the neutrons released during fission collide with other fissionable nuclei. They require a critical mass of a fissionable isotope. A breeder reactor is used to make plutonium-239 from uranium-238, while also producing energy to make electricity. Nuclear fusion occurs when subatomic particles or atomic nuclei collide and fuse. Facilities that harness the enormous energy of hydrogen fusion must operate at temperatures greater than 10^8 K. (Sections 19.8, 19.9)

PARTICULATE PREVIEW WRAP-UP

Carbon-14 has 6 protons and 8 neutrons; therefore, with a neutron-to-proton ratio greater than 1, it will decay to reduce that ratio. When ^{14}C radioactively decays by emitting a β particle, it produces a nitrogen nuclide with a 1:1 neutron:proton ratio (7 protons and 7 neutrons).

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts	Equations	Sample Exercises
Predicting the modes and products of radioactive decay	Neutron-rich nuclides undergo β decay; neutron-poor nuclides undergo positron emission or electron capture.		19.1
Calculating the radioactivity (A) of a sample	where N is the number of atoms of a radionuclide and k, the rate constant of the radioactive decay process, is inversely proportional to the half-life of the process: $k = \frac{0.693}{t_{1/2}}$	$A = kN$ (19.1)	19.2
Calculations involving half-life and radiocarbon dating	where N_t/N_0 is the ratio of the quantity of radionuclide present in a sample at time t (N_t) to the quantity at $t = 0$ (N_0) and $t_{1/2}$ is the half-life of the radionuclide.	$\ln N_t = -0.693\frac{t}{t_{1/2}} + \ln N_0$ (19.3) $t = -\frac{t_{1/2}}{0.693}\ln\frac{N_t}{N_0}$ (19.4)	19.3, 19.4
Estimating effective dose	Effective dose = absorbed dose × RBE		19.5
Calculating the energy released in a nuclear reaction	$E = mc^2$, where m is the mass difference between reactants and products.		19.6

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

Figure P19.1 highlights six elements whose isotopes play important roles in nuclear chemistry.

1. Which of the highlighted elements currently plays a key role in the controlled fusion of hydrogen?
2. Exposure to which of the highlighted elements could cause anemia and bone disease?
3. Which of the highlighted elements are part of the decay series of uranium-238?

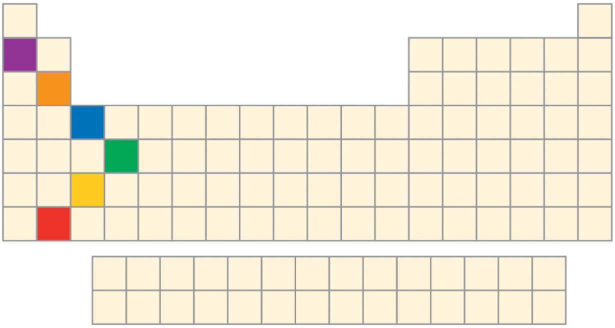


FIGURE P19.1

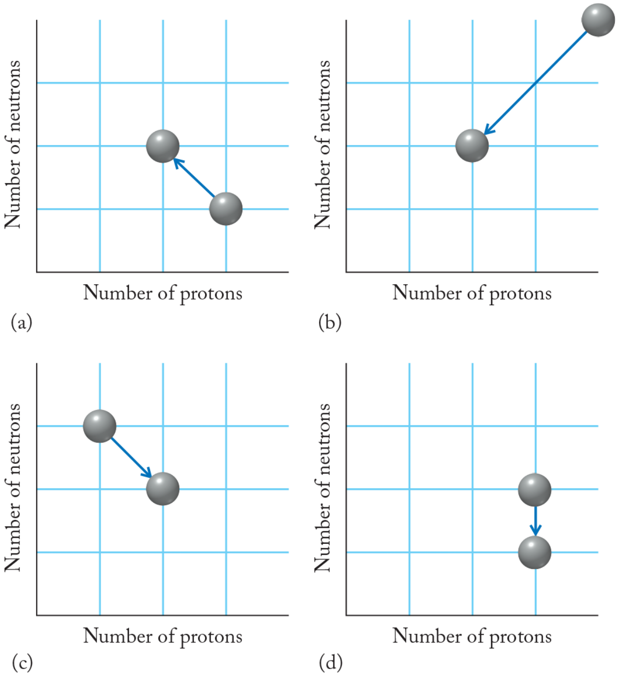
Refer to Figure P19.2 to answer Problems 19.2–19.5.

Which radioactive decay processes are represented by graphs (a) and (b) in Figure P19.2?



Number of neutrons
Number of protons
(a)
Number of neutrons
Number of protons
(b)
Number of neutrons
Number of protons
(c)
Number of neutrons
Number of protons
(d)

FIGURE P19.2

Which of the graphs in Figure P19.2 illustrates β decay?

Which of the graphs in Figure P19.2 illustrates the likely decay pathway for

1. ^{131}I
2. carbon-11
3. ^{222}Rn

In 1932, James Chadwick discovered neutrons by bombarding ^{9}Be with α particles to form ^{13}C, which then decayed to ^{12}C and a neutron. Which of the graphs in Figure P19.2 describes this decay process?

Which of the curves in Figure P19.6 represents the decay of an isotope that has a half-life of 2.0 days?

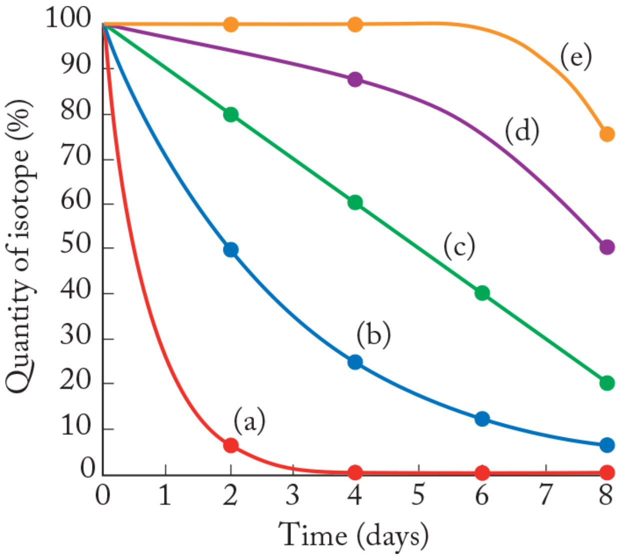


FIGURE P19.6

Which of the curves in Figure P19.6 do(es) *not* represent a radioactive decay curve?

Which of the models in Figure P19.8 represents fission and which represents fusion?

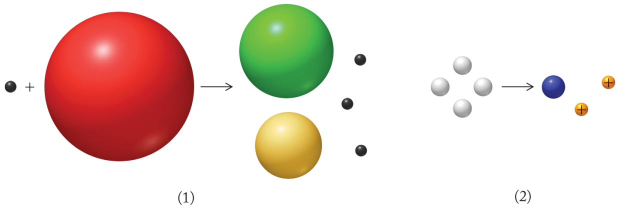

FIGURE P19.8

Isotopes in a nuclear decay series emit particles with a positive charge and particles with a negative charge. The two kinds of particles penetrate a column of water as shown in Figure

P19.9. Is the “X” particle the positive or the negative one?

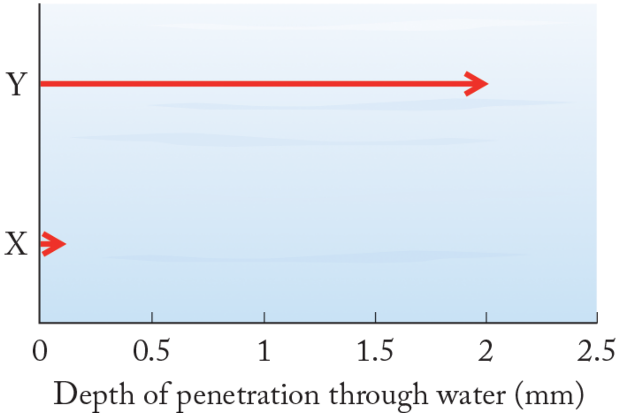

FIGURE P19.9

Use representations [A] through [I] in Figure P19.10 to answer questions (a)–(f).

1. Which image depicts β decay? Write a balanced nuclear equation to represent the image.
2. Which image depicts fusion? Write a balanced nuclear equation to represent the image.
3. Which image depicts positron emission? Write a balanced nuclear equation to represent the image.
4. Which image depicts nuclear fission? Write a balanced nuclear equation to represent the image.
5. Which nuclide will undergo α decay? Write a balanced nuclear equation to depict these decay processes.
6. Which nuclides will undergo β decay? Write a balanced nuclear equation to depict these decay processes.

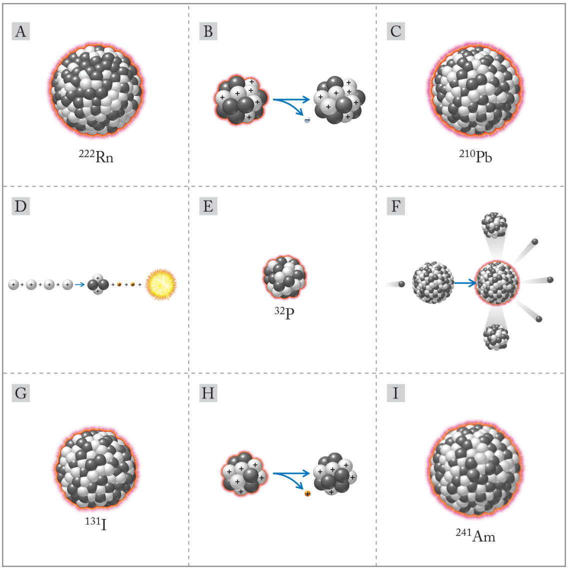

FIGURE P19.10

QUESTIONS AND PROBLEMS

Energy and Nuclear Stability

Concept Review

What do the terms *mass defect* and *binding energy* mean?

Do nuclear decay processes follow the law of conservation of mass and law of conservation of energy?

Why is energy released in a nuclear fusion process when the product is an element preceding iron in the periodic table?

Titanium has five stable isotopes. Do you expect the release of energy in nuclear fusion processes that produce any of these isotopes?

Problems

What is the binding energy of a deuteron?

What is the binding energy of ^{6}Li, which has a nuclear mass of 9.98561×10^{-27} kg?

Our Sun is a fairly small star that has barely enough mass to fuse hydrogen into helium. Along the way, an isotope of helium, helium-3, is formed. Calculate the binding energy per nucleon of helium-3 on the basis of the following masses: $^{3}_{2}\text{He}$ (3.01693 u), $^{1}_{1}\text{p}$ (1.00728 u), and $^{1}_{0}\text{n}$ (1.00866 u).

What is the binding energy per nucleon of ^{12}C, which has an atomic mass of 12.00000 u? (*Note*: Atomic mass includes the mass of 6 electrons.)

Unstable Nuclei and Radioactive Decay

Concept Review

If the mass number of a nuclide is more than twice its atomic number, is its neutron-to-proton ratio less than, greater than, or equal to 1?

Compare positron-emission and electron-capture processes.

The ratio of neutrons to protons in stable nuclei increases with increasing atomic number. Use this trend to explain why multiple α decay steps in the ^{238}U decay series are often followed by β decay.

Copper-64 is an unusual radionuclide in that it may undergo β decay, positron emission, or electron capture. Using Figure 19.2 as a guide, explain why ^{64}Cu decays in these multiple ways?

Problems

Iodine-137 decays to give xenon-137, which decays to give cesium-137. What are the modes of decay in these two reactions?

Write a balanced nuclear equation describing (a) α decay of curium-242; (b) β decay of magnesium-28; (c) positron emission by xenon-118; (d) electron capture by cadmium-104.

Arrange the following nuclides in order of increasing neutron:proton ratio. Which has the greatest number of neutrons? (a) ^{25}Al; (b) ^{24}Na; (c) ^{11}B, (d) ^{14}C

In each of the following pairs of nuclides, select the one that has more protons and the one that has more neutrons. Also indicate which, if any, of the pairs have the same number of neutrons or protons. (a) ^{63}Cu and ^{65}Cu; (b) ^{71}Ga and ^{71}Ge; (c) ^{39}K and ^{40}Ar; (d) ^{94}Sr and ^{88}Y.

Medical Applications of ^{64}Cu and ^{89}Zr Copper-64 and zirconium-89 are two of the radionuclides used in positron emission tomography. Both are produced in nuclear reactors by bombarding targets of other metals with protons.

1. Which transition metals would you choose as the targets to make ^{64}Cu and ^{89}Zr by proton bombardment?
2. Write radiochemical equations describing the production of ^{64}Cu and ^{89}Zr. Assume one proton was captured by each target nucleus and one free neutron was produced in addition to the desired radionuclide.
3. Do the target nuclides you used to answer part (b) have to be stable isotopes of the target metals? Explain why or why not?

Manufacturing Isotopes The isotopes used in positron emission tomography are all prepared in nuclear reactors. One route to these isotopes is through proton bombardment followed by loss of a neutron in a cyclotron.

1. Which metal isotopes would yield ^{67}Ga and ^{111}In by this process?
2. Would bombarding target metals with neutrons instead of protons be another way to produce radionuclides for PET? Explain why you do or don’t think so.

Predict the mode(s) of decay for the following radioactive isotopes: (a) ^{10}C; (b) ^{19}Ne; (c) ^{51}Ti.

Predict the mode(s) of decay of the following radionuclides: (a) ^{24}Ne; (b) ^{38}K; (c) ^{45}Ti; (d) ^{237}Np.

Elements in a Supernova The isotopes ^{56}Co and ^{44}Ti were detected in supernova SN 1987A. Predict the decay pathway for these radioactive isotopes.

There are isotopes of nitrogen that have as few as 5 or as many as 11 neutrons in each of their nuclei. Write a balanced nuclear equation describing the decay of the isotope with 11 neutrons.

Chlorine has isotopes with mass numbers from 32 through 39. Two of them, ^{35}Cl and ^{37}Cl, are stable.

1. Which three of the other isotopes emit positrons?
2. Which of the other isotopes emit β particles?
3. Which one of the other isotopes can emit *either* positrons or β particles?

Bromine has isotopes with mass numbers from 74 through 90. Two of them, ^{79}Br and ^{81}Br, are stable.

1. How many of the others emit positrons or undergo electron capture?
2. How many of the others emit β particles?

3. Which one of the other isotopes can emit *either* positrons or β particles?

Measuring and Expressing Radioactivity; Calculations Involving Half-Lives of Radionuclides

Concept Review

Why does nuclear decay follow first-order reaction kinetics?

Barium-140 undergoes β decay to lanthanum-140 with a half-life of 12.8 d. Lanthanum-140 also undergoes β decay to cerium-140 with a half-life of 40 h. Which step is rate-determining for the overall decay of ^{140}Ba to ^{140}Ce?

What property of radioactivity allows it to be detected by a Geiger counter?

Which of the following quantities of radioactivity is most likely to be found in a household appliance such as a smoke detector: (a) 1 KCi; (b) 1 Ci; (c) 1 mCi; (d) 1 μCi?

Problems

The half-life of radon-222, a radioactive gas found in some basements, is 3.82 d. Calculate the decay rate constant of radon-222.

The decay rate constant of sodium-24, a tracer used in blood studies, is $4.6 \times 10^{-2}\ \mathrm{h}^{-1}$. What is the value of its half-life?

Explosions at a disabled nuclear power station in Fukushima, Japan, in 2011 may have released more cesium-137 ($t_{1/2} = 30.2$ yr) into the ocean than any other single event. How long will it take the radioactivity of this radionuclide to decay to 5.0% of the level released in 2011?

Spent fuel removed from nuclear power stations contains plutonium-239 ($t_{1/2} = 2.41 \times 10^4$ yr). How long will it take a sample of this radionuclide to reach a level of radioactivity that is 2.5% of the level it had when it was removed from a reactor?

Radiometric Dating

Concept Review

Explain why radiocarbon dating is reliable only for artifacts less than about 50,000 years old.

Which of the following statements about ^{14}C dating are true?

1. The amount of ^{14}C in all sources of carbon is the same.
2. Carbon-14 is unstable and decays rapidly in the atmosphere.
3. The ratio of ^{14}C to ^{12}C in the atmosphere is a constant.
4. Green plants incorporate ^{12}C, ^{13}C, and ^{14}C during photosynthesis.

Why is ^{40}K dating ($t_{1/2} = 1.28 \times 10^9$ yr) useful only for rocks older than 300,000 years?

Where does the ^{14}C in biological samples come from?

Problems

First Humans in South America Archeologists continue to debate the arrival of the first humans in the Western Hemisphere. Radiocarbon dating of charcoal from a cave in Chile was used to establish the earliest date of human habitation in South America as 8700 years ago. What fraction of the ^{14}C initially present remained in the charcoal after 8700 years?

Early Financial Records For thousands of years Native Americans living along the north coast of Peru used knotted cotton strands called *quipu* (Figure P19.48) to record financial transactions and governmental actions. A particular quipu sample is 4800 years old. Compared with the fibers of cotton plants growing today, what is the ratio of carbon-14 to carbon-12 in the sample?

FIGURE P19.48

Rings in Sequoia Trees Figure P19.49 shows a close-up of the center of a giant sequoia tree cut down in 1891 in what is now Kings Canyon National Park. It contained 1342 annual growth rings. If samples of the tree were removed for radiocarbon dating today, what would be the difference in $^{14}C/^{12}C$ ratio in the innermost (oldest) ring compared with that ratio in the youngest ring?

FIGURE P19.49

Dating Volcanic Eruptions Geologists who study volcanoes can develop historical profiles of previous eruptions by determining the $^{14}C/^{12}C$ ratios of charred plant remains entrapped in old magma and ash flows. If the uncertainty in determining these ratios is 0.1%, could radiocarbon dating distinguish between debris from the eruptions of Mt. Vesuvius that occurred in the years 472 and 512? (*Hint*: Calculate the $^{14}C/^{12}C$ ratios for samples from the two dates.)

Age of Mammoth Tusk Figure P19.51 shows a carved mammoth tusk that was uncovered at an ancient campsite in the Ural Mountains in 2001. The $^{14}C/^{12}C$ ratio in the tusk was only 1.19% of that in modern elephant tusks. How old is the mammoth tusk?

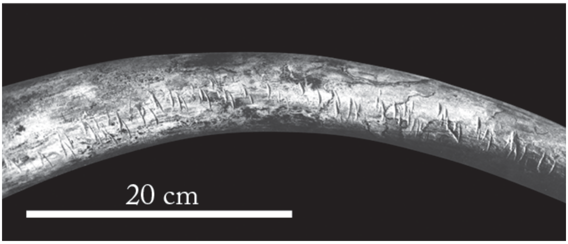

FIGURE P19.51

Destruction of Jericho The Bible describes the Exodus as a period of 40 years that began with plagues in Egypt and ended with the destruction of Jericho. Archeologists seeking to establish the exact dates of these events have proposed that the plagues coincided with a huge eruption of the volcano Thera in the Aegean Sea.

1. Radiocarbon dating suggests that the eruption occurred around 1360 bce, although other records place the eruption of Thera in the year 1628 bce. What is the percent difference in the ^{14}C decay rate in biological samples from these two dates?
2. Radiocarbon dating of blackened grains from the site of ancient Jericho provides a date of 1315 bce ± 13 years for the fall of the city. What is the ^{14}C/^{12}C ratio in the blackened grains compared with that of grain harvested last year?

Biological Effects of Radioactivity

Concept Review

What is the difference between a *level* of radioactivity and a *dose* of radioactivity?

What are some of the molecular effects of exposure to radioactivity?

Describe the dangers of exposure to radon-222.

Food Safety Periodic outbreaks of food poisoning from meat contaminated by *E. coli* have renewed the debate about irradiation as an effective treatment of food. In one newspaper article on the subject, the following statement appeared: “Irradiating food destroys bacteria by breaking apart their molecular structure.” How would you improve or expand on this explanation?

Problems

Radiation Exposure from Dental X-rays Dental X-rays expose patients to about 5 μSv of radiation. Given an RBE of 1 for X-rays, how many grays of radiation does 5 μSv represent? For a 50 kg person, how much energy does 5 μSv correspond to?

Radiation Exposure at Chernobyl Some workers responding to the explosion at the Chernobyl nuclear power plant were exposed to 5 Sv of radiation, killing many of them. If the exposure was primarily in the form of γ rays with an energy of 3.3×10^{-14} J and an RBE of 1, how many γ rays did an 80-kg person absorb?

Strontium-90 in Milk In the years immediately following the explosion at the Chernobyl nuclear power plant, the concentration of ^{90}Sr in cow's milk in southern Europe was slightly elevated. Some samples contained as much as 1.25 Bq/L of ^{90}Sr radioactivity. The half-life of strontium-90 is 28.8 yr.

1. Write a balanced nuclear equation describing the decay of ^{90}Sr.
2. How many atoms of ^{90}Sr are in a 200 mL glass of milk with 1.25 Bq/L of ^{90}Sr radioactivity?
3. Why would strontium-90 be more concentrated in milk than other foods, such as grains, fruits, or vegetables?

Radium Watch Dials If exactly 1.00 μg of ^{226}Ra was used to paint the glow-in-the-dark dial of a wristwatch made in 1914, how radioactive is the watch today? Express your answer in microcuries and becquerels. The half-life of ^{226}Ra is 1.60×10^3 years.

In 1999 the U.S. Environmental Protection Agency set a maximum radon level for drinking water at 4.0 pCi per milliliter.

1. How many decay events occur per second in a milliliter of water for this level of radon radioactivity?
2. If the 4.0 pCi/mL level were due to decay of ^{222}Rn ($t_{1/2}$ =

3.8 days), how many ^{222}Rn atoms would there be in 1.0 mL of water?

Death of a Spy A former Russian spy died from radiation sickness in 2006 after dining at a London restaurant where he apparently ingested polonium-210. The other people at his table did not suffer from radiation sickness, even though they were very near the radioactive tea the victim drank. Why were they unaffected?

Medical Applications of Radionuclides

Concept Review

How does the selection of an isotope for radiotherapy relate to (a) its half-life, (b) its mode of decay, and (c) the properties of the products of decay?

For imaging, why is an isotope with a shorter half-life preferable to one with a longer $t_{1/2}$?

Are the same radioactive isotopes likely to be used for both imaging and cancer treatment? Why or why not?

Iridum-192 is used in some cancer treatments. ^{192}Ir decays by three pathways: β decay, positron emission, and electron capture. Could all three decay pathways be used in imaging?

Problems

Predict the most likely mode of decay for the following isotopes used as imaging agents in nuclear medicine: (a) ^{197}Hg (kidney); (b) ^{75}Se (parathyroid gland); (c) ^{18}F (bone).

Predict the most likely mode of decay for the following isotopes used as imaging agents in nuclear medicine: (a) ^{133}Xe (cerebral blood flow); (b) ^{57}Co (tumor detection); (c) ^{51}Cr (red blood cell mass); (d) ^{67}Ga (tumor detection).

A 1.00 mg sample of ^{192}Ir was inserted into the artery of a heart patient. After 30 days, 0.756 mg remained. What is the half-life of ^{192}Ir?

In a treatment that decreases pain and reduces inflammation of the lining of the knee joint, a sample of dysprosium-165 with a radioactivity of 1100 counts per second was injected into the knee of a patient suffering from rheumatoid arthritis. After 24 h, the radioactivity had dropped to 1.14 counts per second. Calculate the half-life of ^{165}Dy.

Study of Tourette's Syndrome Tourette's syndrome is a condition whose symptoms include sudden movements and vocalizations. Iodine isotopes are used in brain imaging of people with Tourette's syndrome. To study the uptake and distribution of iodine in cells, researchers treated mammalian brain cells in culture with a solution containing ^{131}I with an initial radioactivity of 108 counts per minute. The cells were removed after 30 days, and the remaining solution was found to have a radioactivity of 4.1 counts per minute. What percentage of the ^{131}I ($t_{1/2} = 8.1$ days) is absorbed by the brain?

Mercury Test of Kidney Function A patient is administered mercury-197 to evaluate kidney function. Mercury-197 has a half-life of 65 h. What fraction of an initial dose of mercury-197 remains after 6 days?

Carbon-11 is an isotope used in positron emission tomography and has a half-life of 20.4 min. How long will it take for 99% of the ^{11}C injected into a patient to decay?

Leukemia Treatment Using Sodium Sodium-24 is used to treat leukemia and has a half-life of 15 h. In a patient injected with a salt solution containing sodium-24, what percentage of the ^{24}Na remains after 48 h?

Boron Neutron-Capture Therapy In boron neutron-capture therapy (BNCT), a patient is given a compound containing ^{10}B that accumulates inside cancer tumors. Then the tumors are irradiated with neutrons, which are absorbed by ^{10}B nuclei. The product of neutron capture is an unstable form of ^{11}B that undergoes α decay to ^{7}Li.

1. Write a balanced nuclear equation for the neutron absorption and the α decay process.
2. Calculate the energy released by each nucleus of boron-10 that captures a neutron and undergoes α decay, given the following masses of the particles in the process: ^{10}B (10.0129 u), ^{7}Li (7.01600 u), ^{4}He (4.00260 u), and ^{1}n (1.00866 u).
3. Why is the formation of a nuclide that undergoes α decay a particularly effective cancer therapy?

Balloon Angioplasty and Arteriosclerosis Balloon angioplasty is a common procedure for unclogging arteries in patients suffering from arteriosclerosis. Iridium-192 therapy is being tested as a treatment to prevent reclogging of the arteries. In the procedure, a thin ribbon containing pellets of ^{192}Ir is threaded into the artery. The half-life of ^{192}Ir is 74 days. How long will it take for 99% of the radioactivity from 1.00 mg of ^{192}Ir to disappear?

Nuclear Fission

Concept Review

How is the rate of fission controlled in a nuclear reactor used to generate electrical power?

How does a breeder reactor create fuel and energy at the same time?

Why are neutrons always by-products of the fission of the most massive nuclides? (*Hint*: Look closely at the neutron-to-proton ratios shown in Figure 19.2.)

Seaborgium (Sg, element 106) is prepared by the bombardment of curium-248 with neon-22, which produces two isotopes, ^{265}Sg and ^{266}Sg. Write balanced nuclear reactions for the formation of both isotopes. Are these reactions better described as fusion or fission processes?

Problems

The fission of uranium produces dozens of isotopes. For each of the following fission reactions, determine the identity of the unknown nuclide:

a. $^{235}\text{U} + {}^{1}_{0}\text{n} \rightarrow {}^{96}\text{Zr} + ? + 2\,{}^{1}_{0}\text{n}$

b. $^{235}\text{U} + {}^{1}_{0}\text{n} \rightarrow {}^{99}\text{Nb} + ? + 4\,{}^{1}_{0}\text{n}$

c. $^{235}\text{U} + {}^{1}_{0}\text{n} \rightarrow {}^{90}\text{Rb} + ? + 3\,{}^{1}_{0}\text{n}$

For each of the following fission reactions, determine the identity of the unknown nuclide:

a. $^{235}\text{U} + {}^{1}_{0}\text{n} \rightarrow {}^{137}\text{I} + ? + 2\,{}^{1}_{0}\text{n}$

b. $^{235}\text{U} + {}^{1}_{0}\text{n} \rightarrow {}^{137}\text{Cs} + ? + 3\,{}^{1}_{0}\text{n}$

c. $^{235}\text{U} + {}^{1}_{0}\text{n} \rightarrow {}^{141}\text{Ce} + ? + 2\,{}^{1}_{0}\text{n}$

Thorium-Based Reactors Thorium-232 has been proposed as an alternative to uranium as the fuel for nuclear reactors. The relevant nuclear reactions are

$$^{232}_{90}\text{Th} \xrightarrow{{}^{1}_{0}\text{n}} {}^{233}_{90}\text{Th} \xrightarrow[t_{1/2} = 22.2\text{ min}]{{}^{0}_{-1}\beta} {}^{233}_{91}\text{Pa} \xrightarrow[t_{1/2} = 27\text{ d}]{{}^{0}_{-1}\beta} {}^{233}_{92}\text{U}$$

1. Do any of these reactions represent fission?
2. Why is there no danger of an uncontrolled chain reaction in a ^{232}Th-powered reactor?
3. The exact masses of ^{232}Th and ^{233}U are 232.03805 and 233.0395 u, respectively. How much energy is released per atom of ^{232}Th?

The Discovery of Fission The fission of uranium was suspected by

Lise Meitner, Fritz Strassman, and Otto Hahn in 1938 after they observed that bombardment of uranium with neutrons produced barium.

1. How is the observation of Ba from this reaction evidence for fission?
2. If the ^{140}Ba is the result of fission of ^{235}U, what is the other product if three neutrons are also produced?
3. Explain how this process could lead to a chain reaction?

Nuclear Fusion and the Quest for Clean Energy

Concept Review

In what ways are the fusion reactions that formed α particles during primordial nucleosynthesis different from those that fuel our Sun today?

How are the fusion reactions that are the basis for power production in the tokamak described in Section 19.9 different from those that power our Sun?

Problems

All of the following fusion reactions produce ^{28}Si. Calculate the energy released in each reaction from the masses of the isotopes: ^{2}H (2.0146 u), ^{4}He (4.00260 u), ^{10}B (10.0129 u), ^{12}C (12.00000 u), ^{14}N (14.00307 u), ^{16}O (15.99491 u), ^{24}Mg (23.98504 u), ^{28}Si (27.97693 u).

1. ${}^{14}\text{N} + {}^{14}\text{N} \rightarrow {}^{28}\text{Si}$
2. ${}^{10}\text{B} + {}^{16}\text{O} + {}^{2}\text{H} \rightarrow {}^{28}\text{Si}$
3. ${}^{16}\text{O} + {}^{12}\text{C} \rightarrow {}^{28}\text{Si}$
4. ${}^{24}\text{Mg} + {}^{4}\text{He} \rightarrow {}^{28}\text{Si}$

All of the following fusion reactions produce ^{32}S. Calculate the energy released in each reaction from the masses of the isotopes: ^{4}He (4.00260 u), ^{6}Li (6.01512 u), ^{12}C (12.00000 u), ^{14}N (14.00307 u), ^{16}O (15.99491 u), ^{24}Mg (23.98504 u), ^{28}Si (27.97693 u), ^{32}S (31.97207 u).

1. $^{16}\mathrm{O} + {}^{16}\mathrm{O} \rightarrow {}^{32}\mathrm{S}$
2. $^{28}\mathrm{Si} + {}^{4}\mathrm{He} \rightarrow {}^{32}\mathrm{S}$
3. $^{14}\mathrm{N} + {}^{12}\mathrm{C} + {}^{6}\mathrm{Li} \rightarrow {}^{32}\mathrm{S}$
4. $^{24}\mathrm{Mg} + 2\,{}^{4}\mathrm{He} \rightarrow {}^{32}\mathrm{S}$

Tokamak Radiochemistry What is the change in energy per nucleus of tritium during the following reactions?

a. $^{1}_{0}\mathrm{n} + {}^{6}_{3}\mathrm{Li} \rightarrow {}^{4}_{2}\mathrm{He} + {}^{3}_{1}\mathrm{H}$

b. $^{1}_{0}\mathrm{n} + {}^{7}_{3}\mathrm{Li} \rightarrow {}^{4}_{2}\mathrm{He} + {}^{3}_{1}\mathrm{H} + {}^{1}_{0}\mathrm{n}$

It has been proposed that electrical power production in the future might be based on the fusion of deuterium to helium-4.

1. Write a radiochemical equation describing the reaction (assume that ^{4}He is the only product).
2. Calculate how much energy is released during the formation of 1 mole of ^{4}He.

Additional Problems

Powering a Starship Thirty years before the creation of antihydrogen, television producer and *Star Trek* creator Gene Roddenberry (1921–1991) proposed to use this form of antimatter to fuel the powerful “warp” engines of the fictional starship *Enterprise.*

1. Why would antihydrogen have been a particularly suitable fuel?
2. Describe the challenges of storing such a fuel on a starship.

Accuracy in Labeling Tiny concentrations of radioactive tritium ($^{3}_{1}\mathrm{H}$) occur naturally in rain and groundwater. The half-life of $^{3}_{1}\mathrm{H}$ is 12 years. Assuming that tiny concentrations of tritium can be determined accurately, could the isotope be used to determine whether a bottle of wine with the year 1969 on its label actually contained wine made from grapes that were grown in 1969? Explain your answer.

The energy released during the fission of $^{235}\mathrm{U}$ is about 3.2×10^{-11} J per atom of the isotope. Compare this quantity of energy with that released by the fusion of four hydrogen atoms to make an atom of helium-4:

$$4\,^{1}_{1}\mathrm{H} \rightarrow {}^{4}_{2}\mathrm{He} + 2\,^{0}_{1}\beta$$

Assume that the positrons are annihilated in collisions with electrons so that the masses of the positrons are converted into energy. In your comparison, express the energies released by the fission and fusion processes in joules per nucleon for $^{235}\mathrm{U}$ and $^{4}\mathrm{He}$, respectively.

How much energy is required to remove a neutron from the nucleus of an atom of carbon-13 (mass = 13.00335 u)? (*Hint*: The mass of an atom of carbon-12 is exactly 12.00000 u.)

Smoke Detectors Americium-241 ($t_{1/2} = 433$ yr) is used in smoke detectors. The α particles from this isotope ionize nitrogen and oxygen in the air, creating an electric current. When smoke is present, the current decreases, setting off the alarm.

1. Does a smoke detector bear a closer resemblance to a Geiger counter or to a scintillation counter?
2. How long will it take for the radioactivity of a sample of $^{241}\mathrm{Am}$ to drop to 1% of its original radioactivity?
3. Why are smoke detectors containing $^{241}\mathrm{Am}$ safe to handle without protective equipment?

Colorectal Cancer Treatment Cancer therapy with radioactive rhenium-188 shows promise in patients with colorectal cancer.

1. Write the symbol for rhenium-188 and determine the number of neutrons, protons, and electrons.
2. Are most rhenium isotopes likely to have fewer neutrons than rhenium-188?
3. The half-life of rhenium-188 is 17 h. If it takes 30 min to bind the isotope to an antibody that delivers the rhenium to the tumor, what percentage of the rhenium remains after binding to the antibody?
4. The effectiveness of rhenium-188 is thought to result from penetration of β particles as deep as 8 mm into the tumor. Why wouldn’t an α emitter be more effective?
5. Using an appropriate reference text, such as the *CRC Handbook of Chemistry and Physics*, pick out the two most abundant isotopes of rhenium. List their natural abundances and explain why the one that is radioactive decays by the pathway that it does.

Synthesis of a New Element In 2006 an international team of scientists confirmed the synthesis of a total of three atoms of $^{294}_{118}\mathrm{Og}$ in experiments run in 2002 and 2005. They had bombarded a $^{249}\mathrm{Cf}$ target with $^{48}\mathrm{Ca}$ nuclei.

1. Write a balanced nuclear equation describing the synthesis of oganesson, Og.
2. The synthesized isotope of Og undergoes α decay ($t_{1/2} = 0.9$ ms). What nuclide is produced by the decay process?
3. The nuclide produced in part (b) also undergoes α decay ($t_{1/2} = 10$ ms). What nuclide is produced by this decay process?
4. The nuclide produced in part (c) also undergoes α decay ($t_{1/2} = 0.16$ s). What nuclide is produced by this decay process?
5. If you had to select an element that occurs in nature and that

has physical and chemical properties similar to Og, which element would it be?

Imaging with Thulium Thulium-165 emits positrons, producing an isotope of erbium that decays, in turn, by electron capture to a stable isotope of holmium. These properties could be exploited in PET. The half-lives for the two decay processes are 30.1 h and 10.3 h, respectively. Which isotope will be present in the greatest amount after 24 h?

Which element in the following series will be present in the greatest amount after one year?

$$\begin{array}{ccccccccc} {}^{214}_{83}\text{Bi} & \xrightarrow{\alpha} & {}^{210}_{81}\text{Tl} & \xrightarrow{\beta} & {}^{210}_{82}\text{Pb} & \xrightarrow{\beta} & {}^{210}_{83}\text{Bi} & \longrightarrow & \\ t_{1/2} = & 20\text{ min} & & 1.3\text{ min} & & 20\text{ yr} & & 5\text{ d} & \end{array}$$

Dating Cave Paintings Cave paintings in Gua Saleh Cave in Borneo have been dated by measuring the amount of ^{14}C in calcium carbonate that formed over the pigments used in the paint. The source of the carbonate ion was atmospheric CO_2.

1. What is the ratio of the ^{14}C radioactivity in calcium carbonate that formed 9900 years ago to that in calcium carbonate formed today?
2. The archeologists also used a second method, uranium–thorium dating, to confirm the age of the paintings by measuring trace quantities of these elements present as contaminants in the calcium carbonate. Shown below are two candidates for the U–Th dating method. Which isotope of uranium do you suppose was chosen? Explain your answer.

$${}^{235}_{92}\text{U} \longrightarrow {}^{231}_{90}\text{Th} \longrightarrow {}^{231}_{91}\text{Pa}$$

$${}^{234}_{92}\text{U} \longrightarrow {}^{230}_{90}\text{Th} \longrightarrow {}^{226}_{91}\text{Pa}$$

Isotope	$t_{1/2}$
^{234}U	2.46 × 10^5 yr
^{231}Th	[illegible]
^{235}U	7.04 × 10^8 yr
^{230}Th	[illegible]

^{231}Pa 3.28×10^4 yr

The synthesis of new elements and specific isotopes of known elements in linear accelerators involves the fusion of smaller nuclei.

1. An isotope of platinum can be prepared from nickel-64 and tin-124. Write a balanced equation for this nuclear reaction. (You may assume that no neutrons are ejected in the fusion reaction.)
2. Substituting tin-132 for tin-124 increases the rate of the fusion reaction 10 times. Which isotope of Pt is formed in this reaction?

Radon in Drinking Water A sample of drinking water collected from a suburban Boston municipal water system in 2002 contained 0.5 pCi/L of radon. Assume that this level of radioactivity resulted from the decay of ^{222}Rn ($t_{1/2} = 3.8$ days).

1. What was the level of radioactivity (Bq/L) of this nuclide in the sample?
2. How many decay events per hour would occur in 2.5 L of the water?

Stone Age Skeletons The discovery of six skeletons in an Italian cave at the beginning of the 20th century was considered a significant find in Stone Age archeology. The age of these bones has been debated. The first attempt at radiocarbon dating indicated an age of 15,000 years. Redetermination of the age in 2004 indicated that two bones were between 23,300 and 26,400 years old. What is the ratio of ^{14}C in a sample 15,000 years old to one 25,000 years old?

Atmospheric testing of nuclear weapons in the 1950s and 1960s produced an increase in the concentration of carbon-14 in the atmosphere. Use one or more balanced nuclear equations to explain how this could have happened.

Dating Prehistoric Bones In 1997 anthropologists uncovered three partial skulls of prehistoric humans in the Ethiopian village of Herto. From the amount of ^{40}Ar in the volcanic ash in which the remains were buried, their age was estimated at between 154,000 and 160,000 years.

1. ^{40}Ar is produced by the decay of ^{40}K ($t_{1/2} = 1.28 \times 10^9$ yr). Propose a decay mechanism for ^{40}K to ^{40}Ar.
2. Why did the researchers choose ^{40}Ar rather than ^{14}C as the isotope for dating these remains?

The rates of chemical reactions increase with increasing temperature, but the rates of nuclear decay do not. Why not?

Glossary

nuclear chemistry	a subdiscipline of chemistry that explores the properties and reactivity of atomic nuclei.
mass defect (δm)	the difference between the mass of a nucleus and the masses of the individual nucleons that make it up.
binding energy (BE)	the energy that would be released when free nucleons combine to form the nucleus of an atom; it is also the energy needed to split the nucleus into free nucleons.
belt of stability	the region on a graph of number of neutrons versus number of protons that includes all stable nuclei.
radioactive decay	the spontaneous disintegration of unstable particles accompanied by the release of radiation.
positron emission	the spontaneous emission of a positron from a neutron-poor nucleus.

electron capture

a nuclear reaction in which a neutron-poor nucleus draws in one of its surrounding electrons, which transforms a proton in the nucleus into a neutron.

scintillation counter

an instrument that determines the level of radioactivity in samples by measuring the intensity of light emitted by phosphors in contact with the samples.

Geiger counter

a portable device for determining nuclear radiation levels by measuring how much the radiation ionizes the gas in a sealed detector.

becquerel (Bq)

the SI unit of radioactivity equal to the decay of one radioactive atom per second.

becquerel (Bq)

the SI unit of radioactivity equal to the decay of one radioactive atom per second.

curie (Ci)

a non-SI unit of radioactivity in which 3.70×10^{10} radioactive atoms decay per second.

curie (Ci)

a non-SI unit of radioactivity in which 3.70×10^{10} radioactive atoms decay per second.

radiometric dating

a method for determining the age of an object on the basis of the quantity of a radioactive nuclide, the products of its decay that the object contains, or both.

radiocarbon dating

a method for establishing the age of a carbon-containing object by measuring the amount of radioactive carbon-14 remaining in the object.

ionizing radiation

high-energy products of radioactive decay that can ionize molecules.

gray (Gy)

the SI unit of absorbed radiation; 1 Gy = 1 J/kg of tissue.

gray (Gy)

the SI unit of absorbed radiation; 1 Gy = 1 J/kg of tissue.

relative biological effectiveness (RBE)

a factor that accounts for the differences in physical damage caused by different types of radiation.

sievert (Sv)

the SI unit used to express the amount of biological damage caused by ionizing radiation.

nuclear fission

a nuclear reaction in which the nucleus of an element splits into two lighter nuclei; the process is usually accompanied by the release of one or more neutrons and energy.

chain reaction

a self-sustaining series of fission reactions in which the neutrons released when nuclei split apart initiate additional fission events and sustain the reaction.

critical mass

the minimum quantity of fissionable material needed to sustain a chain reaction.

breeder reactor

a nuclear reactor in which fissionable material is produced during normal reactor operation.

nuclear fusion

a nuclear reaction in which subatomic particles or atomic nuclei collide with each other at very high speeds and fuse, forming more massive nuclei and releasing energy.

alpha (α) decay

a nuclear reaction in which an unstable nuclide spontaneously emits an alpha particle.

SIMILARITY, DIVERSITY, INTERDEPENDENCE The abundant diversity of life on Earth arises from different combinations of 40 or 50 small molecules. These basic building blocks of life are responsible for the similarity, diversity, and interdependence of all forms of life.

Organic and Biological Molecules
The Compounds of Life

PARTICULATE REVIEW

Finding Functional Groups

In Chapter 20 we explore the relationship between structure and function for carbon-containing compounds.

- Name the functional group present in each molecule shown here.
- Which compound functions as a Brønsted–Lowry acid in water? Which compound functions as a Brønsted–Lowry base in water?
- Which functional group is formed when the Brønsted–Lowry acid and base react?

(Review Sections 2.8, 4.5, and 15.2 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Protonated or Deprotonated?

Glutamic acid is used in the biosynthesis of proteins and contains three functional groups, as shown here. As you read Chapter 20, look for ideas that will help you answer these questions:

- What are the three functional groups in glutamic acid?
- Which functional groups are deprotonated at physiological pH? Which ones are protonated at physiological pH?
- Does glutamic acid exist as a negatively charged, neutral, or positively charged molecule at physiological pH?

Learning Outcomes

- LO1 Recognize constitutional isomers, draw their molecular structures, and identify chiral molecules

  Sample Exercises 20.1, 20.2, 20.3

- LO2 Interpret titration curves for amino acids and use them to define pK_a and pI values

  Sample Exercise 20.4

- LO3 Relate the names and structures of small peptides

  Sample Exercises 20.5, 20.6

- LO4 Describe the four levels of protein structure and explain how intermolecular forces and covalent bonds stabilize these structures

- LO5 Describe the molecular structures of simple sugars and the types of bonds linking them in polysaccharides, and explain how these compounds are used as energy sources and for energy storage
- LO6 Relate the molecular structures of lipids to their physical and chemical properties

  Sample Exercise 20.7

- LO7 Describe the structures of DNA and RNA and how they function together to translate genetic information

  Sample Exercise 20.8

20.1 Molecular Structure and Functional Groups

For all the stunning diversity of the biosphere, from single-cell organisms to elephants, whales, and giant redwoods, all life forms consist of substances made from only about 40 or 50 different small molecules. This small number of starting materials can link together to form large molecules that display astonishing variations in structure and function.

Most of these compounds are organic molecules containing C–C and C–H bonds. The designation *organic* for carbon-containing compounds was first applied to substances produced by living organisms, but that definition has been broadened for two reasons. First, scientists have learned how to synthesize many materials previously thought to be the products only of living systems. Second, chemists also synthesize many carbon-based materials that have *never* been produced by living systems. Today the study of *organic chemistry* encompasses the chemistry of all compounds containing carbon–carbon and carbon–hydrogen bonds, regardless of their origin.

In contrast to organic molecules, biomolecules retain a link to life: a biomolecule is any molecule produced by a living organism. This definition encompasses the four classes of large molecules that we describe in this chapter—proteins, carbohydrates, lipids, and nucleic acids—as well as small molecules that result from biochemical processes such as metabolism. Biochemistry, or biological chemistry, is the study of the chemical processes taking place in living organisms, with a focus on understanding how biomolecules participate in the reactions occurring in living cells. In Chapter 20 we concentrate on the composition and structure of organic molecules and biomolecules that compose our bodies and the other organisms with which we share this planet, as well as the foods we eat and the medicines we take. Many of these molecules are large and complex, but our knowledge of the behavior of small molecules can serve as a framework for understanding the functions and reactions of these compounds in living systems.

An important aspect of studying the biochemical processes associated with life is finding out what happens when something goes wrong. It has been estimated that 70% of inherited diseases in people are caused by the absence of particular proteins or some other defect that causes proteins to function improperly. For example, the malformation or the total absence of the protein dystrophin causes several debilitating diseases collectively referred to as muscular dystrophy (MD). In mild forms of MD, misshapen molecules of dystrophin are unable to build muscle fibers sufficient to function normally. As a result, muscle tissue wastes away and the patient becomes physically disabled. In Duchenne MD, a severe form of the disease, functional dystrophin is absent, and the disability often results in early death. Knowledge of the mechanisms that produce dystrophin has led to promising therapies. Similar approaches based on what we know about disease mechanisms have resulted in the development of new drugs and cell therapies for other inherited and contagious diseases. Scientists frequently use information about the way biomolecules behave in healthy individuals to develop drugs and treatments for all manner of medical problems.

Families Based on Functional Groups

To understand biomolecules and their reactions, we need to review some fundamental concepts and develop additional ideas about the composition, structure, and reactivity of organic molecules. Much of the variety in the chemistry of carbon arises from the carbon atom’s ability to form covalent bonds to other carbon atoms. These carbon atoms, in turn, can bond to more carbon atoms or atoms of other elements, yielding molecules that consist of only a few atoms to molecules that consist of many thousands of atoms. Additional variety is introduced because these molecules may contain a multitude of linear and branched structures as well as rings. In addition to carbon and hydrogen, organic compounds can also contain nonmetallic heteroatoms such as nitrogen, oxygen, sulfur, phosphorus, or the halogens.

CONNECTION We first encountered heteroatoms and functional groups in Section 2.8.

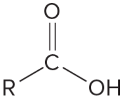
Learning to understand the structures and reactivity of millions of organic compounds requires some organizing concepts. One organizing principle is based on the chemical composition and structure of subunits within molecules. Chemists group organic compounds into families on the basis of *functional groups*—that is, subunits in a molecule that confer particular chemical and physical properties.

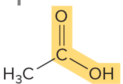
We have encountered many of the most important functional groups in organic chemistry in earlier chapters. These functional groups are reviewed in **Table 20.1**. When discussing functional groups, the convention is to use R to represent the entire molecule except the functional group. All the functional groups in Table 20.1 appear in biologically important molecules. A key learning outcome in this chapter is being able to connect the properties of biomolecules to their structures, including the functional groups within them.

A second organizing principle for organic molecules and biomolecules is based on molecular size. In Section 12.6 we discussed the structure of polymers and the influence of molecular size on the physical properties of large molecules. All of the principles introduced with respect to polymeric materials in Chapter 12 are pertinent to the discussion of large *biopolymers* in this chapter.

TABLE 20.1 Functional Groups of Organic Compounds

Name of Group [a]	General Formula	Example Structural Formula	Example Name
Alkyl (Section 2.8)	CH_3	CH_3CH_3	
Alkene (Section			Ethylene (ethene)
Alkyne (Section 2.8)	$-C\equiv C-$	$H-C\equiv C-H$	Acetylene (ethyne)
Alcohol (Section 2.8)	$R-OH$	H_3C-OH	Methanol
Carboxylic acid (Section 4.5)			



Amine (Section Methylamine	R—NH_2 R—NHR° R—NRR°	H_3C—NH_2	
Aldehyde (Sect Acetaldehyde			
Ketone (Section Acetone			
Aromatic (Sect Benzene	e.g., 		
Ether (Section 10.7) Dimethyl ether R—O—R°			
Ester (Section Methyl acetate			
Amide (Section Acetamide	 b	 b	

*b*One or both H atoms may be replaced by R groups: −NHR or −NRR°.

Note: Functional groups are highlighted in yellow.

Glossary

biomolecule

any molecule produced by a living organism.

biochemistry

the study of chemical processes taking place in living organisms.

Endnotes

- In compounds with two R groups, the two may be the same ($\mathrm{R} = \mathrm{R}^{\circ}$) or they may be different ($\mathrm{R} \neq \mathrm{R}^{\circ}$). Return to reference a

20.2 Organic Molecules, Isomers, and Chirality

In Section 3.1 we explained that Friedrich Wöhler's discovery of urea (H_2NCONH_2; **Figure 20.1a**) occurred during his attempt to synthesize ammonium cyanate, NH_4NCO (**Figure 20.1b**). The chemical formula of both structures can be written CH_4N_2O, but because their structures are not the same, they represent different compounds with different physical and chemical properties. Compounds that have the same number and same kinds of atoms but differ in the arrangement of those atoms are called *isomers*. The existence of isomers is partly responsible for the enormous number and wide variety of organic compounds in the world.

To explore isomers further, let's revisit hydrocarbons, the organic compounds composed exclusively of carbon atoms and hydrogen atoms. We have seen that hydrocarbons in which each carbon atom forms four single bonds to four other atoms are called alkanes. In Table 6.5 we compared the properties of two four-carbon alkanes: butane ($CH_3CH_2CH_2CH_3$) and 2-methylpropane [$CH_3CH(CH_3)CH_3$]. The molecular formula of both structures is C_4H_{10}, but their atoms are connected to each other in different ways, making them constitutional isomers (also called *structural isomers*).

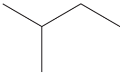
CONNECTION We first mentioned isomers in Section 3.1 in the context of Wöhler’s discovery of two compounds with the same composition.

CONNECTION In Section 2.8 we defined hydrocarbons, alkanes, alkenes, and alkynes. In Section 6.9 we explored straight-chain and branched-chain hydrocarbons. Additional information regarding the rules for naming these compounds (i.e., nomenclature) can be found in Appendix 7.

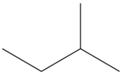
CONNECTION In Section 9.5 we introduced how to draw Kekulé structures that use lines to represent bonds and omit lone pairs.

When presented with the condensed structures or carbon-skeleton structures of two alkanes, how do we determine whether they represent two compounds with different molecular formulas, a single compound, or two constitutional isomers? We begin by translating each structure into a molecular formula. If the molecular formulas are different, then the structures represent two compounds. If the molecular formulas are the same, then we must compare the bonds in the two structures; that is, we must compare the way the atoms are connected to one another. There are two ways we can do this:

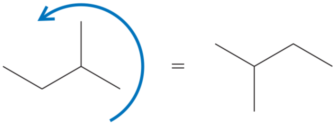
1. Simply inspecting the two structures may reveal that they are identical; however, we may have to reverse or rotate one of the structures. For example, structures (1) and (2) below may seem to be constitutional isomers, but rotating structure (2) by 180° shows that it is the same as structure (1). The two represent the same compound because they have the same composition and the same structure (bonds): a four-carbon *main chain* with a one-carbon *side chain* connected to the carbon atom next to a terminal carbon.



(1)



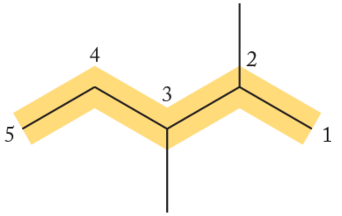
(2)



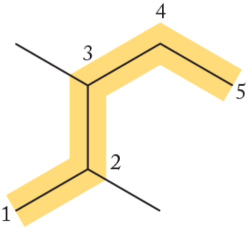
180° rotation

After rotation

2. A second method to determine whether two structures are identical involves drawing the structures being compared with the longest chains positioned horizontally. The longest chains in structures (3) and (4) below are highlighted in yellow. Number the carbons in the longest chain so that the branches have the lowest possible numbers, and then check to see whether the same side chains are attached at the same numbered positions along the longest chain. In this example, the longest chain in both structures is five carbon atoms long, and both chains have methyl (–CH_3) groups on carbon 2 and carbon 3, so they are identical. It is permissible to number some chains right-to-left, as in structure (3), or left-to-right, as in structure (4).



(3)



(4)

SAMPLE EXERCISE 20.1 Recognizing Constitutional Isomers LO1

Do the two structures in each set describe the same compound, constitutional isomers, or compounds with different molecular formulas?

Collect and Organize We have structures showing the connectivity of the atoms and from which we can determine molecular formulas. Identical compounds have the same molecular formula and the same connectivity of the atoms. Constitutional isomers have the same molecular formula but different connectivity.

Analyze In each pair, we check first to see whether the molecular formulas are the same. That means we count the number of each kind of atom present (C and H atoms, in these cases). If the molecular formulas are the same, we may have either one compound drawn two ways or a pair of constitutional isomers. If the carbon skeletons are the same in any pair, the drawings represent the same hydrocarbon.

Solve

1. The molecular formulas are the same: C_7H_{16}. Converting the condensed structure to a carbon-skeleton structure gives us

   $(CH_3)_2CHCH_2CH(CH_3)_2 \rightarrow$

   
   This structure is identical to the carbon-skeleton structure in this set. Therefore, the condensed structure and carbon-skeleton structure represent the same molecule.

2. Both molecules in this set have the molecular formula C_8H_{18}. If we rotate the second structure 180° about a vertical axis, we get the first structure, so the two compounds are identical.

   
   (1) (2) 180° rotation After rotation

3. The left structure contains nine carbon atoms, but the right structure contains only eight, so the two structures represent different compounds.

Think About It Two compounds may have the same molecular formula but they are not necessarily identical; they may be constitutional isomers.

Practice Exercise Do the two structures in each set describe the same compound, constitutional isomers, or compounds with different molecular formulas?

(Answers to Practice Exercises are in the back of the book.)

Hydrocarbons containing one or more carbon–carbon double bonds (alkenes) or triple bonds (alkynes) may also have branches, and their structures are treated just like alkanes to determine their identity. However, another situation arises with alkenes that involves different orientations of groups about the double bond. For example, consider the straight-chain isomers of the alkene that contains five carbon atoms and one double bond (**Figure 20.2**).

Structures (a) and (d) in Figure 20.2 are the same. This is easier to see if we look at the carbon-skeleton structures in the figure. In both cases the double bond is between C1 and C2. As with branched-chain alkanes, we number the carbons from whichever end gives the carbon attached to the branch the lowest number. The same holds for functional groups, as shown here, where the carbons in structure (d) must be numbered from right to left. Structures (b) and (c) are different from (a) and (d), but equivalent to each other. Moreover, they are constitutional isomers of (a) and (d) because they have the same chemical formula, but their double bond is in a different location.

Drawing the carbon-skeleton structures of (b) and (c) in Figure 20.2, however, presents us with a new situation. After we draw the first three atoms of structure (b), we have two options for how we orient the rest of the molecule with respect to the double bond. If we draw a straight dashed line through the double bond, as in **Figure 20.3a**, we can place the bond between C3 and C4 on the same side of the dashed line as the methyl group at C1 (**Figure 20.3b**) or on the opposite side (**Figure 20.3c**).

These two molecules are isomers of each other because they have the same molecular formula but different structures. The isomer in Figure 20.3b is called either the Z isomer (*Z* stands for the German word *zusammen*, or “together”) or the cis isomer (*cis* is Latin for “on this side”), which in this case translates to “the methyl group and the chain after the double bond are both *together* or *on this side* of the structure.” The isomer in Figure 20.3c is called either the

*E*isomer (*E* for *entgegen*, or “opposite”) or the trans isomer (*trans* is Latin for “across”). The system of naming using cis and trans is in wide use and is sufficient for the simple molecules discussed in this text. The *E*/*Z* system is routinely used for more complex molecules in which more than two different substituents are attached to a double bond.

Cis–trans isomers are *not* constitutional isomers: their atoms are actually connected to each other in the same way, but they differ in their three-dimensional structure. Cis–trans isomers are a type of stereoisomer. What makes stereoisomers special is that the arrangement of their atoms in space differs. That is why the prefix “stereo-” is used in the name: stereoisomers are molecules with bonds that connect the same sequence of atoms, but those bonds are oriented in different directions.

The stereoisomers in Figure 20.3 exist because there is no free rotation about the double bond. In Chapter 9 we learned that a double bond consists of a σ bond and a π bond and that the π bond forms from the overlap of two unhybridized *p* orbitals on adjacent carbon atoms. As **Figure 20.4** shows, if the carbon atoms joined in a double bond were to rotate freely, they would have to twist about the bond axis, eliminating the orbital overlap and breaking the π bond. Breaking the π bonds in 1 mole of an alkene requires about 290 kJ of energy, and that much energy is not available to the molecules at room temperature. As a result, rotation about a carbon–carbon double bond is restricted, which leads to the existence of stereoisomers.

CONCEPT TEST

Which of the following alkenes has cis and trans isomers?

1. $CH_2{=}CHCH_2CH_3$

2. 
3. $(CH_3)_2C\square C(CH_3)_2$
4. $(CH_3)_2C\square CH_2$
5. $CH_3CH\square CHCH_3$

(Answers to Concept Tests are in the back of the book.)

Chirality and Optical Activity

Before we discuss the major classes of compounds in living systems, we need to review *chirality*, a property that characterizes many biomolecules. Chirality was introduced in Section 9.5 when we learned about the three-dimensional shapes of molecules. A tangible measure of chirality is called optical activity. As a review, let's look at some familiar items that illustrate the basic principles of chirality and then turn to some important molecules in living systems that have this characteristic. A key point to understand is what is meant by an object being superimposable on its mirror image.

Figure 20.5 illustrates the concept of chirality by starting with the reflection of a plain coffee mug that is *achiral* (not chiral) because the reflected image can be superimposed on the original object. Your two hands, however, are mirror images that cannot be superimposed. Molecules that *can* be superimposed on their mirror images are achiral, whereas molecules that *cannot* be superimposed on their mirror images are chiral.

CONNECTION In Section 9.5 we defined chiral molecules as being not superimposable on their mirror images.

CONNECTION In Section 9.2 we introduced the use of solid and dashed wedges to indicate bonds that should be viewed as coming out of the plane of the paper and projecting behind the plane of the paper, respectively.

Chiral molecules exist as optical isomers; a molecule that has one chiral center exists as two optical isomers. The term “optical” refers to the ways these compounds interact with *plane-polarized* light (**Figure 20.6**). In plane-polarized light, the electric fields that compose the beam oscillate in only one plane. When plane-polarized light passes through a solution of one enantiomer of a chiral pair, the light twists in one direction. However, when the light passes through a solution of the other member of the pair, it twists the same amount but in the opposite direction.

Look carefully at the structure of the molecule alanine in **Figure 20.7**. Alanine is an amino acid, so named because it contains at least one amine (–NH_2) group and at least one carboxylic acid (–COOH) group. Alanine is called an α-*amino acid* because one carbon atom in its structure, called the α-carbon, is bonded to both an –NH_2 group and a –COOH group. The α-carbon atom in alanine is bonded to four *different* groups, making this α-carbon atom a *chiral center*. The two molecules shown in Figure 20.7a and b are both alanine. They have the same formula and the same bonds; they differ only in the three-dimensional orientation of the groups attached to the chiral center. For the most part they have the same physical properties, such as melting point and boiling point; however, they differ in how they interact with plane-polarized light.

Limonene (**Figure 20.8**) is an alkene found in oranges and turpentine. The dashed red circle identifies its chiral center. This chiral carbon atom is part of a six-membered ring, and if we examine the structure of limonene closely, we see that this carbon atom has four different groups bonded to it. The three-carbon alkene group (group 1 in Figure 20.8) and the hydrogen atom represent two of those groups. If we then follow the carbon atoms around the ring, we find a C□C bond three bonds from the circled carbon on the left side, but C□C single bonds on the right side. The presence of the C□C bond makes groups 2 and 3 in Figure 20.8 different. As a result, limonene is chiral, in which case optical isomers of limonene exist.

The two optical isomers of a single molecule are called enantiomers, so enantiomers are nonsuperimposable mirror images. In no orientation do all of the groups on the chiral center of superimposed enantiomers coincide, because the molecules have different shapes in three dimensions. Figure 20.7 shows the two enantiomers of alanine, whereas Figure 20.8 shows the two enantiomers of limonene. If we try to superimpose the two enantiomers of limonene (**Figure 20.9**), then the substituents bonded to the chiral carbon do not coincide. Because enantiomers differ in their three-dimensional structures, they are a type of stereoisomer.

To distinguish between a pair of enantiomers, (+) and (−) signs are added to their names to refer to the specific effect each isomer has on plane-polarized light. When a beam of plane-polarized light passes through a solution containing one member of an enantiomeric pair, the beam rotates as in Figure 20.6. If the beam rotates to the left (counterclockwise), the enantiomer is the *levorotatory* form of the molecule and a (−) sign precedes its name. If the beam rotates to the right (clockwise), the enantiomer is the *dextrorotatory* form and a (+) sign precedes its name. The magnitude of the rotation of plane-polarized light by the (+) isomer will be the same for the (−) isomer but in the opposite direction.

CONNECTION In Section 9.5 we saw how molecular recognition of ethylene gas triggers the ripening process for tomatoes.

The molecules in an enantiomeric pair share the same physical and chemical properties except for those that relate to a few specialized types of behavior. As we saw in Chapter 9, molecular recognition is one of those special behaviors. For example, the (+)-enantiomer of limonene smells like oranges, whereas the (−)-enantiomer smells like turpentine. Part of the process of sensing different aromas involves recognition by receptors in your nasal passages. One receptor is shaped to accommodate (+)-limonene; the other, (−)-limonene. Each enantiomer binds to its own receptor. For similar reasons, the enantiomers of certain chiral drugs have different biological effects. The enantiomer of naproxen (**Figure 20.10**) that rotates light to the right relieves pain and swelling, whereas its mirror image, which rotates light to the left, is toxic to the liver and has no analgesic effects. **Figure 20.11** summarizes the classification of isomers.

SAMPLE EXERCISE 20.2 Recognizing Chiral Molecules LO1

Identify which of the molecules shown are chiral and circle the chiral centers. Structures may have more than one chiral center.

Collect and Organize Chiral molecules are nonsuperimposable on their mirror images. If molecules have carbon atoms with four different groups attached, those carbon atoms are chiral centers and the molecules are chiral.

Analzye In the line structures shown in compounds (b), (c), (d), and (e), some carbon atoms have four bonds drawn, but some have fewer. Although hydrogen atoms are implied in these structures, be sure to consider an implicit hydrogen when counting the number of different groups attached to any one carbon.

Solve The chiral carbon atoms in each structure are circled.

The circled carbon atom in (a) is bonded to four different groups: –H, –NH_2, –COOH, and –CH_2CH_3, so this compound is chiral.

The circled carbon atom in compound (b) is bonded to a –CH_3 group, a –CH_2CH_3 group, a –$CH(CH_3)_2$ group, and an H atom, so the compound, 2,3-dimethylpentane, is chiral.

The chiral center in compound (c) is similar to the chiral center in limonene. The chiral carbon is bonded to a methyl group and an H. Tracing your finger around the ring in both directions from the circled carbon reveals the differences in the remaining two groups bonded to the chiral carbon.

All of the carbon atoms in compound (d) are sp^2 hybridized, giving compound (d) a planar molecular geometry. Planar molecules cannot be chiral because they have a superimposable mirror image. Think of a mirror plane that contains all nine carbons in compound (d): the mirror image is exactly the same.

Compound (e) has three chiral centers. Working from right to left, the first chiral center is similar to the chiral center in compound (a). The other two chiral centers are in the cyclohexane ring. In each case, the carbon atom is bonded to four different groups, so compound (e) is chiral.

Think About It The presence of a chiral center in a molecule means that the molecule has two enantiomeric forms. The molecule is not superimposable on its mirror image. Although structure (d) has no chiral center, it can have cis–trans isomers about the double bond in the chain. The isomer shown has the trans configuration.

Practice Exercise Identify which of the following molecules are chiral. Circle the chiral centers in each structure.

Chiral Mixtures

Chirality is ubiquitous in the organic compounds formed by living systems, and usually only one enantiomer occurs naturally in a particular organism. A molecule might even have more than one chiral center, which means it could exist as two or more optical isomers. Whatever the origin of these compounds, processes requiring molecular recognition in living systems often depend on the selectivity conveyed by chirality. The human body is a chiral environment, so handedness of molecules matters. As many as half of the drugs made by large pharmaceutical companies are chiral and owe their function to recognition by a receptor that favors one enantiomer over the other; in 2014 each of the ten most-prescribed drugs in the United States was chiral. Typically only one of the enantiomers of a chiral drug is active. A classic example of two enantiomers with different activity is the drug ethambutol (**Figure 20.12**). The (+)-enantiomer is effective against tuberculosis, whereas the (−)-enantiomer causes blindness.

When living systems produce chiral compounds, typically only one enantiomer is produced. However, when a molecule with a chiral center is made in a laboratory, both isomers are produced unless special methods are used. When both enantiomers are present in equal amounts in a sample, the material is known as a racemic mixture. Because one isomer rotates the plane of polarized light in one direction, and the other to the same extent in the opposite direction, a racemic mixture does not rotate the plane of polarized light at all.

Because any pair of enantiomers may interact differently with receptors, the pharmaceutical industry routinely faces two choices: devise a special synthetic procedure that yields only the isomer of interest, or separate the two isomers at the end of the manufacturing process. Both approaches are widely used. For the chiral drug sotalol (**Figure 20.13**), one isomer is physiologically active for hypertension and cardiac arrhythmias, whereas the other is inactive. Sotalol is routinely prepared as a racemic mixture that is then separated to isolate the active enantiomer. For a drug such as ethambutol (Figure 20.12), where the biological consequences of administering the undesired isomer are tragic, it is essential to exclude the incorrect isomer from the preparations administered to a patient. This is accomplished by a synthesis that produces a single pure enantiomer.

SAMPLE EXERCISE 20.3 Recognizing Optical Properties of Chiral Molecules LO1

The structure of the antidepressant drug bupropion is shown in **Figure 20.14a** along with two other compounds. Explain which of the following statements is/are true:

1. A mixture of the three compounds in any proportion has the same percent composition.

2. All three compounds rotate a beam of polarized light.
3. A 1:1 mixture of bupropion and the molecule in **Figure 20.14b** rotates a beam of polarized light.
4. The mass spectra of the three compounds are identical.

Collect and Organize We are given the structure of three compounds and asked which of the four statements about their composition and their response to plane-polarized light are true. Mass spectrometry is discussed in Section 3.8.

Analyze Isomers have the same molecular formula but differ in their structures. Compounds with a chiral center can exist as optical isomers called enantiomers. The enantiomers of a compound rotate plane-polarized light equally in opposite directions. The mass spectrum of a compound reflects the connectivity of the atoms.

Solve

1. All three compounds in Figure 20.14 have the same chemical formula, $C_{13}H_{18}NOCl$, so they will have the same percent composition.
2. The chiral centers are circled in Figure 20.14a and b. Chiral molecules are optically active and will rotate plane-polarized light. The compound in **Figure 20.14c** is not chiral and is not optically active.
3. The compounds in Figure 20.14a and b represent a pair of enantiomers. A 1:1 mixture will show no net rotation of plane-polarized light because each enantiomer will rotate plane-polarized light equally but in opposite directions.
4. The compound in Figure 20.14c is a constitutional isomer of the other molecules because the atoms are connected differently. This means that its mass spectrum will also differ from that of the enantiomeric pair. The latter will have identical mass spectra.

Think About It Enantiomers have the same chemical composition and the same molar mass. Their physical properties are identical except for the direction in which their solutions cause plane-polarized light to rotate when it passes through them.

Practice Exercise Identify the chiral carbon atoms in ethambutol (Figure 20.12) and sotalol (Figure 20.13).

Glossary

constitutional isomers

molecules with the same chemical formula but different connections between the atoms.

cis isomer (also called *Z* isomer)

a molecule with two like groups (such as two R groups or two hydrogen atoms) on the same side of the molecule.

cis isomer (also called *Z* isomer)

a molecule with two like groups (such as two R groups or two hydrogen atoms) on the same side of the molecule.

trans isomer (also called *E* isomer)

a molecule with two like groups (such as two R groups or two hydrogen atoms) on opposite sides of the molecule.

stereoisomers

isomers created by differences in the orientations of the bonds in molecules.

optical activity

a property of a compound that refers to the rotation of a beam of plane-polarized light when it passes through a solution of the compound.

optical isomers

molecules that are not superimposable on their mirror images.

amino acid

a molecule that contains at least one amine functional group and one carboxylic acid functional group; in an α-amino acid, the two functional groups are attached to the same (α) carbon atom.

enantiomer

one of a pair of optical isomers of a compound.

racemic mixture

a sample containing equal amounts of both enantiomers of a compound.

Learning Objectives

Recognize constitutional isomers, draw their molecular structures, and identify chiral molecules **Return to Sample Exercises 20.1, 20.2, 20.3**

- Recognize constitutional isomers, draw their molecular structures, and identify chiral molecules **Return to Sample Exercises 20.1, 20.2, 20.3**
- Recognize constitutional isomers, draw their molecular structures, and identify chiral molecules **Return to Sample Exercises 20.1, 20.2, 20.3**

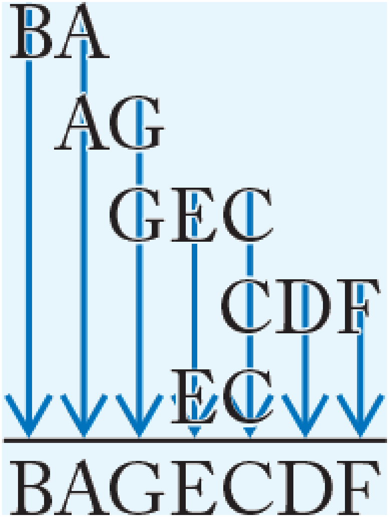
aspartylphenylalanine, so it has one fewer –COOH group than its parent dipeptide. Therefore, the overall charge of a molecule of aspartame at pH 7.4 is zero, whereas the charge on aspartylphenylalanine is 1 −.



20.3 The Composition of Proteins

We opened our discussion of chirality with the α-amino acid alanine. We chose that molecule because amino acids are the small-molecule building blocks of proteins, the most abundant class of biomolecules in all animals, including us. Proteins account for about half the mass of the human body that is not water. They are the major component in skin, muscles, cartilage, hair, and nails. Most of the enzymes that catalyze biochemical reactions are proteins, as are the molecules that transport oxygen to our cells and many of the hormones that regulate cell function and growth. Most proteins are large, with molar masses of 10^5 g/mol or more.

Amino Acids

The molecular structures and biological functions of big biomolecules depend on the identities of their amino acids and the sequence in which those small molecules are connected. About 500 amino acids are known, and about 240 of these occur free in nature, but only 20 common amino acids form proteins in humans (**Table 20.2**).

In addition to its single bonds to the –NH_2 and –COOH groups, the α-carbon atom in each of the amino acids that make up human proteins is bonded to a hydrogen atom and to one of 20 R groups. The structures of these R groups, often called *side-chain groups*, are highlighted in pink in the amino acid structures in Table 20.2. The amino acids are arranged in four categories based on their R groups. In the first category, containing 9 amino acids, the R groups contain mostly carbon and hydrogen atoms and are nonpolar. The R groups of the remaining 11 amino acids contain at least one heteroatom (O, N, or S) bonded to an H atom and are polar. Of these amino acids, two (aspartic acid and glutamic acid) have R groups that contain carboxylic acid functional groups, and three (histidine, lysine, and arginine) have R groups with nitrogen atoms that are weakly basic.

CONCEPT TEST

Identify the organic functional groups in the R groups of the following amino acids in Table 20.2: (a) leucine; (b) phenylalanine; (c) serine; (d) glutamine; (e) aspartic acid; (f) lysine.

Our bodies can synthesize 10 of the 20 amino acids in Table 20.2, but the other 10 must be present in the food we eat. These 10 are marked with a superscript *b* and are referred to as essential amino acids in adults. Arginine is also an essential amino acid because most arginine produced in our bodies is unavailable for protein synthesis. Most proteins from animal sources, including those in meats, eggs, and dairy products, contain all the essential amino acids needed by the human body, and in close to the correct proportions. These foods are sometimes referred to as *perfect foods* or, more precisely, *complete proteins*. In contrast, most plant proteins from foods such as legumes and vegetables do *not* contain all the essential amino acids, so vegetarians must be careful to eat a combination of foods that provide all the essential amino acids. A good example is red beans and rice (**Figure 20.15**), a traditional dish in Latin American cuisine that provides a balance of essential amino acids: rice has all of them but lysine, and beans lack only methionine.

For historical reasons, amino acid enantiomers are designated by the prefixes d- (for *dextro*-, right) and l- (*levo*-, left). These labels refer to how the four groups bonded to each chiral carbon atom are oriented in three-dimensional space. They *do not* refer to the direction in which plane-polarized light rotates as it passes through a solution of the amino acid. In other words, there is no connection between the d- and l- prefixes in the names of amino acids and the *dextrorotatory* and *levorotatory* enantiomers that are designated with (+) and (−) signs based on their optical properties. All the chiral amino acids in the proteins in our bodies are l-enantiomers, even though 9 of the 19 are actually dextrorotatory.

CONCEPT TEST

One of the 20 amino acids in Table 20.2 is not chiral. Identify it and explain why it is not. If any of the amino acids have more than one chiral center, identify them.

Zwitterions

If we dissolve an amino acid in a solution that already contains a strong acid and has a low pH, the carboxylic acid group on each molecule does not ionize. In addition, each amine group, being a weak base, accepts a H^+ ion, forming a *protonated* $–NH_3^+$ group. The result is a molecular ion with an overall positive charge, as illustrated for alanine in **Figure 20.16a**.

Now suppose we add a strong base to this solution, neutralizing the strong acid and raising the pH to about 7.4. We choose this value because it is close to the pH of human blood and of the fluids in most of our tissues. At this *physiological pH*, the –COOH groups in amino acids are mostly ionized, but nearly all the amine groups are still in the protonated $–NH_3^+$ form because $–NH_3^+$ is the conjugate acid of a weak base and is itself a very weak acid. As a result, most of the protonated amine groups still have positive charges and most of the ionized carboxylic acid groups have negative charges. This combination of negatively charged $–COO^-$ groups and positively charged $–NH_3^+$ groups means that these amino acid molecules are zwitterions (literally, *hybridions*). This term is used to describe molecules that contain both negatively and positively charged functional groups. For example, if an amino acid contains one $–COO^-$ group and one $–NH_3^+$ group (**Figure 20.16b**), it would have no net electrical charge.

If we add more base, alanine loses a H^+ from its $NH_3{}^+$ group (we say that it *deprotonates*), and we have a molecular ion with an overall charge of 1− (**Figure 20.16c**). The titration curve for alanine in **Figure 20.17** shows this two-step neutralization process: first the carboxylic acid ionizes, and then the protonated amine deprotonates.

Amino acids with acidic or basic R groups have three-step neutralization processes. For example, an amino acid like glutamic acid or aspartic acid, each of which has a second carboxylic acid group in R, will experience the neutralization of both acidic groups and then the deprotonation of the amine. Which acidic group is the stronger; which deprotonates at lowest pH? Think about the structure of the molecule to answer this. The –COOH group bonded to the α-carbon atom is only one carbon atom away from a positively charged $NH_3{}^+$ group. The side-chain –COOH group is at least two carbon atoms away, and the carboxylate ion that it forms when it ionizes is less stabilized by delocalization of its negative charge toward the cationic group. Therefore, the –COOH group bonded to the α-carbon atom is the stronger acid and ionizes first.

For an amino acid with a basic R group, such as asparagine or glutamine, the order of ionization in a titration also depends on the relative strengths of the groups as proton donors. The –COOH group always ionizes first as base is added; it is the strongest acid in the molecule. The protonated nitrogen groups deprotonate in order of their relative strengths as proton donors.

Each amino acid has a characteristic p*I* value, called the isoelectric point. It represents the pH at which molecules of the amino acid have, on average, zero charge. The pH at the equivalence point between the two pK_a values is the p*I*. Its value is the average of the neighboring pK_a values. At this pH, the amino acid does not migrate in an electric field. If the pH is more acidic than the p*I*, the amino acid is positively charged and migrates to the cathode (negative electrode). At pH values more basic than the p*I*, the amino acid has a net negative charge and migrates toward the anode (positive electrode). This behavior is the basis of several analytical techniques used to characterize and identify amino acids. The p*I* values of neutral amino acids are around pH 7; acidic amino acids have p*I* values much lower than 7, and basic amino acids, much higher.

CONNECTION The inverse relationship between the strengths of acid–base conjugate pairs was introduced in Section 15.3 (see Figure 15.9).

SAMPLE EXERCISE 20.4 Interpreting Acid–Base Titration Curves of Amino Acids LO2

Figure 20.18 shows the titration curve for aspartic acid and its pK_{a1}, pK_{a2}, pK_{a3}values. Draw the molecular structures of the principal form of aspartic acid that is in solution at the start of the titration and at each equivalence point. Estimate the p*I* of aspartic acid.

Collect, Organize, and Analyze Aspartic acid (Table 20.2) has two carboxylic acid groups and one amine group. At low pH the carboxylic acid groups are not ionized and the amine group is protonated. As pH is raised, the –COOH groups ionize first and then, under basic conditions, the protonated amine group releases its proton. The –COOH group bonded to the α-carbon atom should be the stronger acid and ionize first.

Solve At (a), the beginning of the titration, the fully protonated $1+$ ion is present:

At (b), the first equivalence point, the –COOH group bonded to the α-carbon atom is ionized; the charge on the ion is 0.

At (c), the second equivalence point, the side-chain –COOH group is ionized; the charge on the ion is $1-$:

At (d), the third equivalence point in the titration, the amine group is deprotonated, resulting in an ion with a $2-$ charge:

Although there are three equivalence points, the pI is calculated from the first two pK_a values because the pI indicates the pH at which molecules of the amino acid, on average, have a net neutral charge. The pI of aspartic acid can be estimated by taking the value midway between $K_{a1}$and K_{a2}in Figure 20.18: $(1.99 + 3.90)/2 = 2.94$.

Think About It We predicted that the α-COOH group would ionize first, consistent with the observation of two values of K_{a1} and K_{a2}.

Practice Exercise Sketch the titration curve for lysine starting at pH = 1.0, and draw the molecular structure of the principal form of lysine that is in solution at the beginning of the titration and at each equivalence point.

The acid–base characteristics of amino acids are important for their function in enzymes, where protonation/deprotonation controls their activity as catalysts. In addition, the structures of proteins depend in part on hydrogen bonding, which can be disrupted by changes in pH. This process is used in food preparation, when acids such as lemon juice are used to “cook” raw fish in dishes such as ceviche.

Peptides

When amino acids bond they form chainlike molecules with a wide range of sizes. Amino acid *residues* (the name we give to amino acids that are part of a larger molecule) make up each link in the chain. The longest chains, some with molar masses as high as 3 million g/mol, are called proteins, but the shortest chains, called peptides, are only a few links long. The smallest peptides contain only two or three amino acid residues. These molecules are called *dipeptides* and *tripeptides*, respectively. Peptides up to 20 residues long are called *oligopeptides*. Those made of more than 20 are called *polypeptides*. The size at which a polypeptide becomes a protein, or biopolymer, is arbitrary but is typically set around 50–75 amino acid residues.

CONNECTION The formation of amide bonds in reactions between carboxylic acids and amines was described in Section 12.6 (see Figures 12.43 and 12.46).

The type of bond linking the amino acids in peptides and proteins is called a peptide bond (highlighted in blue in **Figure 20.19**) or *peptide linkage*. It forms when the α-carboxylic acid group of one amino acid condenses with the α-amine group of another, with the loss of a molecule of water. The peptide bonds have the same structure as the amide bonds that hold together the monomeric units of synthetic polyamides such as nylon and Kevlar (see Section 12.6). This process is not spontaneous and is driven by being coupled to ATP hydrolysis (see Section 17.9).

The convention for drawing the structures of peptides begins by placing the amino acid that has a free α-amine group at the left end of the peptide chain and the amino acid with a free α-carboxylic acid at the right end. The left end is called the *amine* (or *N*-) *terminus* of the peptide, and the right end is called the *carboxylic acid* (or *C*-) *terminus*. The name of a peptide is based on the names of its amino acids, starting with the one at the N-terminus. The names of all the amino acids except the one at the C-terminus are changed to end in *-yl*. For example, if a peptide bond forms between the α-COOH group of valine (Val) and the α-NH_2 group of serine (Ser), as in Figure 20.19, the resulting dipeptide is called valylserine, or more typically, using the three-letter abbreviation, ValSer.

The artificial sweetener aspartame is the methyl ester of the dipeptide aspartylphenylalanine (**Figure 20.20**). At pH 7.4, aspartame exists as a zwitterion because the aspartic acid amine group is protonated and the carboxylic acid in its R group is ionized. In contrast, its parent dipeptide has a net charge of $1-$ because both –COOH groups are ionized at that pH. In an amino acid that has an amine group in its R group, such as lysine or arginine, that amine group is probably protonated at physiological pH, giving the amino acid a net charge of $1+$. The overall charge on the peptide at physiological pH is the sum of the positive charges on protonated amine groups and the negative charges of ionized carboxylic acid groups.

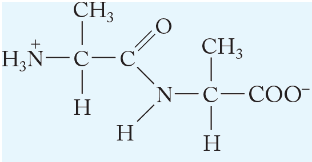
SAMPLE EXERCISE 20.5 Drawing and Naming Peptides LO3

(a) Name all the dipeptides that can be made by reacting an amino acid mixture containing alanine and glycine, and (b) draw their molecular structures in solution at pH 7.4.

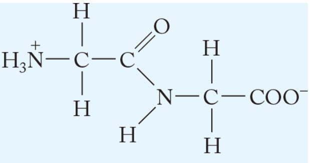
Collect, Organize, and Analyze The structures of alanine and glycine are shown in Table 20.2. Four different peptides can be made from two amino acids: AlaAla, GlyGly, AlaGly, and GlyAla. The R groups in alanine ($–CH_3$) and glycine (–H) have no acidic or basic properties. At pH 7.4, the carboxylic acid terminus –COOH groups should be ionized, and the amine terminus $–NH_2$ groups should be protonated.

Solve

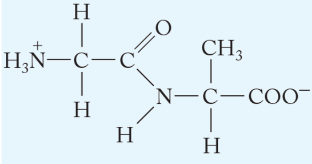
1. The names of the four peptides with the amino acid sequence AlaAla, GlyGly, GlyAla, and AlaGly are alanylalanine, glycylglycine, glycylalanine and alanylglycine, respectively.
2. At pH 7.4, the $–NH_2$ groups of amino acids are protonated and the –COOH groups are ionized, so the principal forms of these dipeptides are



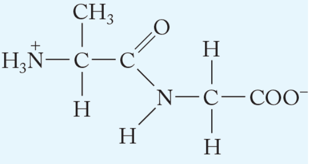
Alanylalanine
(AlaAla)



Glycylglycine
(GlyGly)



Glycylalanine
(GlyAla)



Alanylglycine
(AlaGly)

Think About It Only the N-terminus $–NH_2$ and C-terminus –COOH groups can be protonated or ionized in these dipeptides. Thus, all four of the dipeptides are zwitterionic with a net charge of $(1+) + (1-) = 0$ at pH 7.4.

Practice Exercise How many different tripeptides can be synthesized from one molecule of each of three different amino acids, Gly, Tyr, and Ser?

Only two sequences are possible for a peptide containing two different amino acids. Amino acid A and amino acid B can make dipeptide AB or BA. For a peptide made from three different amino acids—A, B, and C—six sequences are possible. For longer peptides, the number of possibilities becomes enormous. The sequence matters in determining the properties of the peptides, and figuring out the amino acid sequence of peptides and proteins is a significant challenge in biochemistry. One of the fundamental experimental methods used to determine sequence involves finding the identities of individual component amino acids, and then identifying fragments of the structure containing several amino acids and piecing them together like a puzzle. For example, a tripeptide could be broken down into amino acids A, B, and C. Dipeptide fragments BA and AC could then be identified, which means the overall sequence of the tripeptide must be BAC.

SAMPLE EXERCISE 20.6 Determining the Amino Acid Sequence of a Small Peptide LO3

A small peptide was hydrolyzed completely to its component amino acids: A, B, C, D, E, F, and G. Alternative ways to treat the peptide yielded the larger fragments BA, CDF, EC, AG, and GEC. What is the sequence of the amino acids in the peptide?

Collect, Organize, and Analyze We know the identity of seven amino acids that make up a peptide, and we have several dipeptide and tripeptide fragments. We need to arrange them to reveal the complete sequence of the peptide.

Solve Arranging the fragments so that like amino acids are in columns:

The amino acid sequence of the peptide is BAGECDF.

Think About It Complete hydrolysis of the peptide provides less information about the amino acid sequence than longer fragments do.

Practice Exercise The hydrolysis of a peptide yielded the following amino acids: Gly, Ala, Val, Thr, and 2 Leu; and the following larger fragments: LeuThr, AlaLeuLeu, ThrGly, and ValAla. What is the sequence of the amino acids in the peptide?

Glossary

protein	a biological polymer made of amino acids.
essential amino acid	any of the ten amino acids that make up peptides and proteins but are not synthesized in the human body and must be obtained through the food we eat.
zwitterion	a molecule that has both negatively and positively charged groups in its structure.
p*I* (also called isoelectric point)	the pH at which molecules of the amino acid have, on average, zero charge.
p*I* (also called isoelectric point)	

the pH at which molecules of the amino acid have, on average, zero charge.

peptide

a compound of two or more amino acids joined by peptide bonds; small peptides containing up to 20 amino acids are oligopeptides, whereas polypeptides are chains longer than 20 amino acids but shorter than proteins.

peptide bond

the result of a condensation reaction between the carboxylic acid group of one amino acid and the amine group of another.

Endnotes

FIGURE 20.32 (a) The induced-fit model assumes that the shape of the enzyme (purple) changes to allow the enzyme and two substrates (red and green) to form an enzyme-substrate (ES) complex that promotes the formation of the product. In this example the change in shape of the active site distorts the inhibitor B binding site. (b) Inhibitor A blocks the enzyme's active sites. No ES complex can form. (c) Inhibitor B occupies a binding site, preventing the enzyme from attaining the shape needed to form the ES complex.

20.4 Protein Structure and Function

The structure of a protein is crucial to its function. This fact is easiest to appreciate for structural proteins such as the collagens, which impart flexibility, strength, and elasticity to skin and tendons. The functions of nonstructural proteins, such as the ability of enzymes to catalyze biochemical reactions, are also closely linked to their structures. These large biomolecules must assume particular three-dimensional conformations to interact with other molecules and to function properly (**Figure 20.21**). **Table 20.3** lists some of the important functional classifications of proteins and gives examples of each.

TABLE 20.3 Functional Classes of Proteins

Class	**Function**	Example Protein
Structural	Provide strength and structure	Collagen provides strength and flexibility to connective tissue
Enzymes	Catalyze reactions in cells	Sucrase catalyzes conversion of sucrose into simpler sugars
Hormones	Regulate body processes in organisms	Insulin helps cells regulate absorption of glucose
Signaling	Regulate the activity of cells	GTPases regulate intracellular cell dynamics
Defense	Immune response	Antibodies attack bacteria
Storage	Store energy during metabolism	Ovalbumin in egg
Transport	Transports molecules from place to place	Hemoglobin transports oxygen from lungs to cells

Primary Structure

The primary (1°) structure of a protein is the sequence of the amino acids in it, starting with the N-terminus (Figure 20.21a). If two proteins are made up of the same number and type of amino acids but have different amino acid sequences, they are different proteins.

Changing only one amino acid can dramatically alter a protein’s function. In hemoglobin, for example, the sixth amino acid from the N-terminus of a protein strand that is 146 amino acids long is normally glutamic acid. In some people, valine substitutes for glutamic acid at this position. This one substitution alters the solubility of the protein and causes the red blood cell to take on a sickle shape instead of the normal, plump disk shape (**Figure 20.22**). These sickled cells do not pass through capillaries easily and may impede blood circulation. They also break readily and do not last as long as normal blood cells. For people who inherit two copies of the gene mutation that leads to sickled cells, these factors lead to a diminished capacity of the blood to carry oxygen, which is one of the characteristics of the disease called sickle-cell anemia.

Why does switching valine for glutamic acid affect the solubility of hemoglobin? The answer lies in the R groups of these two amino acids (**Figure 20.23**). The side-chain –COOH group of glutamic acid is ionized at physiological pH, and strong ion–dipole interactions with water molecules enhance the protein's solubility. However, if valine, with its nonpolar isopropyl R group, replaces glutamic acid, that strong intermolecular interaction with water is lost. The valine creates a hydrophobic patch on the surface of the protein that results in the deoxygenated forms of hemoglobin sticking to each other, producing stiff fibers inside red blood cells. This, in turn, deforms the red blood cell from its usual smooth disk shape (Figure 20.22a) into a sickle shape (Figure 20.22b).

Sickle-cell anemia is a debilitating disease, but it provides a survival advantage in regions where malaria is endemic. Having sickle-cell anemia does not protect people from contracting malaria or make them invulnerable to the parasite that causes it. However, children infected with malaria are more likely to survive the illness if they have sickle-cell anemia. Exactly why sickle-cell anemia has this effect is not completely understood, but recent work points toward sickle-hemoglobin increasing the production of an enzyme that catalyzes the production of carbon monoxide; the carbon monoxide protects the host from succumbing to malaria without actually interfering with the parasite.

CONCEPT TEST

Which other amino acids besides valine might result in the sickling of the cell when substituted for glutamic acid?

Secondary Structure

The next level of protein structure, the secondary (2°) structure, describes the geometric patterns made by segments of amino acid chains. One common pattern is the α helix, a coiled arrangement with the R groups pointing outward (Figure 20.21b). The helical structure is maintained by hydrogen bonds between –NH groups on one part of the chain and C=O groups on amino acids four residues away from them in the sequence. The α helix looks very much like a spring. One group of proteins that are mostly α-helical is the keratins, the proteins in hair and fingernails.

CONNECTION We discussed in Chapter 10 how ion–dipole and dipole–dipole interactions are the key to the solubility of solutes in water.

Another common pattern of 2° structure is called the β-pleated sheet. These sheets are assemblies of multiple amino acid chains aligned side by side. The pleats are caused by the tetrahedral molecular geometries of the atoms along the chains (**Figure 20.24**). Adjacent chains are linked by hydrogen bonds, and the collection of side-by-side zigzag chains forms a continuous β-pleated sheet. R groups extend above and below the pleats. Sheets may stack on top of one another like two pieces of corrugated roofing. Stacked sheets are held together by the same interactions that hold all proteins together, including ion–ion forces, hydrogen bonds, and dispersion forces, depending on the pairs of R groups involved (**Figure 20.25**).

The proteins that make up strands of silk form thin, planar crystals of β-pleated sheets that are only a few nanometers on a side. Enormous numbers of these crystals form long arrays of sheets stacked together like nanoscale pancakes (**Figure 20.26**). Hydrogen bonds hold the stacks together and reinforce adjacent sheets. As a result of these interactions, strands of silk are stronger than strands of steel with the same mass; indeed, silk is one of the toughest known materials—natural or synthetic.

Some single-stranded proteins exist as α helices on their own but form β-pleated sheets when they clump together in multistrand aggregates. One consequence of this clumping is the formation of insoluble protein deposits called plaques. Abnormal accumulation of plaque can be a serious health risk: plaque formed by a protein called amyloid β has been linked to the onset of Alzheimer’s disease.

Large protein molecules may contain both types of 2° structure as well as other loop and turn structures. In describing a protein, scientists may indicate the percentage of amino acids involved in each type—for example, 50% α-helical, 30% β-pleated sheet, and 20% other structures. **Figure 20.27** shows a model of a protein called carbonic anhydrase, which contains several different types of 2° structure.

CONCEPT TEST

The aqueous solution of proteins in egg whites turns into a solid mass when eggs are cooked or are dropped into an organic solvent such as acetone. Does the solidification process occur as a result of a change in the primary structure of the proteins? Explain your answer.

Tertiary and Quaternary Structure

Large proteins have structure beyond the 1° and 2° levels. Their molecules can fold back on themselves as a result of ion–ion, ion–dipole, or dispersion forces between R groups on amino acids that are considerable distances apart along the protein chain. They may even involve the formation of covalent bonds. For example, the –SH groups on two cysteine residues may combine to form a disulfide linkage that holds two parts of the protein strand together via an intrastrand –S–S– covalent bond (**Figure 20.28**). Interactions and reactions such as these determine a protein's tertiary (3°) structure, the overall three-dimensional shape of the protein that is key to its biological activity (Figure 20.21c). Hydrophobic R groups tend to be positioned in the interiors of proteins in the aqueous environment of living cells, whereas hydrophilic groups (as we saw in normal hemoglobin) are oriented toward the outside, where they interact with nearby molecules of water. Hydrophobic interactions are the primary force that causes protein folding and compaction, but all the other modes of interaction help a large protein form its unique 3° structure.

CONNECTION All the types of intermolecular forces described in Chapter 10 are involved in the *intra*molecular interactions that give proteins their unique 2° and 3° structures.

Hemoglobin and some other proteins exhibit an even higher order of structure. One hemoglobin unit (**Figure 20.29a**) contains four protein strands, each of which enfolds a porphyrin ring containing one Fe^{2+} ion. The combination of four protein strands to make one hemoglobin assembly is an example of quaternary (4°) structure (Figure 20.21d). The strands in these structures are held together by many of the same intermolecular forces and covalent bonds that determine tertiary structures, such as disulfide linkages that help protein strands with α-helical 2° structures coil around each other to make even larger coils (**Figure 20.29b**). When the protein strands in keratin structures are held together mostly by dispersion forces, as they are in the keratin in skin tissue, the structures are flexible and elastic. If they are also restrained by many covalent bonds, as in Figure 20.29b, they produce tissues that are hard and less flexible, like fingernails and the beaks of birds.

Enzymes: Proteins as Catalysts

We introduced *enzymes* as biological catalysts in Section 13.6. As described there, the chemical reactions involved with metabolism—both *catabolism* (breaking down of molecules) and *anabolism* (synthesis of complex materials from simple feedstocks)—are mediated in large part by enzymes. Both catabolism and anabolism are organized in sequences of reactions called *metabolic pathways*, and each step in a metabolic pathway is catalyzed by a specific enzyme.

CONNECTION In Section 13.6 we described enzymes as homogeneous catalysts that selectively speed up biochemical reactions.

Enzymes are highly selective: each catalyzes a particular reaction involving particular reactants. For example, an enzyme called lactase catalyzes only the reaction by which lactose (the sugar in milk) is broken down during digestion. People who lack this enzyme cannot metabolize this sugar; they are said to be *lactose intolerant*. If they consume dairy products, unmetabolized lactose passes into their large intestines where bacteria ferment it, and unpleasant and painful abdominal disturbances result.

Synthetic reaction pathways catalyzed by enzymes are usually more rapid and involve fewer steps than uncatalyzed pathways to make the same product. The products also tend to be optically pure materials. These advantages can significantly reduce the cost of production of, for example, biological pharmaceuticals. However, biocatalytic reactions often run best in very dilute solutions, which limits production. A key issue driving interest in such processes is that an enantiomerically pure pharmaceutical is likely to be more potent and produce fewer side effects than a racemic mixture of the same product, as we saw with the drug ethambutol in Section 20.2.

The drug thalidomide (**Figure 20.30**) is a racemic mixture of two enantiomeric forms: the (+)-enantiomer is a sedative and is effective in treating morning sickness, but the (−)-enantiomer is a teratogen (an agent that disturbs the development of a fetus). More than 10,000 children were born in the late 1950s and early 1960s with serious, frequently fatal, deformities as a result of their mothers taking the racemic drug. The individual isomers can be interconverted *in vivo*, so administering only the (+)-enantiomer does not avoid the serious effects. Today, thalidomide is prescribed to treat multiple myeloma (a type of cancer) and Hansen’s disease (leprosy).

The phosphorylation of glucose in Section 17.9 (Figure 17.21) is the first step in glycolysis, one of the pathways by which we metabolize glucose. The reaction requires both ATP so that $\Delta G < 0$ and an enzyme to catalyze the reaction. The molecular structure of enzymes contains a region called an active site that binds the reactant molecule, called the substrate. The action of enzymes was originally explained by a lock-and-key analogy in which the substrate is the key and the active site is the lock (**Figure 20.31**). The substrate is held in the active site by the same kinds of intermolecular interactions that hold any biomolecules together. Some enzymes become covalently bonded to intermediates in the catalytic process. Once in the active site, the substrate is converted into product via a reaction having a lower-energy transition state than it would without the enzyme. The reaction of a substrate (S) with an enzyme (E) produces an *enzyme–substrate* (ES) *complex* that decomposes, forming a product P and regenerating the enzyme:

$$\mathrm{E} + \mathrm{S} \rightleftharpoons \mathrm{ES} \rightarrow \mathrm{E} + \mathrm{P}$$

The lock-and-key analogy, however, does not fully account for enzyme behavior. A more accurate view is provided by the *induced-fit model*, which assumes that the substrate does more than just fit into the existing shape of an active site. This model assumes that as the ES complex forms, the binding site undergoes subtle changes in its shape to more precisely fit the three-dimensional structure of the transition state. The binding energy between the enzyme and the substrate creates a lower-energy transition state, thereby lowering the activation energy barrier. A simplified illustration of such an interaction is shown in **Figure 20.32a**.

The induced-fit model helps explain the behavior of compounds called inhibitors, which can diminish or destroy the effectiveness of enzymes. For example, as the concentration of glucose-6-phosphate exceeds a particular threshold, the compound starts to inhibit the enzyme. An inhibitor may bind to an active site and block it from interacting with the substrate (**Figure 20.32b**) and, from that position, prevent the enzyme from achieving its active shape (i.e., the shape necessary to bind the substrate). Alternatively, an inhibitor may disable the enzyme by preventing it from assuming its active shape. That is, the inhibitor may bind to the enzyme at a site other than the active site (**Figure 20.32c**).

Natural enzyme inhibitors play important roles in regulating the rates of reactions that are catalyzed by enzymes. In a multistep reaction pathway, for example, the product of a later step may inhibit an enzyme that catalyzes an earlier reaction. This kind of negative feedback keeps the sequence of reactions from running too quickly and perhaps jeopardizing the health of the organism as the result of an accumulation of undesirable products or intermediates.

Enzyme inhibitors may also be used to fight disease. Powerful drugs have been developed that inhibit enzymes called proteases involved in virus maturation. Several such drugs have been particularly effective in treating HIV.

Glossary

primary (1°) structure
the sequence in which amino acid monomers occur in a protein chain.

secondary (2°) structure
the pattern of arrangement of segments of a protein chain.

β-pleated sheet
a puckered two-dimensional array of protein strands held together by hydrogen bonds.

tertiary (3°) structure
the three-dimensional, biologically active structure of a protein that arises because of interactions between the R groups on its amino acids.

quaternary (4°) structure
the larger structure functioning as a single unit that results when two or more proteins associate.

active site
the location on an enzyme where a reactive substance binds.

substrate
the reactant that binds to the active site in an enzyme-catalyzed reaction.

inhibitor
a compound that diminishes or destroys the ability of an enzyme to catalyze a reaction.

α helix
a coil in a protein chain’s secondary structure held together by hydrogen bonds.

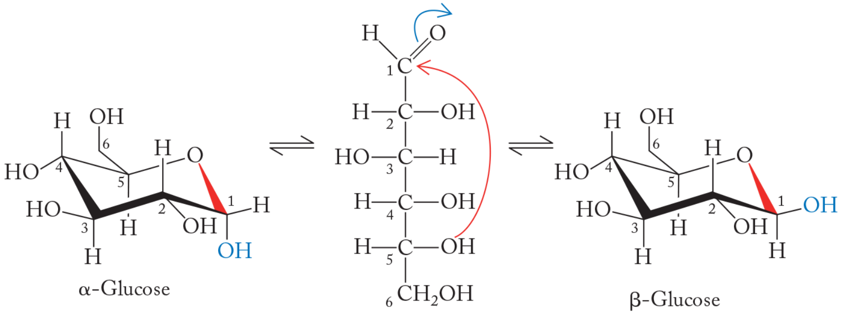

FIGURE 20.33 An equilibrium exists between the linear structure of glucose and the two cyclic forms α-glucose and β-glucose. The difference between the two cyclic structures is the orientation of the –OH group on C1 (highlighted in blue), which is formed by the O atom on C1 as indicated by the blue arrow. The new bond between oxygen and carbon atoms is shown in red in the cyclic structures and is formed by the reaction of the –OH on C5 and C1 as indicated by the red arrow.

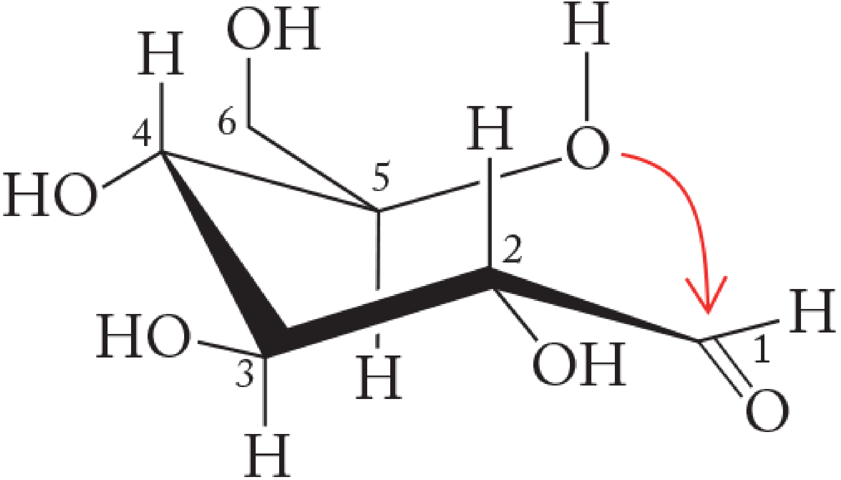

FIGURE 20.34 The –OH group on C5 may approach the aldehyde at C1 from either side of the plane defined by the C, H, and O atoms in the aldehyde group. In the approach shown here the product is the α isomer.

In the presence of sufficient O_2, the oxidation of pyruvate proceeds via the TCA cycle. When there is insufficient dissolved O_2 available, as in the fermentation of yeast, the pyruvate may be converted to ethanol.

20.5 Carbohydrates

Carbohydrates have the generic formula $C_x(H_2O)$**y**. This formula gives us a clue about where the name *carbohydrate*, or *hydrate of carbon*, comes from. The smallest carbohydrates are monosaccharides (the name means "one sugar"), which bond to form more complex carbohydrates called polysaccharides. Many organisms use monosaccharides as their main energy source but convert them to polysaccharides for the purpose of energy storage. Starch is the most abundant energy-storage polysaccharide in plants. Polysaccharides in the form of cellulose also provide structural support in plants. Plants produce over 100 billion tons of cellulose each year—the woody parts of trees are more than 50% cellulose and cotton is 99% cellulose.

The principal building block of both starch and cellulose is the monosaccharide glucose. The different properties and functions of these polysaccharides come from the subtle differences in the molecular geometries of the glucose monomers in their structures and the way the monomers are bonded. Molecules of most monosaccharides, including glucose, contain several chiral centers, so multiple optical isomers exist. This complexity gives rise to another major function of carbohydrates: molecular recognition. For example, combinations of carbohydrates and proteins, called *glycoproteins*, on the surfaces of blood cells determine the blood type of an individual.

Molecular Structures of Glucose and Fructose

Glucose is the most abundant monosaccharide in nature and in the human body. It is also called *dextrose*—a kind of abbreviation for *dextro*-glucose. Fructose is the principal monosaccharide in many fruits and root vegetables. Given the importance and abundance of these sugars, let's examine their structures and properties more closely.

Three molecular views of glucose are shown in **Figure 20.33**. All three have the same chemical formula ($C_6H_{12}O_6$), so they are all isomers of one another. The middle structure contains an aldehyde (–CH□O) group and all three structures contain multiple alcohol (–C□OH) groups. The polarities of these groups and their capacities to form hydrogen bonds give glucose its high molar solubility in water (5.0 *M* at 25°C, or about 9 g in 10 mL of water).

The cyclic structures of glucose form when the carbon backbone of the linear form curls around so that the –OH group bonded to the carbon atom labeled number 5 (C5) comes close to the aldehyde group on C1 (as shown by the red arrow in Figure 20.33). The aldehyde and alcohol groups react to form a six-membered ring made up of five carbon atoms (C1 to C5) and the oxygen atom of the C5 alcohol. Notice a small but significant difference in the two cyclic structures. In the molecule on the left, called α-glucose, the –OH group on C1 points down. In the molecule on the right, called β-glucose, the C1 –OH group points up. These two orientations are possible because there are two ways that the carbon chain in the middle structure can form a cyclic structure: the –OH group on C5 can approach C1 from either of the two sides of the plane defined by the C1 carbon atom and the O and H atoms bonded to it. When the C5 –OH group approaches C1 as shown in **Figure 20.34**, the α isomer is produced. Approaching C1 from the other side yields the β isomer. In the linear form, C1 is an aldehyde and is not a chiral center, but cyclization creates a new chiral center in the cyclic molecule.

The β form is slightly more stable than the α form and accounts for 64% of glucose molecules in aqueous solution; the α form accounts for the remaining 36%. Both cyclic forms are more stable than the straight-chain form, which exists only as an intermediate between the two cyclic forms. The energy differences are small, however, so glucose molecules in solution are constantly opening and closing in a dynamic structural equilibrium.

Figure 20.35 shows the structures of the linear and cyclic forms of fructose, commonly known as fruit sugar and contained in honey and many fruits. The C□O group in the linear form is not on the terminal carbon atom because fructose is a ketone rather than an aldehyde. It forms a five-membered ring, not a six-membered ring, when the –OH group at C5 reacts with the carbonyl carbon atom at the C2 position. The product is a ring with two –CH_2OH groups that are either on the same side of the ring (α-fructose) or on opposite sides (β-fructose).

Disaccharides and Polysaccharides

Sucrose, or ordinary table sugar, is a *disaccharide* (“two sugars”) that consists of one molecule of α-glucose bonded to one molecule of β-fructose (**Figure 20.36**). The bond between them forms when the –OH group on the C1 carbon atom of α-glucose reacts with the C2 carbon atom of β-fructose, producing a C□O□C glycosidic bond or *glycosidic linkage*. Water is also produced, making this reaction another example of a condensation reaction, as is peptide bond formation. The glycosidic bond in sucrose is called an α,β-1,2 linkage because of the orientations (α and β) of the two –OH groups involved and their positions (C1 and C2) in the cyclic structures of the two monosaccharides.

Another important glycosidic bond involves the –OH groups on the C1 and C4 carbon atoms of glucose molecules. When glucose molecules link at these positions they can form long-chain polysaccharides. If the starting monomer is α-glucose, the bonds between them are α-1,4-glycosidic linkages, and the product of bond formation is starch (**Figure 20.37a**). The conversion of α-glucose into starch is an effective way for plants to store energy because formation of the α-1,4 linkage is reversible. With the aid of digestive enzymes, α-1,4 bonds can be hydrolyzed and starch converted back into glucose by plants that make the starch or by animals that eat the plants.

The cellulose that plants synthesize to build stems and other organs has a structure (**Figure 20.37b**) slightly different from that of starch because the building blocks of cellulose are β-glucose instead of α-glucose, so the monomers are linked by β-1,4-glycosidic bonds. This structural difference is important because it enables starch to coil and make granules for efficient energy storage, whereas cellulose forms structural fibers.

Carbohydrates in plants are a major part of the total organic matter in any given ecological system; that is, they make up much of the system's biomass. People have used various forms of biomass, including wood and animal dung, as fuel for thousands of years. More recently, we have begun to convert biomass into a liquid *biofuel*, ethanol, for use as a gasoline additive and substitute. Ethanol contains oxygen, which improves the combustion of a hydrocarbon fuel such as gasoline and reduces carbon monoxide emissions. An important industrial application of starch hydrolysis is the conversion of cornstarch into glucose and then, through fermentation, into ethanol:

$$C_6H_{12}O_6(aq) \rightarrow 2\ CH_3CH_2OH(aq) + 2\ CO_2(g)$$

This exothermic reaction provides energy to the yeast cells whose biological processes drive fermentation.

Unlike grazing animals, humans cannot digest cellulose because we do not have microorganisms in our digestive tracts that have enzymes called cellulases, which catalyze hydrolysis of β-glycosidic bonds. The challenge of reproducing what the cellulose-eating bacteria do in a laboratory or on an industrial scale is the focus of an enormous research effort as scientists try to develop efficient procedures for converting cellulose to glucose and then to ethanol. This research has focused on more efficient, less energy-intensive ways to break apart cellulose fibers. In addition, scientists are genetically engineering microorganisms like those in cattle stomachs to increase the supply of cellulases.

If this research is successful, it will address several major problems associated with ethanol as a gasoline additive or alternative fuel, including the cost of production. Today it costs more to produce ethanol from cornstarch than to produce gasoline from crude oil. One reason for this is that most of the mass of a corn plant, or any plant, is cellulose, not starch. Ethanol production from cornstarch is also energy intensive: more than 70% of the energy contained in ethanol is expended in producing it; therefore, the net energy value of ethanol from corn is less than 30%. If ethanol could be produced from cellulose instead of starch, its net energy value could be as high as 80%. Finally, the use of edible cornstarch in fuel production has driven up the price of foods derived from corn, including livestock feed. The impacts of this inflation have been felt worldwide and have been particularly painful in developing countries. The use of agricultural land and consumption of increasingly scarce water resources for ethanol production raise further concerns.

CONCEPT TEST

Cellobiose is a disaccharide made from the degradation of cellulose. We cannot digest cellobiose. Which of the two structures in **Figure 20.38** represents a molecule of cellobiose?

Energy from Glucose

Glycolysis is the series of reactions by which most animal cells, including those in our bodies, metabolize glucose. The product of these reactions is pyruvate ions (**Figure 20.39**), the conjugate base of pyruvic acid. Pyruvate sits at a metabolic crossroads and can be converted into different products, depending on the type of cell in which it is generated, the enzymes present, and the availability of oxygen (**Figure 20.40**). In yeast cells growing under low-oxygen conditions, pyruvate is converted into ethanol and CO_2.

Another series of reactions, called the tricarboxylic acid (TCA) cycle or the *citrate cycle*, occurs in the presence of sufficient dissolved O_2 and is fundamental to the conversion of glucose to energy in humans and other animals. A key step prior to the TCA cycle occurs when pyruvate loses CO_2 and forms an acetyl group, which then combines with coenzyme A. The resulting product, acetyl-coenzyme A, is a reactant in many biosynthetic pathways, including the production of fats.

Glossary

carbohydrate

an organic molecule with the generic formula $C_x(H_2O)_y$.

monosaccharide

a single-sugar unit and the simplest carbohydrate.

polysaccharide

a polymer of monosaccharides.

glycosidic bond

a C–O–C bond between sugar molecules.

biomass

the total mass of organic matter in any given ecological system.

tricarboxylic acid (TCA) cycle

a series of reactions that continue the oxidation of pyruvate formed in glycolysis.

20.6 Lipids

Lipids, unlike carbohydrates and proteins, are *not* biopolymers. Lipids are best described by their physical properties, such as their hydrophobicity, rather than by any common structural subunit.

Because they are insoluble in water, they are ideal components of cell membranes, which separate the aqueous solutions within cells from the aqueous environments outside them. An important class of lipids called glycerides are esters formed between glycerol and long-chain fatty acids (**Figure 20.41**). The three –OH groups on glycerol allow for mono-, di-, and triglycerides, with the last group being the most abundant. Glycerides account for over 98% of the lipids in the fatty tissues of mammals. When we look at lipids, glycerides, and fatty acids, we will see examples of both kinds of stereoisomers we discussed in Section 20.2 (enantiomers and cis–trans isomers), frequently all in one molecule.

CONNECTION We introduced glycolysis in Section 17.9 as part of a discussion of the thermodynamics of coupled reactions.

Table 20.4 lists some common fatty acids. The most abundant ones have an even number of carbon atoms because the fatty acids are built *in vivo* from two-carbon subunits. Their biosynthesis begins with the conversion of pyruvate to acetyl-coenzyme A. Most fatty acids contain between 14 and 22 carbon atoms. Some have no carbon–carbon double or triple bonds and are called *saturated* because they have as much hydrogen in their structures as the carbon atoms can hold. Other fatty acids have carbon–carbon double or triple bonds, or both, and are called *unsaturated* because they do not have all the hydrogen their carbon atoms could possibly hold; they have the capacity to add hydrogen to those multiple bonds.

CONNECTION Alkanes are classified as saturated hydrocarbons (Section 6.9) because they contain the maximum ratio of hydrogen atoms to carbon atoms.

A type of fatty acid much in the news because of its alleged health benefits is the family of omega-3 fatty acids. These fatty acids are *polyunsaturated*, meaning that they have more than one carbon–carbon multiple bond. The name “omega-3” comes from the location of the first double bond counted from the methyl end of the chain, which is known as the omega (ω) end of the molecule. Omega-3 fatty acids are found in fish oils and some plant oils. α-Linolenic acid (see Table 20.4) is an omega-3 fatty acid.

TABLE 20.4 Names and Structural Formulas of Common Fatty Acids

Common Name (chemical name) (source)	Formula
SATURATED FATTY ACIDS	
Lauric acid (dodecanoic acid) (coconut oil)	$CH_3(CH_2)_{10}COOH$
Myristic acid (tetradecanoic acid) (nutmeg butter)	$CH_3(CH_2)_{12}COOH$
Palmitic acid (hexadecanoic acid) (animal and vegetable fats)	$CH_3(CH_2)_{14}COOH$
Stearic acid (octadecanoic acid) (animal and vegetable fats)	$CH_3(CH_2)_{16}COOH$
UNSATURATED FATTY ACIDS	
Oleic acid (*cis*-9-octadecenoic acid) (animal and vegetable fats)	$CH_3(CH_2)_7CH{=}CH(CH_2)_7COOH$
Linoleic acid (*cis,cis*-9,12-octadecadienoic acid) (linseed oil, cottonseed oil)	$CH_3(CH_2)_4CH{=}CHCH_2CH{=}CH(CH_2)_7COOH$
Linolenic acid (*cis,cis,cis*-9,12,15-octadecatrienoic acid) (linseed oil)	$CH_3CH_2CH{=}CHCH_2CH{=}CHCH_2CH{=}CH(CH_2)_7COOH$

SAMPLE EXERCISE 20.7 Identifying Triglycerides LO6

How many different triglycerides (including constitutional isomers and stereoisomers) can be made from glycerol combining with two different fatty acids (symbolized by the letters X and Y to simplify the structures) if each molecule of triglyceride contains at least one molecule of each fatty acid?

Collect and Organize We are asked to determine how many different triglycerides can be made from glycerol and two different fatty acids. A triglyceride contains three fatty acid units.

Analyze Each fatty acid may bond to one of three –OH groups in glycerol. Each triglyceride has at least one X and one Y residue, and two formulas are possible: X_2Y and Y_2X. Each of these formulas has two constitutional isomers, depending on whether the single fatty acid in the formula is bonded to the middle carbon or to one of the end carbon atoms. Finally, if a structure has an X on one end carbon atom and a Y on the other, then the middle carbon atom is a chiral center, which means that there are two enantiomeric forms of that compound.

Solve We can generate four different molecular structures by attaching X and Y in four different sequences to the glycerol –OH groups:

Structures (1) and (3) have chiral centers, so each of these isomers has two enantiomeric forms. As a result, there are a total of six different triglycerides possible.

Think About It Reacting three –OH groups in glycerol with two different fatty acids should allow for more than two products because there are two different sites in glycerol for reaction with the fatty acids even if we restrict each product to contain at least one of each fatty acid.

Practice Exercise How many different triglycerides can be made from glycerol and one molecule each of three different fatty acids? To simplify the drawings, use the letters A, B, and C to symbolize the different fatty acids.

Function and Metabolism of Lipids

Lipids are an important energy source in our diets, providing more energy per gram than carbohydrates or proteins. Fats are glycerides composed primarily of saturated fatty acids. They are solids at room temperature because the molecules can pack very tightly together. Oils are glycerides composed predominantly of unsaturated fatty acids and are liquids at room temperature because their chains have kinks in them caused by the double bonds, which prevent the chains from packing together as closely as the saturated chains can. Oils can be converted into solid, saturated glycerides by hydrogenation. In the hydrogenation of corn oil, for example, which is a mixture of mostly two unsaturated fatty acids (oleic and linoleic acids), hydrogen is added to convert some or all of the $–\mathrm{CH}\square\mathrm{CH}–$ subunits into $–\mathrm{CH_2}\square\mathrm{CH_2}–$ subunits. Hydrogenation converts the oil into a solid at room temperature that is whipped with skim milk, coloring agents, and vitamins to produce the food spread we know as margarine.

The consumption of certain fats is associated with increased risk of coronary heart disease. The Mediterranean diet, which reduces the amount of saturated fats, promotes the inclusion of greater amounts of vegetables and wild-caught fish and the use of olive oil in cooking. Olive oil is a liquid composed of glycerides containing more than 80% oleic acid, an unsaturated fatty acid. In contrast, animal fats such as butter and lard contain more saturated fats. Fish in particular are rich in omega-3 fatty acids such as linolenic acid. The origins of the cardiovascular benefits of omega-3 fatty acids aren’t fully understood, but one hypothesis suggests that they may be more readily metabolized than other glycerides. Sunflower oil also contains unsaturated fats but fewer omega-3 fatty acids and more omega-6 (ω-6) fatty acids such as linoleic acid. The latter do not appear to carry the same health benefits and may actually contribute to poor heart health. The difference between these two fatty acids is the absence of the double bond located between the third and fourth carbon in linoleic acid and other ω-6 fatty acids.

Another problem with hydrogenating vegetable oil arises when the oils are only partially hydrogenated. Partial hydrogenation alters the molecular structure around their remaining $\mathrm{C}\square\mathrm{C}$ double bonds, changing them from their natural cis isomers into trans isomers (**Figure 20.42**). Unsaturated trans fats such as elaidic acid tend to be solids at room temperature because their molecules pack together more uniformly than do molecules of cis unsaturated fatty acids. Consumption of trans fatty acids is associated with increased levels of cholesterol in the blood and other health risks.

CONCEPT TEST

The mixture of lipids in the legs of reindeer living close to the Arctic Circle changes as a function of distance from the hoof: the closer to the hoof, the higher the percentage of unsaturated fatty acids. Why would this be an advantage for these reindeer?

The lipids in some prepared foods have been modified to reduce their caloric content but still provide the taste, aroma, and “mouth feel” we associate with lipid-rich foods. The active sites of enzymes that break down natural lipids accommodate triglycerides formed from glycerol and fatty acids. However, chemically modified esters made from the same fatty acids, but attached to an alcohol other than glycerol, cannot be metabolized by these enzymes. Such molecules, if they have the appropriate physical properties and are nontoxic, can be incorporated into foods without adding any calories because they are not metabolized.

Olestra is one such product (**Figure 20.43**). It is an ester made from long-chain fatty acids and the carbohydrate sucrose. (Remember, sugars have –OH groups and are technically alcohols.) Each of the eight –OH groups in a sucrose molecule reacts with a molecule of fatty acid to make the ester in olestra. The resultant material is used to deep-fry potato chips. Any olestra that remains on the chip does not add calories because it cannot be processed by enzymes that recognize only fatty acid esters on a glycerol scaffold.

CONCEPT TEST

Olestra may be “calorie-free” as a food subject to metabolism in the living system, but how would it compare with a common triglyceride in terms of kilojoules of heat released per mole in a calorimeter experiment?

The enzymes that metabolize triglycerides hydrolyze the esters and release glycerol and the fatty acids that were bonded to them. Glycerol enters the metabolic pathway for glucose. The fatty acids are oxidized in a series of reactions known as β-oxidation—a process that removes two carbon atoms at a time. For example, stearic acid (the saturated C_{18} fatty acid) is transformed into a C_2 fragment and the C_{16} acid, palmitic acid. Palmitic acid yields another C_2 fragment and myristic acid, and so forth, until the fatty acid is completely degraded. Electrons released from this oxidative process eventually are donated to O_2. The energy released by this process powers metabolism.

Other Types of Lipids

Cells contain other types of lipids in addition to triglycerides. One type, phospholipids (**Figure 20.44a**), plays a key role in cell structure. A phospholipid molecule consists of a glycerol molecule bonded to two fatty acid chains and to one phosphate group that is also bonded to polar substituents. The presence of nonpolar fatty acid chains and a polar region in the same molecule makes phospholipids ideal for forming cell membranes. In an aqueous medium, phospholipids form a lipid bilayer, a double layer enclosing each cell and isolating its interior from the outside environment. The phospholipid molecules of the bilayer align so that the nonpolar groups interact with each other inside the membrane, whereas the polar groups interact with water molecules outside it (**Figure 20.44b**). Membranes exist both to isolate the contents of cells and to serve as the locus of communication between processes that occur within and outside the cells.

Cholesterol is a lipid and a key component in the structure of cell membranes. It is also a precursor of the bile acids that aid in digestion and of steroid hormones, which regulate the development of the sex organs and secondary sexual traits, stimulate the biosynthesis of proteins, and regulate the balance of electrolytes in the kidneys. Biosynthesis of cholesterol, like the biosynthesis of fatty acids, begins with the conversion of pyruvate to acetyl-coenzyme A (Figure 20.40). In a healthy person, synthesis and use of cholesterol are tightly regulated to prevent overaccumulation and consequent deposition of cholesterol in coronary arteries (**Figure 20.45**). We clearly need cholesterol, but deposition in the arteries can lead to serious coronary disease.

Glossary

lipid
a class of water-insoluble, oily organic compounds used as common structural materials in cells.

glyceride
a lipid consisting of esters formed between fatty acids and the alcohol glycerol.

fatty acid
a carboxylic acid with a long hydrocarbon chain that may be either saturated or unsaturated.

fat
a solid triglyceride containing primarily saturated fatty acids.

oil
a liquid triglyceride containing primarily unsaturated fatty acids.

phospholipid
a molecule of glycerol with two fatty acid chains and one polar group containing a phosphate; phospholipids are major constituents of cell membranes.

lipid bilayer
a double layer of molecules whose polar head groups interact with water molecules and whose nonpolar tails interact with each other.

20.7 Nucleotides and Nucleic Acids

Nucleic acids are our fourth class of biomolecules and third class of biopolymers. We focus on two types: deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). Even though nucleic acids make up only about 1% of a higher organism's mass, they control the metabolic activity of all its cells. The fraction is much higher in yeast and bacteria because those organisms are packed with ribosomes, which are themselves half RNA. DNA carries the genetic blueprint of an organism, and a variety of RNAs use that DNA blueprint to guide the production of proteins.

A nucleic acid is a polymer composed of monomeric units called nucleotides. Each nucleotide unit consists of three subunits: a five-carbon sugar, a phosphate group, and a nitrogen-containing base (**Figure 20.46**). The phosphate group in each nucleotide is attached to a carbon in the side chain of the sugar called the 59 carbon atom (the prime number refers to the position of the carbon atom in the sugar molecule). The nitrogen-containing base is attached to the 19 carbon atom in each sugar molecule. The sugar in Figure 20.46 is called *ribose*, which makes this a nucleotide in a strand of *ribo*nucleic acid (RNA). If the sugar were *deoxyribose* instead, there would be a H atom in place of the –OH group on the 29 carbon atom, and the nucleotide would be a building block of *deoxyribo*nucleic acid (DNA). Because of the ionized phosphate groups, both DNA and RNA are polyanions. Their anionic character is important because it enables them to interact with proteins but does not allow them to pass through cell membranes.

The nitrogen-containing base in Figure 20.46 is called adenine (A). Structural formulas of adenine and the other four bases in nucleic acids—cytosine (C), guanine (G), thymine (T), and uracil (U)—are shown in **Figure 20.47**. The point of attachment of the sugar–phosphate groups on each base is indicated by –R. In addition to the difference in their sugars, RNA and DNA also differ in one of the bases in their nucleotides: RNA contains A, C, G, and U, whereas DNA contains A, C, G, and T.

In a polymeric strand of nucleic acid, each phosphate is also linked to the 39 carbon atom in the sugar of the monomer that precedes it in the chain, as shown for a strand of DNA in **Figure 20.48**. Both DNA and RNA strands are synthesized in the cell from the 59 to the 39 direction (downward in Figure 20.48). The structures of DNA and RNA are frequently written using only the single-letter labels of their bases, beginning with the free phosphate group on the 59 end of the chain and reading toward the free 39 hydroxyl group at the other terminus.

When scientists first isolated DNA and began to analyze its composition, they made a pivotal observation about the abundance of the nitrogen-containing bases. A typical molecule of DNA consists of thousands of nucleotides, and the percentages of the four bases in different samples of DNA can vary over a wide range. However, the percentage of A in a sample always matches the percentage of T. Likewise, the percentage of C always matches that of G. This result makes sense if the bases are paired because a molecule of A can form two hydrogen bonds to a molecule of T, whereas a molecule of C can form three hydrogen bonds with a molecule of G. Therefore, A–T and G–C pairings maximize the number of hydrogen bonds possible (**Figure 20.49a**). More important, the base pairs assembled this way all have the same width and fit together in a regular structure.

The normal structure of DNA has two strands of nucleotides wrapped around each other in a form that is called a *double helix* (**Figure 20.49b**). The nucleotide backbone is on the outside of the spiraling strands, with hydrogen bonds between the complementary bases keeping the two strands together. Notice also that the base pairs are parallel to each other and perpendicular to the helical axis. The fidelity of this base-pairing—A always with T, and C always with G—gives DNA the ability to copy itself. If a pair of complementary strands is unzipped into two single strands, each strand provides a template on which a new complementary strand can be synthesized via the process called replication (**Figure 20.50**).

During replication, the two strands are separated by enzymes called helicases that break the hydrogen bonds between the two strands. This process forms a structure called the *replication fork*. The fork advances through the DNA as replication proceeds. One of the two resulting strands, the leading strand, is unzipped in the 3’–5’ direction, which allows the new complementary strand to be continuously synthesized in the 5’–3’ direction. The replication of the second strand, called the lagging strand, is more complicated. It proceeds in short fragments, which are then assembled into a continuous strand later in the process.

SAMPLE EXERCISE 20.8 Using Base Complementarity in DNA LO7

If 31.6% of the nucleotides in a sample of DNA are adenine, what are the percentages of cytosine, guanine, and thymine?

Collect, Organize, and Analyze We know how much adenine is in a DNA sample and need to calculate the rest of the nucleotide composition. We also know that nucleotides are paired so that A always pairs with T, and C always pairs with G. So, the percentage of T must equal the percentage of A in the sample, and the percentage of C must equal the percentage of G.

Solve If A $= 31.6\%$, then T $= 31.6\%$. This leaves $(100 - 2 \times 31.6) = 36.8\%$ left to be equally distributed between G and C. Therefore, G $=$ C $= 36.8/2 = 18.4\%$.

Think About It The percentages should total 100%, and they do.

Practice Exercise Indicate the sequence of the complementary strand on the double helix formed by each of the following sequences of nucleotides:

1. CGGTATCCGAT
2. TTAAGCCGCTAG

DNA's double-stranded structure is also the key to its ability to preserve genetic information. The two strands carry the same information, much like an old-fashioned photograph and its negative. Genetic information is duplicated every time a DNA molecule is replicated, a process that is essential whenever a cell divides into two new cells.

From DNA to New Proteins

Proteins are formed from amino acids in accordance with the *genetic code* contained in the base sequences of DNA strands. The bases A, T, G, and C are the alphabet in this code, and the "words" in the code are three-letter combinations of these four letters, with each word representing a particular amino acid or a signal to begin or end protein synthesis. Using four letters to write three-letter words means there are $4^3 = 64$ combinations possible, more than enough to encode the 20 amino acids found in cells. The function of the genetic code is to specify the protein's primary structure—the sequence of amino acids in proteins. The flow of genetic information goes from DNA to RNA to proteins, a sequence sometimes called the *central dogma of molecular biology*.

Protein synthesis begins with a process called transcription (**Figure 20.51a**), in which double-stranded DNA unwinds and its genetic information guides the synthesis of a single strand of a molecule called messenger RNA (mRNA). This strand of mRNA has the complementary base sequence of the original DNA. It carries the 3-letter words of that DNA, in the form of three-base sequences called codons (**Table 20.5**), from the nucleus of the cell into the cytoplasm, where the mRNA binds with a cellular structure called a ribosome. A sequence of A, C, G, and T in the original DNA is transcribed into the following sequence in mRNA:

DNA: . . . ACGT . . .

mRNA: . . . UGCA . . .

At the ribosome, the genetic information in the mRNA directs the synthesis of particular proteins in a process called translation. Another type of RNA, called transfer RNA (tRNA), plays a key role in translation. There are 20 different forms of tRNA in the cell, one for each amino acid. To see how tRNA works, look at **Figure 20.51b**. The first codon in this piece of an mRNA strand is AUG, which codes for the amino acid methionine (see Table 20.5). In the cytoplasm surrounding the ribosome, molecules of tRNA are reversibly bonded to molecules of every amino acid. The particular tRNA molecules that are bonded to methionine also contain the sequence UAC, the complement of AUG, at a site that allows the tRNA to interact with mRNA. As Figure 20.51b shows, the segment of mRNA with the AUG codon links with the complementary strand on the tRNA molecule bonded to methionine. In doing so, the methionine is put into a position to unlink from the tRNA and to be the first amino acid residue in the protein being synthesized.

TABLE 20.5 mRNA Codons

Amino Acid	Codons	Amino Acid	Codons
Ala	GCU, GCC, GCA, GCG	Leu	UUA, UUG, CUU, CUC, CUA, CUG
Arg	CGU, CGC, CGA, CGG, AGA, AGG	Lys	AAA, AAG
Asn	AAU, AAC	Met	AUG
Asp	GAU, GAC	Phe	UUU, UUC
Cys	UGU, UGC	Pro	CCU, CCC, CCA, CCG
Gln	CAA, CAG	Ser	UCU, UCC, UCA, UCG, AGU, AGC
Glu	GAA, GAG	Thr	ACU, ACC, ACA, ACG
Gly	GGU, GGC, GGA, GGG	Trp	UGG
His	CAU, CAC	Tyr	UAU, UAC
Ile	AUU, AUC, AUA	Val	GUU, GUC, GUA, GUG
Start	AUG	Stop	UAG, UGA, UAA

This sequence of events is repeated many times. In Figure 20.51b, the second codon, GUU, links up with a molecule of tRNA that has a CAA binding site and a molecule of valine in tow. In this way valine moves into position to become the next amino acid residue in the protein and to form a peptide bond with the N-terminal methionine. Valine is followed by threonine, which is followed by glycine, and so on, until a Stop codon finally signals the end of the translation process.

CONCEPT TEST

If a GUU codon attracts valine to the translation site, does a UUG codon do the same thing? Explain your answer.

Glossary

nucleic acid
: one of a family of large molecules; nucleic acids include deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), molecules that store the genetic blueprint of an organism and control the production of proteins.

nucleotide

a monomer unit from which nucleic acids are made.

replication

the process by which one double-stranded DNA forms two new DNA molecules, each one containing one strand from the original molecule and one new strand.

transcription

the process of copying the information in DNA to RNA.

messenger RNA (mRNA)

the form of RNA that carries the code for synthesizing proteins from DNA to the site of protein synthesis in a cell.

codon

a three-nucleotide sequence that codes for a specific amino acid.

translation

the process of assembling proteins from the information encoded in RNA.

transfer RNA (tRNA)

the form of the nucleic acid RNA that delivers amino acids, one at a time, to polypeptide chains being assembled by the ribosome–mRNA complex.

Learning Objectives

- Describe the structures of DNA and RNA and how they function together to translate genetic information **Return to Sample Exercise 20.8**

FIGURE 20.52 NASA scientists who analyzed the samples collected by the *Stardust* spacecraft were careful to avoid contaminating it with biological material from Earth. Doing so meant isolating themselves from the sample as they prepared it for analysis.

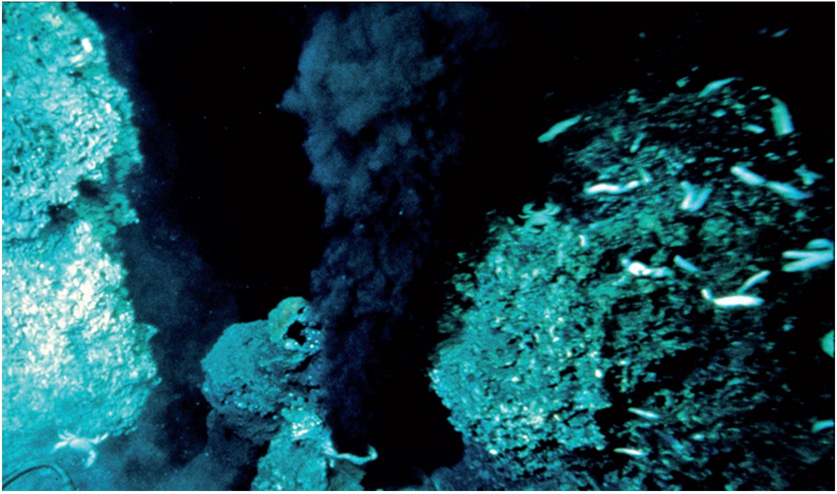

FIGURE 20.53 Black clouds of transition metal oxides and sulfides

flow into the sea through chimneys like this one at a deep-ocean hydrothermal vent. Some scientists believe that these particles may have guided and catalyzed the formation of the first self-replicating molecules on Earth.

20.8 From Biomolecules to Living Cells

We end Chapter 20 by addressing two fundamental questions about the major classes of biomolecules and their roles in sustaining life: (1) how were they first formed on prebiotic Earth, and (2) how did they assemble into living cells? Experiments conducted in the 1950s at the University of Chicago by chemistry professor Harold Urey (1893–1981) and his student Stanley Miller (1930–2007) showed that amino acids could form from H_2O, CH_4, NH_3, and H_2. Although the reactants the two scientists chose are now thought to be different from those present on early Earth, the result still stands: inorganic molecules can react to produce the organic molecules found in living systems.

CONNECTION The results of the Miller–Urey experiment were discussed in Section 3.1.

Evidence also exists that some biomolecules may have reached Earth from extraterrestrial origins. In 2006 the NASA spacecraft *Stardust* returned to Earth with samples collected from the tail of a comet that is believed to have formed at about the same time as the solar system (**Figure 20.52**). Subsequent analyses disclosed the presence of glycine in the comet. This was not the first experiment to detect amino acids in space. A class of meteorites called carbonaceous chondrites contain isovaline and other amino acids. Interestingly, most of the amino acids from meteorites, which are believed to be fragments of asteroids and comets, are l-enantiomers, the same form that dominates our biosphere. These observations have led to intriguing suggestions that l-amino acids are somehow “favored” and that life on Earth was “seeded” from elsewhere.

As we have seen in this chapter, RNA is needed to guide the assembly of amino acids into proteins. Since the 1990s, groups of scientists have explored the possibility that strands of RNA may have formed spontaneously from solutions of nucleotides in contact with clay minerals. The crystalline structures of these minerals provide three-dimensional templates that guide the self-assembly of the nucleotides into long strands of RNA. Pools of oligonucleotides made in this way usually contain many chains with random sequences, but some can actually catalyze their own replication. This ability to self-replicate is crucial to life, and the observation that molecules can speed up their own replication on a clay surface suggests that processes essential to the formation of living cells could have happened spontaneously. Much controversy still exists about these ideas, but the fact that RNA can act as both a source of information and a catalyst is part of the *RNA world hypothesis*. This hypothesis proposes that a world filled with life based on RNA predates the current world of life based on DNA and proteins. The capacity of RNA to both store information like DNA *and* act as a catalyst like an enzyme suggests that RNA alone could have supported cellular or precellular life-forms.

Current research is also testing the hypothesis that life on Earth may have evolved near deep-ocean hydrothermal vents. Entire ecosystems have been discovered at these locations since they were first explored in the 1970s. They are sustained by geothermal and chemical energy rather than energy from the Sun. It may be that life actually began in such environments, with hydrothermal energy driving reactions in which inorganic compounds such as carbon dioxide and hydrogen sulfide formed small organic compounds. As with the reactions on the surfaces of clay minerals, the synthesis reactions at hydrothermal vents may have been catalyzed and guided by reactants adsorbed on solid compounds such as FeS and MnO_2, which pour into the sea in dense black clouds near some vents (**Figure 20.53**). Among the known products of these reactions are acetate ions (CH_3COO^-). Acetate is a key intermediate in many biosynthetic pathways in living organisms. In modern bacteria, the systems that make acetate depend on a catalyst made of iron, nickel, and sulfur that has a structure much like that of particles produced by “black smokers” on the ocean floor.

To take the next step toward forming living cells, large biomolecules must have assembled themselves into even larger structures, such as membranes, that allow cells and structures within them to collect materials and retain them at concentrations different from those in the surrounding medium. Molecules in these assemblies are not necessarily connected by covalent bonds, but rather are held together by the intermolecular interactions we have discussed in this chapter.

SAMPLE EXERCISE 20.9 Integrating Concepts: Liquid Oil to Solid Fat

Imagine we have a research project to turn soybean oil into a solid for use in a butter substitute. We can accomplish this by hydrogenating the oil. Suppose we are working at the level of a small-scale industrial facility to test the feasibility of this process. A particular sample of soybean oil contains the following percentages by mass:

Composition of Soybean Oil

Fatty Acid	Percentage
Linoleic $(CH_3(CH_2)_4CH=CHCH_2CH=CH(CH_2)_7COOH)$	54
Oleic $CH_3(CH_2)_7CH=CH(CH_2)_7COOH$	24
Palmitic $CH_3(CH_2)_{14}COOH$	18

We need to hydrogenate 10.0 kg of soybean oil. Our source of hydrogen is the steam-reforming of methane:

$$H_2O(g) + CH_4(g) \rightarrow CO(g) + 3\ H_2(g)$$

1. What volume of methane at 20°C and 1.00 atm of pressure do we need to produce the amount of hydrogen required to completely hydrogenate 10.0 kg of soybean oil?
2. How many different compounds could result from the hydrogenation of a triglyceride that contained one of each of the three fatty acids in this study: linoleic acid, oleic acid, and

palmitic acid?

Collect and Organize We need to determine how much methane is needed in the steam-reforming reaction to supply enough hydrogen to react completely with the unsaturated fats present in a 10.0-kg sample of soybean oil. We know the oil contains three fatty acids: linoleic, oleic, and palmitic acid.

Analyze According to the structures in Table 20.4, palmitic acid is a saturated fatty acid, which means it does not react with hydrogen. Oleic acid has one C=C double bond per molecule and linoleic acid has two. Therefore, 1 mole of oleic acid combines with 1 mole of H_2, and 1 mole of linoleic acid combines with 2 moles of H_2. We can use the given weight percentages (24% oleic acid and 54% linoleic acid) to calculate that a 10.0-kg sample contains 2.4 kg of oleic acid and 5.4 kg of linoleic acid. The structures of these two fatty acids can be used to write their molecular formulas, and from those formulas we can calculate their molar masses. Converting these masses into grams and dividing these masses by the molar masses of the two fatty acids yields the moles of each in the sample. We then use the 1:1 and 1:2 hydrogenation reaction stoichiometries to calculate the number of moles of H_2 we need, and we use the stoichiometry of the steam-reforming reaction (1 mol CH_4:3 mol H_2) to convert moles of H_2 into moles of CH_4. The number of moles of CH_4 needed, along with the given temperature and pressure of the gas, can then be used in the ideal gas law equation to calculate the volume of CH_4 needed.

Solve

1. Using the condensed structure of the two unsaturated fatty acids to determine their molecular formulas and calculate their molar masses:

Fatty Acid	**Molecular Formula**	**Molar Mass (g/mol)**
Oleic acid	$C_{18}H_{34}O_2$	282.46
Linoleic acid	$C_{18}H_{32}O_2$	280.45

   Converting the masses of these fatty acids in the sample into moles:

$$2.4\ \cancel{\text{kg}}\ \text{oleic acid} \times \frac{1000\ \cancel{\text{g}}}{1\ \cancel{\text{kg}}} \times \frac{1\ \text{mol}}{282.46\ \cancel{\text{g}}} = 8.5\ \text{mol oleic acid}$$

$$5.4\ \cancel{\text{kg}}\ \text{linoleic acid} \times \frac{1000\ \cancel{\text{g}}}{1\ \cancel{\text{kg}}} \times \frac{1\ \text{mol}}{280.45\ \cancel{\text{g}}} = 19\ \text{mol linoleic acid}$$

Calculating the total moles of CH_4 needed:

$$8.5\ \cancel{\text{mol oleic acid}} \times \frac{1\ \cancel{\text{mol H}_2}}{1\ \cancel{\text{mol oleic acid}}} \times \frac{1\ \text{mol CH}_4}{3\ \cancel{\text{mol H}_2}} = 2.8\ \text{mol CH}_4$$

$$19\ \cancel{\text{mol linoleic acid}} \times \frac{2\ \cancel{\text{mol H}_2}}{1\ \cancel{\text{mol linoleic acid}}} \times \frac{1\ \text{mol CH}_4}{3\ \cancel{\text{mol H}_2}} = 13\ \text{mol CH}_4$$

Total moles of $CH_4 = 2.8 + 13 = 15.8$ mol CH_4.

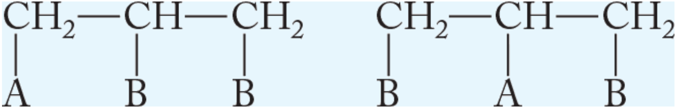
$$PV = nRT$$

$$(1.00\ \text{atm})V = 15.8\ \text{mol} \times \frac{0.08206\ \text{L} \cdot \text{atm}}{\text{K} \cdot \text{mol}} \times 293\ \text{K}$$

$$V = \frac{15.8\ \cancel{\text{mol}} \times \dfrac{0.08206\ \text{L} \cdot \cancel{\text{atm}}}{\cancel{\text{K}} \cdot \cancel{\text{mol}}} \times 293\ \cancel{\text{K}}}{1.00\ \cancel{\text{atm}}} = 3.80 \times 10^2\ \text{L}$$

Reported to the correct number of significant figures, the reaction requires 3.8×10^2 L of methane.

2. If a single triglyceride contained one of each of the saturated fatty acids that result from this process, it would contain one unit of palmitic acid, which was saturated in the original material and unchanged by the hydrogenation, and two units of stearic acid, the C_{18} saturated fatty acid that is the product of hydrogenation of oleic acid and linoleic acid. We can represent this symbolically, letting A = palmitic acid and B = stearic acid. Two constitutional isomers of triglycerides result:



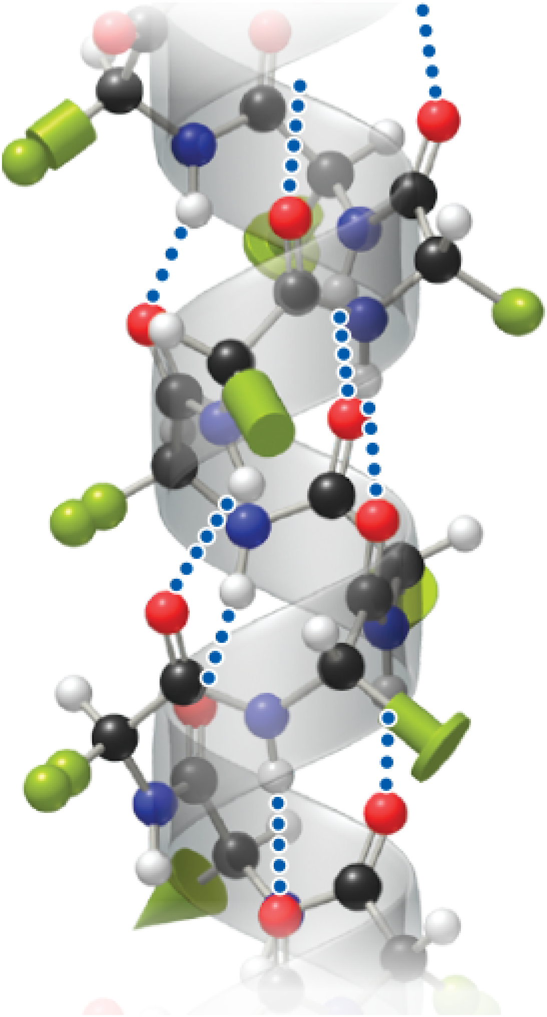
$$\underset{\mid \atop \text{A}}{\text{CH}_2}—\underset{\mid \atop \text{B}}{\text{CH}}—\underset{\mid \atop \text{B}}{\text{CH}_2} \qquad \underset{\mid \atop \text{B}}{\text{CH}_2}—\underset{\mid \atop \text{A}}{\text{CH}}—\underset{\mid \atop \text{B}}{\text{CH}_2}$$

The structure on the left also has two enantiomeric forms because the carbon in the –CH– unit is a chiral center. Therefore, the products are two constitutional isomers, one of which also has two enantiomers (stereoisomers), for a total of three different triglycerides.

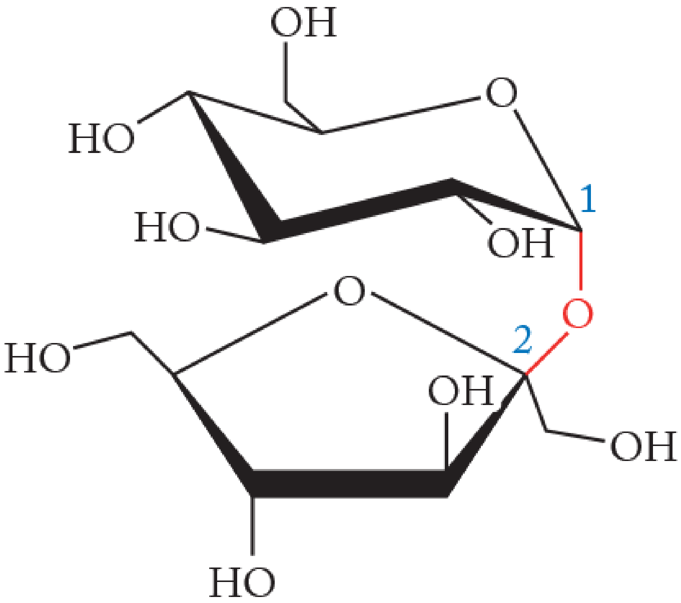
Think About It The number of moles of methane required seems reasonable according to our estimate. Actual soybean oil probably has several different triglycerides in it that are a combination of saturated and unsaturated fatty acid components, resulting in the observed composition by weight. Natural oils can be quite complex mixtures.

SUMMARY

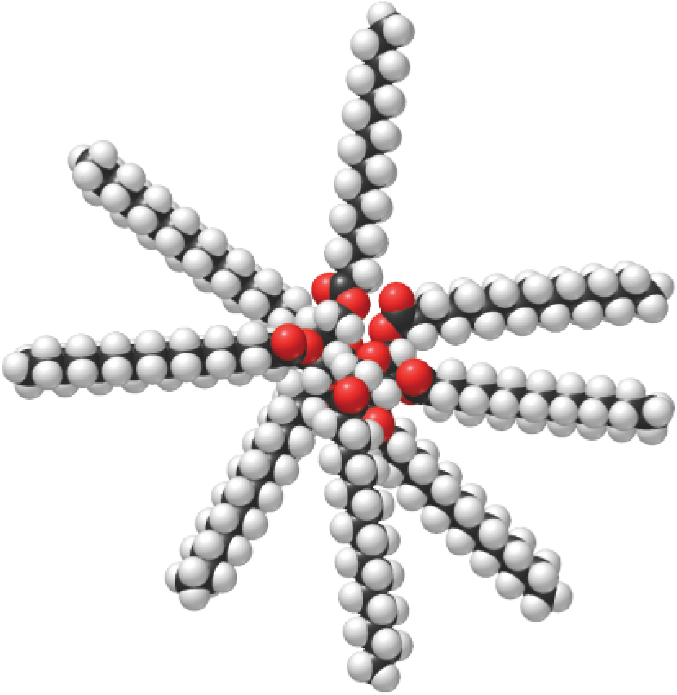
- LO1 Isomers may be constitutional isomers, which are distinguished by the connectivity of their atoms, or they may be stereoisomers, which are distinguished by their arrangement in three-dimensional space. Many biologically important molecules are chiral, resulting in optical isomers, a type of stereoisomer. (Section 20.2)
- LO2 The acid–base properties of amino acids (including their pK_a and pI values) are important for structural and functional reasons. We can define these properties by using data derived from titrations. (Sections 20.2 and 20.3)
- LO3 The proteins and peptides in the human body are composed of 20 α-amino acids covalently linked by peptide bonds. The sequence of amino acids in peptide and protein chains matters in determining their properties. (Section 20.3)



- LO4 The structure of a protein is crucial to its function. It is defined by the sequence of amino acids in the chain (its primary structure), the geometric pattern that segments of a chain adopt (its secondary structure), the overall three-dimensional shape of the protein (its tertiary structure), and any larger structure formed when two or more proteins interact and function as a single unit (its quaternary structure). (Section 20.4)



- LO5 Carbohydrates are produced from CO_2 and H_2O, and organisms derive energy from glycolysis and the tricarboxylic acid (TCA) cycle, the reaction pathways by which glucose is oxidized back to CO_2 and H_2O. Monosaccharides are joined through glycosidic bonds into polysaccharides such as starch for energy storage and cellulose for structural support in plants. (Section 20.5)



Olestra

- LO6 Lipids include important families of molecules, including glycerides, fats, and oils. Some lipids are a major source of energy in our diet, and others play key roles in cell structure. The physical properties of oils (liquids) and fats (solids) reflect differences in the amounts of unsaturated versus saturated fatty acids. (Section 20.6)

- LO7 The nucleic acids DNA and RNA contain an organism’s genetic information and control protein synthesis through transcription and translation. Living cells may have formed as a result of chemical reactions in which inorganic molecules combined to form small organic molecules such as amino acids and nucleotides. (Section 20.7)

PARTICULATE PREVIEW WRAP-UP

Glutamic acid contains an amine (R–NH_2) functional group and two carboxylic acid (R–COOH) functional groups. At physiological pH (~7.4), the carboxylic acid groups are deprotonated (R–COO^-), but the amine is still protonated (R–NH_3^+), meaning that the glutamic acid molecule has an overall negative charge at physiological pH.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts and Equations	Sample Exercises
Recognizing constitutional isomers	Establish that the compounds have the same molecular formula, and if they do, look for different arrangements of bonds.	**20.1**
Identifying chiral molecules	Identify carbon atoms with four different groups attached.	**20.2, 20.3**
Interpreting acid–base titration curves of amino acids	All amino acids have at least two ionizable H atoms, one each from –COOH and –NH_3^+. Side-chain carboxylic acid and amine groups may also impart acidic and basic strength to amino acids.	**20.4**
Drawing and naming peptides	Connect the α-amine of one amino acid to the α-carboxylic acid of another with a peptide bond. Starting with the free amine (N-) terminus on the left, name each amino acid residue by changing the ending of the name of the parent amino acid to *-yl* in all but the last (C-terminal) amino acid.	**20.5**
Determining the amino acid sequence of a small peptide	Merge fragments that overlap to reveal the sequence of the peptide.	**20.6**
Identifying triglycerides	The –COOH groups of fatty acids react with the –OH groups in glycerol to form triglycerides and water.	**20.7**
Using base complementarity in DNA	Identify the base pairs: A pairs with T, and G pairs with C. The percentage of T should equal the percentage of A, and the percentage of C should equal the percentage of G.	**20.8**

VISUAL PROBLEMS

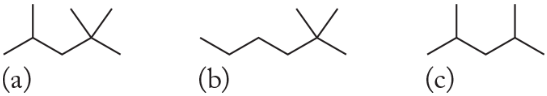
P20.29

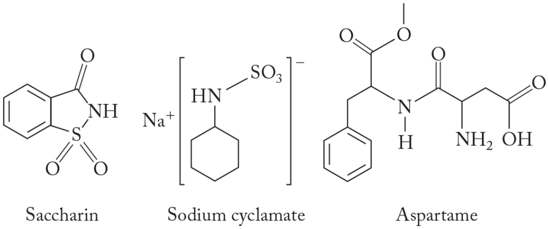
Which, if any, of the molecules shown in Figure P20.30 contains a chiral center?



(a) (b) (c)

FIGURE P20.30

Artificial Sweeteners Artificial sweeteners are fundamental to the diet food industry. Figure P20.31 shows three artificial sweeteners that have been used in food. Saccharin is the oldest, dating to 1879. Cyclamates were banned in the United States in 1969 after research suggested they led to tumors. Aspartame may be more familiar to you under the name NutraSweet. Each of these sweeteners contains between zero and two chiral carbon atoms. Circle the chiral center(s) in each compound.



Saccharin Sodium cyclamate Aspartame

FIGURE P20.31

Smoother Skin Researchers at Tufts University have found that a fungal toxin called cytochalasin B (Figure P20.32) can restore elasticity and shrink skin cells in mice without causing any ill effects. Mice treated with a cream containing this molecule had smoother skin than mice treated with a plain cream. Circle the chiral centers in the molecule.

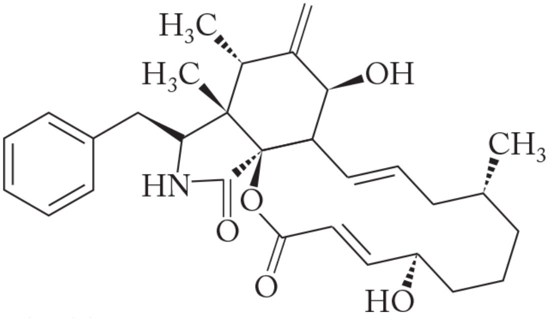


FIGURE P20.32

Lowering Cholesterol Statins such as rosuvastatin calcium (Figure P20.33) are the most widely prescribed class of drugs for lowering concentrations of cholesterol and other lipids in the blood.

1. Is the anion in the figure chiral? If so, how many chiral centers does it have?
2. Are any other kinds of stereoisomerism possible for the anion?

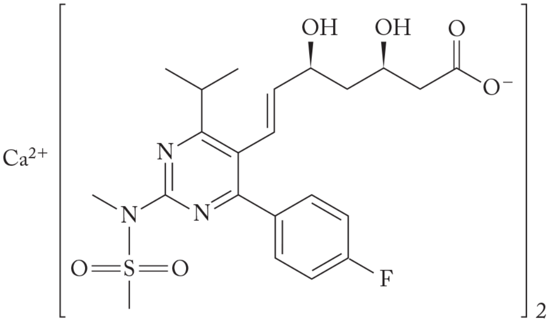

FIGURE P20.33

Preventing Blood Clots In 2009 Plavix (Figure P20.34) was the second-highest-selling pharmaceutical in the world. It is prescribed to prevent blood clots in heart attack and stroke patients.

1. Is Plavix optically active? If so, identify the chiral center(s) in the structure.
2. Plavix contains an ester group. Identify it. Draw the carboxylic acid and the alcohol you could react together to make Plavix.

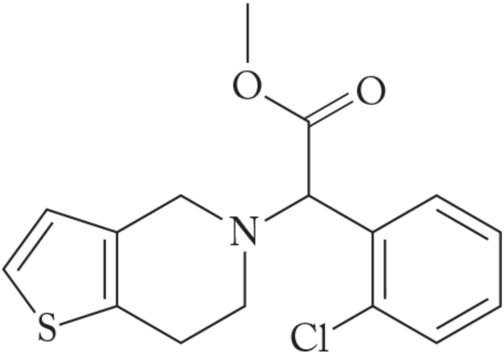

FIGURE P20.34

The Composition of Proteins

Concept Review

In living cells, amino acids combine to make peptides and proteins. Are these processes accompanied by increases or decreases in entropy of the reaction system?

What is the difference between a peptide bond and an amide bond?

Into the Wild Jon Krakauer, the author of *Into the Wild,* postulated that the main character in the book died in the Alaskan wilderness because he accidentally ate seeds containing a toxin called β-ODAP (Figure P20.37). This substance is a neurotoxin; its mechanism of action is not fully understood, but it is referred to as a “glutamic acid mimic.” Compare the structure of β-ODAP to that of glutamic acid and describe the similarities between the two molecules.

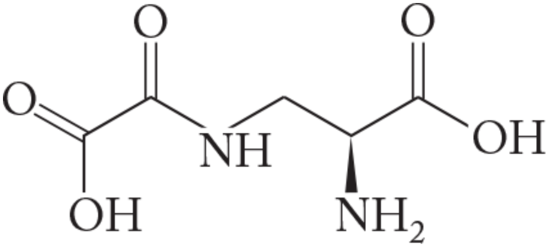

FIGURE P20.37

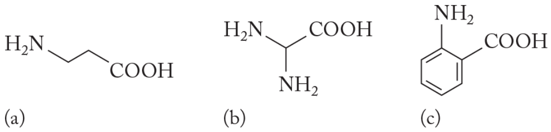
Metabolic Disease in Dogs Cystinuria is a metabolic disease that occurs in some breeds of dogs. It is characterized by the presence of kidney stones made of cystine, a dimer formed when two cysteine residues covalently link through an –S□S– bond (see Figure 20.28).

1. Draw the structure of the dipeptide Cys-Cys.
2. Is cystine a dipeptide? Why or why not?

Meteorites contain more l-amino acids, which are the forms that make up the proteins in our bodies, than d-amino acids. What do the prefixes l- and d- mean?

Do any of the amino acids in Table 20.2 have more than one chiral carbon atom per molecule?

Which of the compounds in Figure P20.41 is/are *not* an α-amino acid?



(a) (b) (c)

FIGURE P20.41

Which of the compounds in Figure P20.42 is/are α-amino acids?

FIGURE P20.42

Why do most amino acids exist in the zwitterionic form at physiological pH (~7.4)?

Draw the condensed structural formulas of the amino acid tyrosine that you would expect to predominate in:

1. strongly acidic aqueous solution
2. strongly basic aqueous solution
3. an aqueous solution in which pH = p*I*

Protein Structure and Function

Concept Review

Which type of intermolecular interaction plays the dominant role in holding strands of proteins together in β-pleated sheets and stabilizing α helices?

Which level of protein structure is associated with ion–ion interactions and disulfide bond formation?

When protein strands fold back on themselves in forming stable tertiary structures, lysine residues are often paired up with glutamic acid residues. Why?

Ion–ion interactions are particularly effective at stabilizing tertiary structures of proteins. Suggest a pair of amino acid residues that would be attracted to each other via ion–ion interactions at pH = 7.4.

Problems

Draw structures and name all possible dipeptides produced from condensation reactions of the following l-amino acids:

1. alanine + isoleucine
2. serine + tyrosine
3. valine + phenylalanine

Draw structures of the peptides produced from condensation reactions of the following l-amino acids. Assume the amino acids bond in the order given.

1. glycine + tyrosine + aspartic acid
2. serine + threonine + leucine
3. asparagine + lysine + histidine

Identify the amino acids in the dipeptides shown in Figure P20.51.

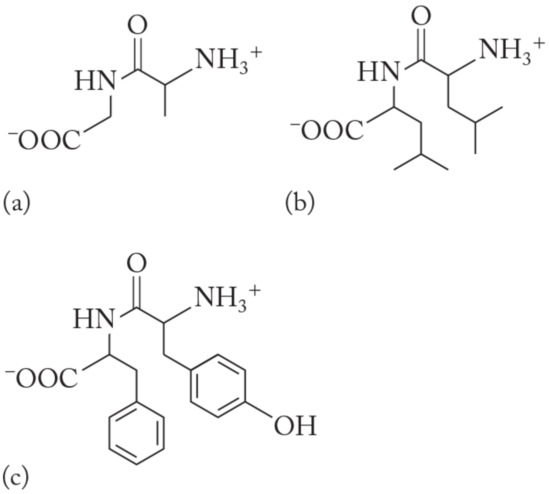

FIGURE P20.51

Identify the amino acids in the tripeptides in Figure P20.52.

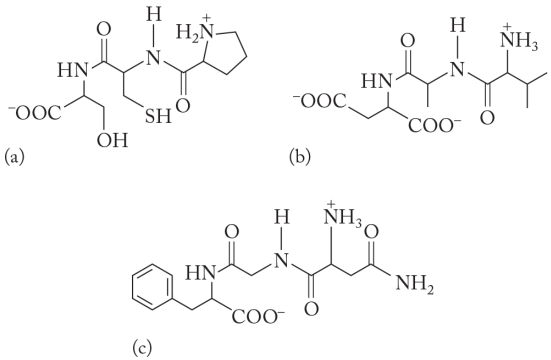

FIGURE P20.52

Identify the missing product in the metabolic reaction shown in Figure P20.53.

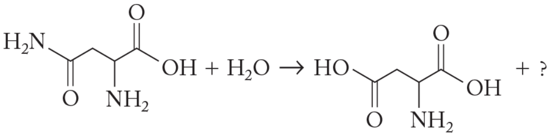

FIGURE P20.53

Five carbons are single bonded to each other in straight. The first carbon at the top is single bonded to hydrogen at the left and double-bonded to oxygen at the right. The last carbon is single bonded to C H 2 O H. The second carbon is single bonded to hydrogen at the left and O H at the right. The third and fourth carbon is single bonded to H O at the left and hydrogen at the right. The fifth carbon is single bonded to hydrogen at the left and O H at the right.

The molecular formula for glycine is $C_2H_5NO_2$. What is the molecular formula of the linear peptide formed when ten glycine molecules are linked together in peptide bonds?

Carbohydrates

Concept Review

What are the structural differences between starch and cellulose?

Why is the discovery of enzymes that catalyze cellulose hydrolysis a worthwhile objective?

Is the fuel value (see Section 6.9) of glucose in the linear form the same as that in the cyclic form?

Without doing the actual calculation, estimate the fuel values of glucose and starch by considering average bond energies. Do you predict the fuel values of the two substances to be the same or different?

The second step in glycolysis converts glucose-6-phosphate into fructose-6-phosphate. Can you think of a reason why ΔG° for this reaction is close to zero?

Which of the following statements are correct about glycosidic bonds in carbohydrates?

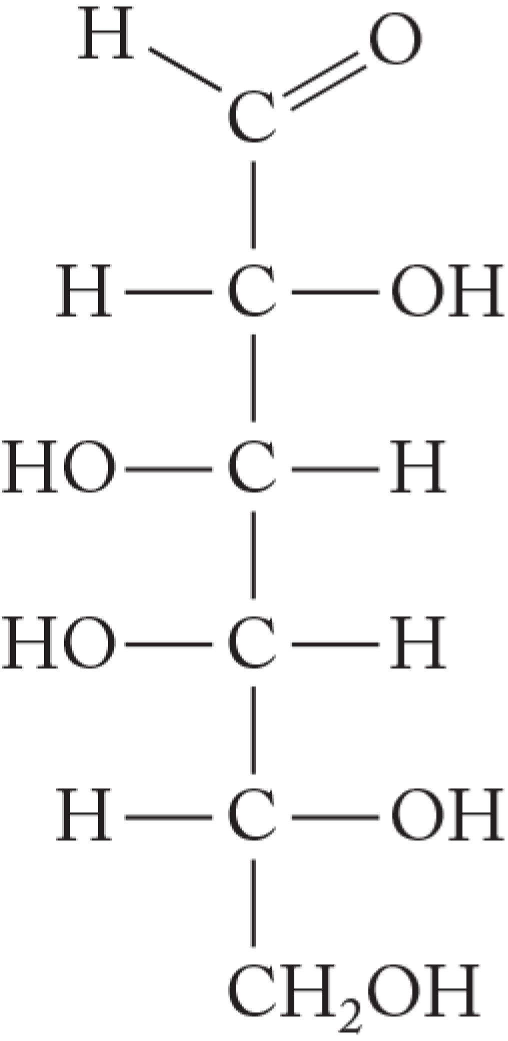
1. The glycosidic bond in maltose is hydrolyzed by people who are lactose intolerant.
2. A glycosidic bond links glucose and fructose together to form sucrose.
3. A glycosidic bond is an ether linkage, but all ether linkages are not glycosidic bonds.

How do we calculate the overall free-energy change of a process consisting of two steps?

During glycolysis a monosaccharide is converted to pyruvate. Do you think this process produces an increase or decrease in the entropy of the system? Explain your answer.

Problems

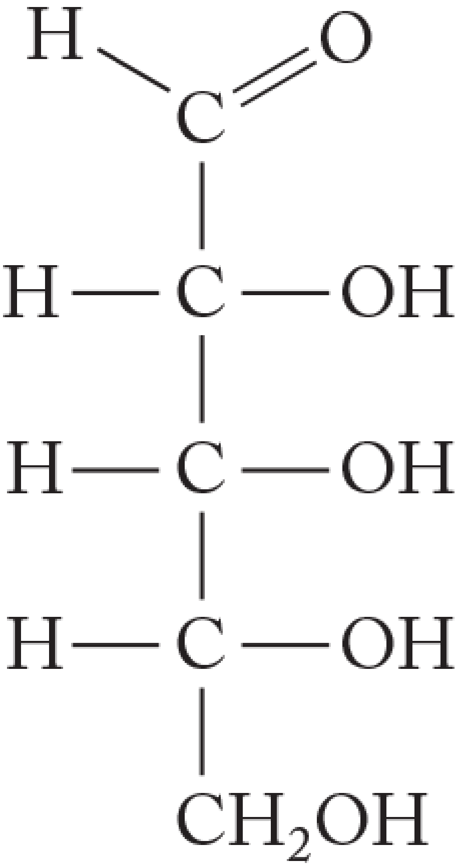
Describe the similarities and differences in the structures of the α and β isomers formed when galactose (Figure P20.63) forms a six-membered ring.



Galactose

FIGURE P20.63

Describe the similarities and differences in the structures of the α and β isomers formed when ribose (Figure P20.64) forms a five-membered ring.



Ribose

FIGURE P20.64

Which, if any, of the structures in Figure P20.65 are β isomers of a monosaccharide?

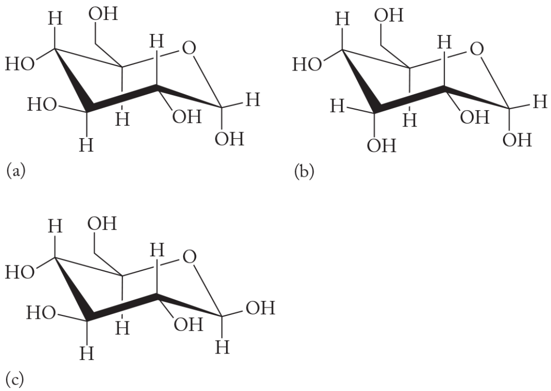


FIGURE P20.65

Which, if any, of the structures in Figure P20.66 are α isomers?

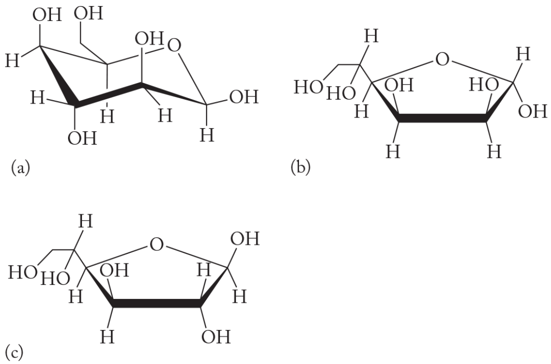

FIGURE P20.66

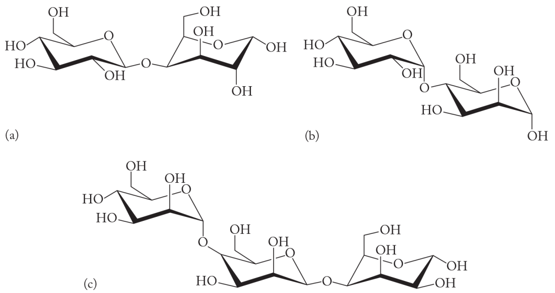
Which of the saccharides in Figure P20.67 is digestible by humans?



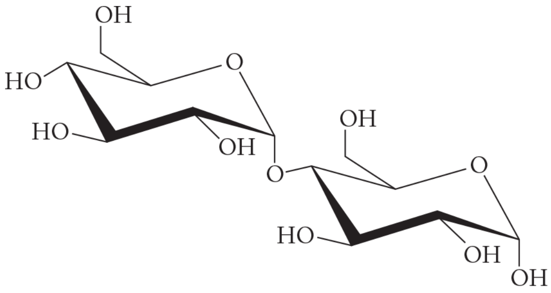
P20.67 **FIGURE**

For any of the disaccharides in Problem 20.67 that are not digestible by humans, draw an isomer that would be digested.

The structure of the disaccharide maltose appears in Figure P20.69. Hydrolysis of 1 mole of maltose ($\Delta G^\circ_f = -2246.6$ kJ/mol) produces 2 moles of glucose ($\Delta G^\circ_f = -1274.4$ kJ/mol):

Maltose + H_2O → 2 glucose

If the value of ΔG°_f for water is -285.8 kJ/mol, what is the change in free energy of the hydrolysis reaction?



Maltose

P20.69 **FIGURE**

If the maltose in Problem 20.69 were replaced by another disaccharide, would you expect the free-energy change for the hydrolysis to be exactly the same or just similar in value? Explain your answer.

Lipids

Concept Review

What is the difference between a saturated and an unsaturated fatty acid?

Which of the following lipids would have the lowest energy value in terms of human nutrition: olive oil, margarine, olestra, or butter? Explain your answer.

Dining in the Arctic Some Arctic explorers have eaten sticks of butter on their explorations. Give a nutritional reason for this unusual cuisine.

If you agitate a mixture of fatty acids in water, an emulsion forms, in which spherical structures called micelles are dispersed throughout the water. Micelles form when the carboxylic acid groups of the fatty acids face the solvent and their hydrocarbon tails are directed toward the inside of the sphere.

1. Explain why these structures form with this orientation.
2. It is sometimes possible to “break” an emulsion, destroying the micelles by adding a strong acid to the mixture. Why would this destroy the micelles?
3. One can also sometimes break an emulsion by adding salt (NaCl) to the mixture. Why would this destroy the micelles?

Do triglycerides have a chiral center? Explain your answer.

Using your knowledge of molecular geometry and intermolecular forces, why might polyunsaturated triglycerides be more likely to be liquid than saturated triglycerides?

Problems

Oleic acid and α-linolenic acid (Table 20.4) are both unsaturated fats and are liquids at room temperature. They can be converted into solid saturated fats by hydrogenation.

1. Which would consume more hydrogen: 1.0 kg of oleic acid or 0.50 kg of α-linolenic acid?
2. Could you distinguish between the two fatty acids by determining the identity of their hydrogenation products? Explain your answer.

For each of the pairs of fatty acids in Figure P20.78, indicate whether they are constitutional isomers, stereoisomers, or unrelated compounds.

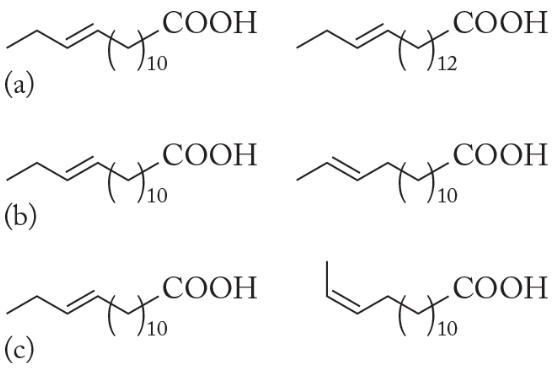


FIGURE P20.78

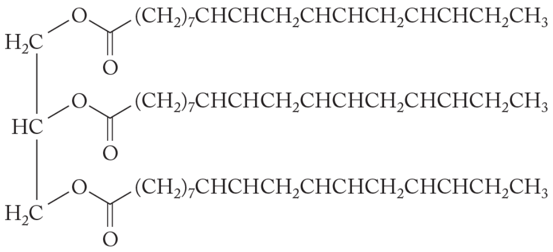
Draw the structures of the three fats formed by reaction of glycerol with (a) octanoic acid ($C_7H_{15}COOH$), (b) decanoic acid ($C_9H_{19}COOH$), and (c) dodecanoic acid ($C_{11}H_{23}COOH$).

Oil-Based Paints Oil-based paints contain linseed oil, a triglyceride formed by esterification of glycerol with linolenic acid (Figure P20.80).

1. Draw the line structure of linolenic acid.
2. Are the double bonds in linolenic acid conjugated?



Linseed oil

FIGURE

P20.80

Nucleotides and Nucleic Acids

Concept Review

What are the three kinds of molecular subunits in DNA? Which two form the “backbone” of DNA strands?

Explain how DNA and RNA differ (a) in molecular composition, (b) in structure, and (c) in function.

What kind of intermolecular force holds together the strands of DNA in the double-helix configuration?

DNA is a highly charged polyanion. If a solution of DNA is heated, the DNA will separate into individual strands, a process called denaturation. If the salt concentration of the solution is increased, the temperature at which denaturation occurs increases. Suggest a reason why.

Problems

Draw the structure of adenosine 59-monophosphate, one of the four ribonucleotides in a strand of RNA.

Draw the structure of deoxythymidine 59-monophosphate, one of the four nucleotides in a strand of DNA.

In the replication of DNA, a segment of an original strand has the sequence T-C-G.

1. What is the sequence of the opposite strand?
2. Draw the structure of this section of the double helix, clearly showing all hydrogen bonds.

If the sequence of one strand of DNA is 59 ATTGCCA 39, what is the sequence (in the 59 to 39 direction) of the other strand?

Additional Problems

Salsa Salsa has antibacterial properties because it contains dodecenal (Figure P20.89), a compound found in the cilantro used to make salsa.

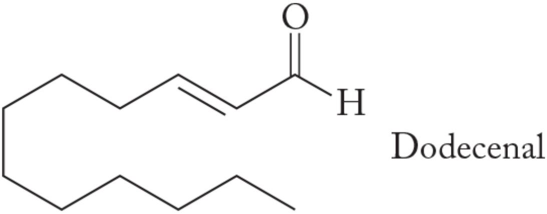


FIGURE P20.89

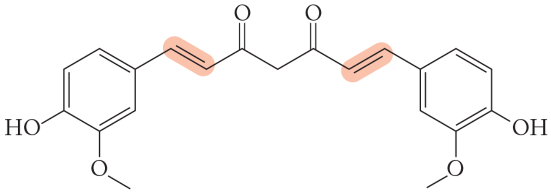
1. How many carbon atoms are in dodecenal?
2. What functional groups are present in dodecenal?
3. What types of isomerism are possible in dodecenal?

Turmeric Turmeric is commonly used as a spice in Indian and Southeast Asian dishes. Turmeric contains a high concentration of curcumin (Figure P20.90), a potential anticancer drug and a possible treatment for cystic fibrosis.

1. Are the substituents on the C□C double bonds highlighted in red in cis or trans configurations?
2. Draw two other stereoisomers of this compound.

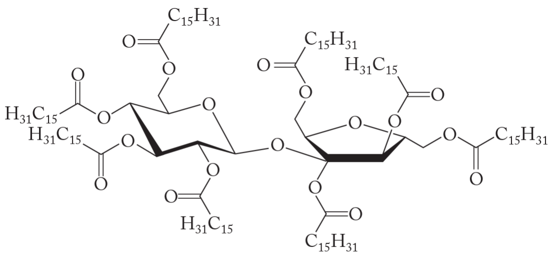


Curcumin

FIGURE P20.90

Fat Substitutes Olestra is a calorie-free fat substitute. The core of the olestra molecule (Figure P20.91) is a disaccharide that has reacted with a carboxylic acid; this results in the conversion of hydroxyl groups on the disaccharide into the depicted structure.

1. What is the name of the disaccharide core of the olestra molecule?
2. What functional group has replaced the hydroxyl groups on the disaccharide?
3. What is the formula of the carboxylic acid used to make olestra?



Olestra

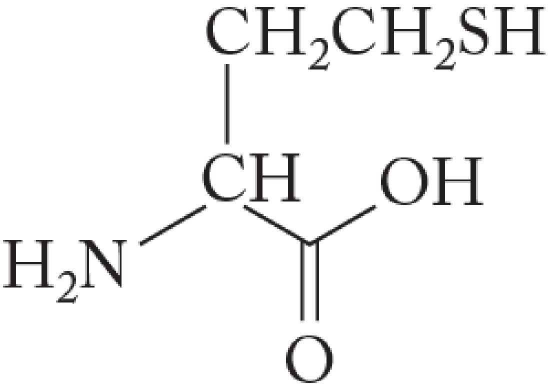
FIGURE P20.91

When scientists at the University of California, Santa Cruz, directed UV radiation at an ice crystal containing methanol, ammonia, and hydrogen cyanide, three amino acids (glycine, alanine, and serine) were detected among the products of photochemical reactions. The formation of these amino acids suggests that they may also be synthesized in comets approaching the Sun (and Earth). Determine the standard free-energy change of the hypothetical formation of glycine in comets, using standard free energies of formation of the reactants and products in this reaction [ΔG°_f for HCN(g) is +125 kJ/mol and for solid glycine is − 368.4 kJ/mol; other ΔG°_f values are in Appendix 4].

$$CH_3OH(\ell) + HCN(g) + H_2O(\ell) \rightarrow H_2NCH_2COOH(s) + H_2(g)$$

Homocysteine (Figure P20.93) is formed during the metabolism of amino acids. A mutation in some people’s genes leads to high concentrations of homocysteine in the blood and a consequent increase in their risk of heart disease and incidence of bone fractures in old age.

1. What is the structural difference between homocysteine and cysteine?
2. Cysteine is a chiral compound. Is homocysteine chiral?



Homocysteine

FIGURE P20.93

Amino Acids in Comets Some scientists believe life on Earth can be traced to amino acids and other molecules brought to Earth by comets and meteorites. In 2004, a new class of amino acids called diamino acids (Figure P20.94) were found in the Murchison meteorite.

1. Which of these diamino acids is/are *not* an α-amino acid?
2. Which of these diamino acids is/are chiral?

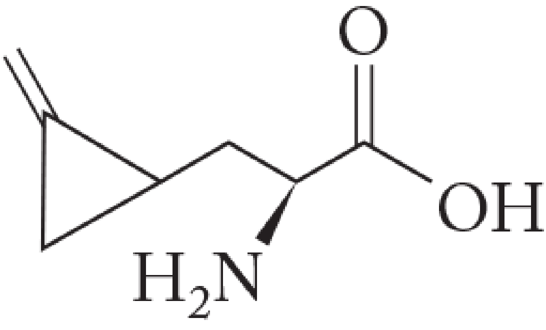
Jamaican Fruit Ackee, the national fruit of Jamaica, is a staple in many Jamaican diets. Unfortunately, a potentially fatal sickness known as Jamaican vomiting disease is caused by the consumption of unripe ackee fruit, which contains the amino acid hypoglycin (Figure P20.95). Is hypoglycin an α-amino acid?



Hypoglycin

FIGURE

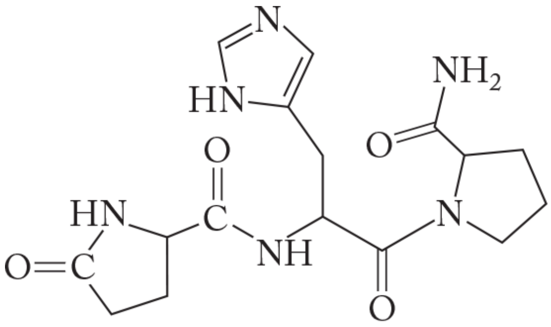
P20.95

In Section 20.2 we discussed the rotation of a beam of plane-polarized light when it passes through a solution containing an optically active molecule. Equimolar solutions of α-glucose and β-glucose rotate plane-polarized light by +112° and +18.7°, respectively. If these two solutions are then mixed and allowed to reach equilibrium, the solution then rotates the polarized light by +53.4°. Calculate the percent glucose in the α and β forms in this solution.

Amino Acid Supplements Supplements containing BCAAs (branched-chain amino acids) have been studied for their effects on athletic performance (in terms of the perception of exertion) and mental fatigue. Current research does not support that they have either of these effects, but they are used medically to slow muscle wasting in bedridden patients. BCAAs are amino acids having hydrocarbon side chains with a branch, a carbon atom bound to more than two other carbon atoms. Consult Table 20.2 and draw the structures of the BCAAs among the common amino acids.

In response to specific neural messages, the human hypothalamus may secrete several polypeptides, including the tripeptide shown in Figure P20.98.

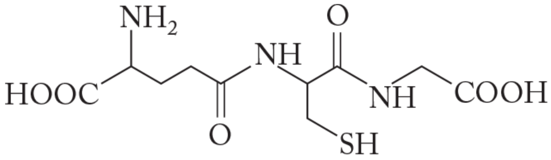
1. Sketch the structures of the three amino acids that combine to make this tripeptide.
2. Which, if any, of the constituent amino acids are among the 20 α-amino acids in proteins?



Thyrotropin-releasing factor

FIGURE P20.98

Glutathione (Figure P20.99) is an essential molecule in the human body. It acts as an activator for enzymes and protects lipids from oxidation. Which three amino acids combine to make glutathione?



Glutathione

FIGURE P20.99

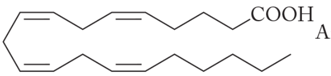
Three amino acids—glutamic acid, arginine, and tryptophan—are dissolved in a gel that is buffered at a pH of 5.9. Two electrodes are placed in the gel and an electric current is applied.

1. Toward which electrode does each amino acid migrate?
2. Draw the forms of each amino acid present in the gel at a pH of 5.9.

Without doing the actual calculation, estimate the fuel values of leucine and isoleucine by considering average bond energies. Should the fuel values of the two amino acids be the same? Actual calorimetric measurements show that isoleucine has a lower fuel value than leucine. Explain why.

Sucralose (see Figure P20.9) is about 600 times sweeter than sucrose (see Figure 20.36). All substances that taste sweet have functional groups that form hydrogen bonds with “sweetness” receptor sites on the tongue. What does the difference in sweetness between sucralose and sucrose tell you about additional intermolecular interactions between sweet compounds and receptor sites that contribute to their sweet taste?

Inflammation-Causing Molecules Prostaglandins, naturally occurring compounds in our bodies that cause inflammation and other physiological responses, are formed from arachidonic acid, an unsaturated hydrocarbon containing four C□C double bonds and a carboxylic acid functional group. The stereoisomer containing all cis double bonds is shown in Figure P20.103. How many stereoisomers other than this one are possible? Draw the isomer containing all trans double bonds.



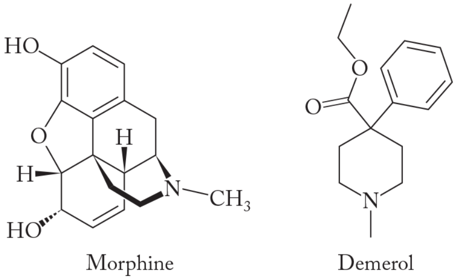
Arachidonic acid

FIGURE P20.103

A newspaper article contains the wording, “Made primarily by the liver, cholesterol begins with tiny pieces of sugar . . .” What does this statement mean at the molecular level?

Which amino acids are zwitterions at physiological pH (~7.4), but exist as neutral molecules?

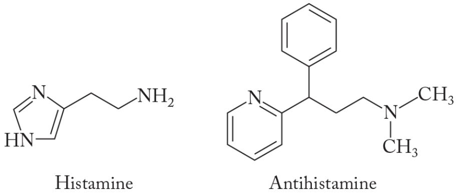
Opioids The structures of morphine and demerol, two powerful pain medicines, are shown in Figure P20.106. They interact similarly with receptors because they share similar structural features, including one part of the molecule that is flat or planar and another part that can bind to the receptor site. Identify these two structural features.



Morphine Demerol

FIGURE P20.106

Antihistamines Figure P20.107 shows the structure of the histamine molecule that causes sneezing and itching in allergy sufferers. Antihistamines are a class of molecules that reduce allergy symptoms by preferentially binding to the same receptor sites as histamines. What structural features would permit these molecules to bind to the same receptor?



Histamine Antihistamine

FIGURE P20.107

Pain Relievers The structures of aspirin, acetaminophen, and ibuprofen are shown in Figure P20.108. What structural features do these molecules share?

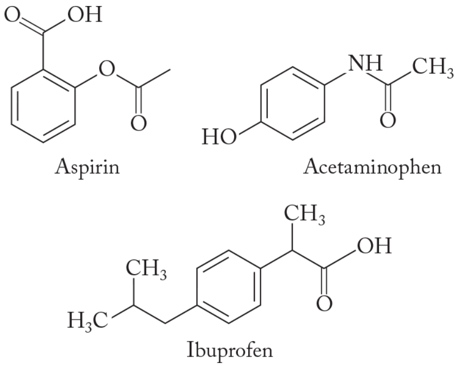


FIGURE P20.108

Glossary

constitutional isomers

molecules with the same chemical formula but different connections between the atoms.

stereoisomers

isomers created by differences in the orientations of the bonds in molecules.

optical isomers

molecules that are not superimposable on their mirror images.

amino acid

a molecule that contains at least one amine functional group and one carboxylic acid functional group; in an α-amino acid, the two functional groups are attached to the same (α) carbon atom.

protein

a biological polymer made of amino acids.

peptide

a compound of two or more amino acids joined by peptide bonds; small peptides containing up to 20 amino acids are oligopeptides, whereas polypeptides are chains longer than 20 amino acids but shorter than proteins.

peptide bond

the result of a condensation reaction between the carboxylic acid group of one amino acid and the amine group of another.

carbohydrate
an organic molecule with the generic formula $C_x(H_2O)_y$.

tricarboxylic acid (TCA) cycle
a series of reactions that continue the oxidation of pyruvate formed in glycolysis.

monosaccharide
a single-sugar unit and the simplest carbohydrate.

glycosidic bond
a C□O□C bond between sugar molecules.

polysaccharide
a polymer of monosaccharides.

lipid
a class of water-insoluble, oily organic compounds used as common structural materials in cells.

glyceride
a lipid consisting of esters formed between fatty acids and the alcohol glycerol.

fat
a solid triglyceride containing primarily saturated fatty acids.

oil
a liquid triglyceride containing primarily unsaturated fatty acids.

nucleic acid
one of a family of large molecules; nucleic acids include deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), molecules that store the genetic blueprint of an organism and control the production of proteins.

transcription
the process of copying the information in DNA to RNA.

translation
the process of assembling proteins from the information encoded in RNA.

nucleotide
a monomer unit from which nucleic acids are made.

primary (1°) structure
the sequence in which amino acid monomers occur in a

protein chain.

secondary (2°) structure

the pattern of arrangement of segments of a protein chain.

tertiary (3°) structure

the three-dimensional, biologically active structure of a protein that arises because of interactions between the R groups on its amino acids.

quaternary (4°) structure

the larger structure functioning as a single unit that results when two or more proteins associate.

The Main Group Elements

Life and the Periodic Table

PARTICULATE REVIEW

Nitrogen, Sulfur, and Phosphorus: One, Two, or All Three?

In Chapter 21 we survey the roles of main group elements in living organisms. In addition to carbon, hydrogen, and oxygen, atoms of nitrogen, sulfur, and phosphorus are fundamental building blocks for important biological molecules in plants and animals.

Which of these structures contains sulfur atoms? Where are the sulfur atoms?
- Which two structures contain phosphorus atoms? Where are the phosphorus atoms?
- All three structures contain nitrogen atoms. List the functional group(s) that contains nitrogen atoms in each structure.

(Review Chapter 20 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

Charge versus Size: Selective Transport

Shown here are representations of four essential cations involved in selective ion transport through channels in cell membranes: Ca^{2+}, H_3O^+, K^+, and Na^+. The size of each cation is listed. As you read Chapter 21, look for ideas that will help you answer these questions:

- Identify each of the four ions pictured.
- The Na^+ channel is selective, allowing only Na^+ cations and one of the other three cations to pass through it. Which other ion—Ca^{2+}, H_3O^+, or K^+—is most likely to undergo selective transport through the sodium channel?
- Which of the other three ions, if any, is likely to pass through the K^+ channel?

Learning Outcomes

- LO1 Distinguish between essential and nonessential elements and between major, trace, and ultratrace elements
- LO2 Describe the pathways and calculate the free energy and electrochemical potential driving ion transport across cell membranes

  Sample Exercise 21.1

- LO3 Balance equations, draw structures, and carry out calculations relevant to the behavior of major, trace, and ultratrace elements and their compounds *in vivo*

  Sample Exercises 21.2, 21.3, 21.4

- LO4 Describe the function of the essential and nonessential group 14–16 elements in the human body
- LO5 Describe the health hazards posed by some radioactive isotopes of main group elements and the use of others in medical diagnosis and therapy

  Sample Exercise 21.5

- LO6 Describe how compounds containing main group elements are used in therapy and in other biomedical applications

FIGURE 21.1 The labels on multivitamin supplements may not list DRI or RDA values but rather *% daily values* (DVs). Daily values are based on RDA or DRI values, but there can be inconsistencies, particularly among the ultratrace essential elements.

21.1 Main Group Elements and Human Health

How many of the elements in the periodic table are in the human body? Moreover, which of them are important to the health of humans?

Roughly one-third of the 90 naturally occurring elements have an identifiable role in human health and in organisms in general. Essential elements are defined as those that have a beneficial physiological effect, including those whose absence impairs functioning of the organism (**Table 21.1**). Some—such as carbon, hydrogen, oxygen, nitrogen, sulfur, and phosphorus—are the principal constituents of all plants and animals. The alkali metal cations Na^+ and K^+ act as charge carriers, maintain osmotic pressure, and transmit nerve impulses. The alkaline earth cation Mg^{2+} is important in photosynthesis, and Ca^{2+} ions are components of bones and teeth. Chloride ions balance the charge of Na^+ and K^+ ions to maintain electrical neutrality in living cells. Other main group elements, such as iodine and selenium, are required in tiny amounts in our bodies to regulate metabolism and as components of the enzymes that catalyze biochemical reactions.

TABLE 21.1 Essential Elements Found in the Human Body

Major ([illegible] of body mass)
Calcium
Carbon
Chlorine
Hydrogen
Magnesium
Nitrogen
Oxygen
Phosphorus
Potassium
Sodium
Sulfur

Trace ([illegible] of body mass)
[illegible]

Ultratrace ([illegible] of body mass)
Chromium
Cobalt
Copper
Manganese
Molybdenum
Nickel
Selenium
Vanadium

The essential elements are further classified as major, trace, or ultratrace essential elements. Major essential elements are present in gram quantities in the human body and are required in large amounts in our diet. Almost all foods are rich in compounds containing carbon, hydrogen, oxygen, nitrogen, sulfur, and phosphorus. Salt is perhaps the most familiar dietary source of sodium and chloride ions, although both are ubiquitous in food. Vegetables such as broccoli and Brussels sprouts and fruits such as bananas are rich in potassium. Calcium is found in dairy products and is often added to orange juice as a dietary supplement.

Many nonessential elements are also present in the body but have no known function (**Table 21.2**). Some are useful in medicine as either diagnostic tools or therapeutic agents. Some radioactive isotopes may be used as imaging agents for organs and tumors, for example, whereas others are used to treat disease. Drugs containing lithium ions are used to treat depression. Compounds of bismuth act as mild antibacterial agents for treatment of diarrhea, and antimony compounds represent one of the few options for patients suffering from the tropical disease leishmaniasis, caused by protozoan parasites.

TABLE 21.2 Nonessential Elements Found in the Human Body

[illegible]
Antimony
[illegible]
Cesium
Germanium
Rubidium
Strontium

In some cases, the presence of a nonessential element has a stimulatory effect, which means that the consumption of small amounts of the element causes increased activity or growth in an organism. The effect may be beneficial or not, and often the mechanism of the effect is not understood. For example, small amounts of the nonessential element antimony promote growth in some mammals when added to their diets. Nonessential elements, and even toxic elements, are often incorporated into our bodies because their chemical properties are similar to those of an essential element. For example, Rb^+ ions are retained by the human body because they are similar to K^+ ions in size, charge, and chemistry, making rubidium the most abundant nonessential element in humans.

Oxygen, in the form of O_2 gas, occurs in the body in elemental form; oxygen is also incorporated into many compounds, such as H_2O, and many ions, such as HCO_3^-. When we speak of any element in the body other than oxygen, however, we usually refer to an ion or compound containing that element rather than the pure element. For example, when we describe calcium as an essential element, we are referring to calcium ions, Ca^{2+}, not calcium metal.

TABLE 21.3 Comparative Composition[a] of the Universe, Earth's Crust, Seawater, and the Human Body

[illegible]
Hydrogen

Oxygen	[illegible]
Carbon	[illegible]
Nitrogen	[illegible]
Calcium	[illegible]
Phosphorus	[illegible]
Chlorine	[illegible]
Potassium	[illegible]
Sulfur	[illegible]
Sodium	[illegible]
Magnesium	[illegible]
Helium	[illegible]
Silicon	[illegible]
Aluminum	[illegible]
Neon	[illegible]
Iron	[illegible]
Bromine	[illegible]
Titanium	[illegible]
All other elements	[illegible]

Table 21.3 compares the elemental compositions of the human body, the universe, Earth's crust, and seawater. The composition of our bodies most closely resembles the composition of seawater. The match would be even closer if it were not for the biological processes in the sea that remove essential elements such as nitrogen and phosphorus and that store others in solid structures like the $CaCO_3$ that makes up corals and mollusk shells.

TABLE 21.4 Dietary Reference Intake (DRI) and Recommended Dietary Allowance (RDA) for Selected Essential Elements [a]

Element	RDA
Calcium	1200 mg
Chlorine	2300 mg
Chromium	25–35 μg
Copper	900 μg
Fluorine	3–4 mg
Iodine	150 μg
Iron	8–18 mg
Magnesium	320–400 mg

Manganese	1.8–2.3 mg
Molybdenum	45 μg
Phosphorus	700 mg
Potassium	4700 mg
Selenium	55 μg
Sodium	1500 mg
Zinc	8–11 mg

Our diet should supply us with sufficient quantities of all essential elements. In the United States and Canada, these quantities are called *dietary reference intake* (DRI) values. They are based on the recommendations of the Food and Nutrition Board of the National Academy of Sciences and are frequently updated in response to research. For many essential elements, DRI values have replaced the *recommended dietary allowance* (RDA) values you may be familiar with from labels on food and vitamin packages (**Figure 21.1**). **Table 21.4** compares the DRI and RDA values for several major, trace, and ultratrace essential elements.

Some elements, such as radon, beryllium, and lead, are toxic. As described in Section 19.6, inhaled radon gas poses serious health hazards when it undergoes α decay inside the body. Beryllium toxicity is most often encountered in industrial settings where beryllium-contaminated dust is inhaled; the Be^{2+} ion replaces Mg^{2+} in the body, where it inhibits Mg^{2+}-catalyzed RNA and DNA synthesis in cells. Lead ions, Pb^{2+}, are incorporated into teeth and bones because they are similar to Ca^{2+} ions in size and charge. Lead also interferes with the functioning of enzymes that require calcium ions and thereby causes chronic neurological problems and blood-based disorders, especially in children. This issue became a major news story early in 2016 when it was discovered that a budget-cutting decision to switch drinking-water sources in Flint, Michigan, had exposed as many as 8000 children under age 6 to unsafe levels of lead. In June 2014, the city’s source of water was changed from Lake Huron to the Flint River. The river water proved more corrosive than the lake water and leached lead from old water pipes, causing lead levels to rise to more than 100 ppb; the U.S. Environmental Protection Agency’s action level for lead in drinking water is 15 ppb. Unsafe levels of lead have been identified in other cities with aging water systems.

In this chapter we review the periodic properties of the main group elements and survey the roles of selected elements in the human body, as well as their importance to good health. At the same time, we call on the knowledge and skills you have acquired in your study of general chemistry to solve problems that link concepts from prior chapters to the central question of this chapter: What are the roles of the main group elements in the chemistry of life? The roles of transition metal ions such as Fe^{2+}, Fe^{3+}, and Zn^{2+} in biology are addressed in Chapter 22.

Glossary

essential element
an element present in tissue, blood, or other body fluids that has a physiological function.

ultratrace essential element
an essential element present in the body in average concentrations less than 1 μg of element per gram of body mass.

nonessential element
an element present in humans that has no known function.

stimulatory effect
increased activity, growth, or other biological response to the presence of a nonessential element.

major essential element
an essential element present in the body in average concentrations greater than 1 mg of element per gram of body mass, resulting in gram quantities in the human body.

trace essential element
an essential element present in the body in average concentrations between 1 and 1000 μg of element per gram of body mass.

21.2 Periodic Properties of Main Group Elements

The main group or representative elements are found in groups 1, 2, and 13–18 in the periodic table. These eight groups, comprising 44 naturally occurring elements, include five elements for which no stable isotopes are known: Fr, Ra, Po, At, and Rn. Relatively little is known about the chemistry of francium or astatine, both of which are exceedingly rare. Estimates indicate that the outermost kilometer of Earth's crust contains at most 44 mg of At and only 15 g of Fr. They have no proven uses, so we will largely ignore them in our discussions. Before turning to the role of the main group elements in life, it is useful to review what we have already learned about the physical and chemical properties of these elements and to look for periodic trends in these properties.

CONNECTION The origin of some periodic trends is discussed in Sections 7.10 to 7.12.

The atomic radii of the main group elements increase as we descend a group and increase right to left across a period (**Figure 21.2a**). In other words, the largest elements are found in the lower left-hand corner of the periodic table. The first ionization energies and electronegativities of the main group elements increase as we ascend a group and increase left to right across a period (**Figure 21.2b**). An overall trend toward more negative electron affinities is seen left to right across a period, although several anomalies are also observed. Each of these periodic trends reflects the changes in the effective nuclear charge and shielding of the valence electrons by core electrons as atomic numbers increase and inner shells fill with electrons.

A survey of the main group elements reveals a variety of physical properties. The alkali metal and alkaline earth elements are all solids, whereas all the group 18 elements (the noble gases) are gases at standard temperature and pressure. All group 17 elements (the halogens) exist as diatomic molecules. Group 17 is also the only group that contains elements in all three phases of matter at room temperature: bromine is one of two liquid elements in the periodic table, iodine is a volatile solid, and the remaining elements are gases. Groups 13–16 include seven elements classified as semimetals (B, Si, Ge, As, Sb, Te, and At), as well as elements with metallic properties (Al, Ga, In, Tl, Sn, Pb, Bi, and Po). The remaining elements in these groups behave as nonmetals with the properties described in Chapter 2: they are gases (N_2, O_2) or brittle solids that are poor conductors of electricity (C, P, S, and Se). For groups 13–16, metallic properties increase down a group.

The melting and boiling points of the metallic and semimetallic main group elements decrease down groups 1 and 2, but this trend is reversed for the nonmetals in groups 17 and 18 (**Table 21.5**). These trends can be understood in terms of the different types of forces holding the atoms together. The increase in the size of the metallic elements when descending groups 1 and 2 leads to weaker metallic bonds and lower boiling points. In groups 17 and 18, however, increasing size leads to greater London dispersion forces as the polarizability of the atoms increases. The trends in melting points for groups 13–16 do not fit a clear pattern, in part because the properties of the elements change from nonmetallic to metallic down these groups.

TABLE 21.5 Summary of Periodic Trends for the Main Group Elements

[illegible]
[illegible]
[illegible]

Of the main group elements, only hydrogen, carbon, nitrogen, oxygen, sulfur, and the six noble gases exist in nature in elemental form. The remaining elements are found exclusively in ionic or covalent compounds. The group 1 and 2 elements readily lose their valence electrons, forming 1+ and 2+ cations, respectively, which can react with group 17 anions to produce familiar ionic compounds such as NaCl and KI (**Figure 21.3**). Halogen compounds of groups 13–17 generally contain covalent bonds; however, the heavier group 13 and 14 elements form insoluble ionic salts such as $PbCl_2$ and TlCl. The metallic elements in groups 1, 2, and 13 react with oxygen to yield oxides, including K_2O, CaO (quicklime, used in the manufacture of steel), and Al_2O_3 (alumina, used in orthodontics).

CONNECTION Ionic compounds were defined in Section 2.6, and organic compounds were introduced in Section 2.8. Covalent bonding was discussed in detail in Chapters 8 and 9.

CONNECTION The organization of the periodic table was introduced in Chapter 2. Periodic properties were discussed in Chapter 7, and the stability of nuclei was addressed in Chapter 19.

The lighter elements of groups 13–17 tend to form covalent bonds rather than ionic bonds. The result is a library of more than 150 million organic compounds, covalently bonded substances composed primarily of carbon, nitrogen, hydrogen, and oxygen. More than 95% of the new compounds registered in a given year are classified as organic compounds.

Hydrogen, the smallest and lightest element, is difficult to classify. Most periodic tables include hydrogen in group 1 on the basis of its electron configuration of a half-filled *s* orbital and on the dissociation of acids to protons and anions, analogous to the dissolution of alkali metal salts to $1+$ cations and anions. Hydrogen also has a complete valence shell after gaining an electron to form a hydride ion, H^-, which is isoelectronic with He, a noble gas. Compounds called metal hydrides form between hydrogen and group 1, 2, or 13 metals, and they behave as salts containing a metal cation and a hydride anion. However, hydrogen is most commonly covalently bonded in compounds to oxygen (as water, H_2O) or to another group 14–16 element.

21.3 Major Essential Elements

The 11 elements shown in red in **Figure 21.4** and listed in the first column of Table 21.1 are the major essential elements. Together they account for more than 99% of the mass of the human body. Oxygen is the most abundant element by mass, followed by carbon and hydrogen. Although life depends on the presence of elemental oxygen in the form of O_2 gas, much of the oxygen in our bodies is combined with hydrogen in water molecules.

The most abundant elements in the human body include seven nonmetals: C, H, O, Cl, S, P, and N. They are the building blocks for most of the body's molecular compounds and its principal polyatomic ions, HCO_3^-, SO_4^{2-}, and $H_2PO_4^-$, which are dissolved in body fluids. The average concentrations of the four major metals in the human body—Ca^{2+}, K^+, Na^+, and Mg^{2+}—are listed in **Table 21.6**. In this section we explore some of the roles that sodium, potassium, magnesium, calcium, chlorine, nitrogen, phosphorus, and sulfur play in the biochemistry of the human body. As we do, we revisit several of the chemical principles discussed in earlier chapters.

Sodium and Potassium

Regulated concentrations of sodium and potassium ions are crucial to cell function. For some people, consuming too much Na^+ has been linked to hypertension (high blood pressure). To maintain a constant concentration of these two alkali metal ions in body fluids, the ions must be able to move into and out of cells. As noted in Section 20.6, the membrane surrounding a typical cell is a lipid bilayer, with polar groups containing phosphate groups on the two surfaces of the cell membrane and nonpolar fatty acids oriented toward the interior of the membrane. Direct diffusion of Na^+ and K^+ through the lipid bilayer is difficult because these polar cations do not dissolve in the nonpolar interior.

As **Figure 21.5** shows, the cell membrane is pierced by ion channels, which are groups of protein complexes that allow selective transport of ions. The ion channels control which ions pass through the membrane on the basis of the size and charge of the ion as well as the shape of the protein. For example, the protein of the potassium ion channel has amino acids oriented in such a fashion that favorable ion–dipole interactions occur only for ions with the radius of a K^+ ion (138 pm) but not for Na^+ (102 pm) or any other cation. The sodium ion channel is also selective, excluding K^+ and Ca^{2+} even though the radii of Na^+ and Ca^{2+} (100 pm) differ by only 2 pm. Another difference between the Na^+ and K^+ channels is the ability of H_3O^+ (hydronium ion, radius 113 pm) to pass through Na^+ channels but not K^+ channels.

TABLE 21.6 Average Concentration of Four Metallic Elements in the Human Body

Element	% of Body Mass
Calcium	1.50
Potassium	2.0
Sodium	1.5
Magnesium	0.5

Living organisms also contain oxygen-rich molecules such as the Lewis base nonactin (**Figure 21.6**) that bond to Ca^{2+}, K^+, Na^+, and Mg^{2+} ions (Lewis acids) through strong ion–dipole forces. The resulting complex ions consist of a polar, charged alkali metal ion encapsulated in a nonpolar exterior. Because the complex ion has both a polar portion and a nonpolar portion, it does not require a channel for passage through a cell membrane. Instead, the complex ion carries its alkali metal cation through both the polar and nonpolar regions of the bilayer, providing an alternative to ion channels for the transport of these metal ions. We revisit the bonding between Lewis acids and bases in more detail in Chapter 22.

In addition to ion channels and diffusion of complex ions, alkali metal cations can be transported by a third mechanism, one involving Na^+–K^+ ion pumps. An ion pump is a system of membrane proteins that exchange ions inside the cell (e.g., Na^+) with those in the intercellular fluid (e.g., K^+). Unlike diffusion or transport through ion channels, transport via the Na^+–K^+ pump requires energy, which is provided by the hydrolysis of ATP to ADP. An example of how the Na^+–K^+ ion pump works is the response of a nerve cell to touch. Stimulation of the nerve cell causes Na^+ to flow into the cell and K^+ to flow out via ion channels; this two-way flow of ions produces the nerve impulse. The ion pump then "recharges" the system by pumping Na^+ out of the cell and K^+ into the cell so that another impulse can immediately be transmitted along the nerve.

CONNECTION In Section 10.3 we described how alkali metal cations dissolved in water are surrounded by six water molecules (a sphere of hydration). Each water molecule is oriented so that the oxygen atoms point toward the cation (see Figure 10.6). In Sections 16.5 and 16.6 we described this interaction as an example of a Lewis acid (cation, electron-pair acceptor) interacting with a Lewis base or ligand (water, electron-pair donor).

The unequal concentrations of Na^+, K^+, and other ions on opposite sides of a cell membrane result in an electrochemical equilibrium potential or reversal potential (E_{ion}) for each ion that can be calculated using the following variation of the Nernst equation (introduced in Section 18.6), in which n now represents the charge on an ion and Q is now the ratio of the concentrations of the ion outside the cell to inside the cell:

A related overall membrane potential (E_{membrane}) represents contributions from all the major ions, both cations and anions, inside and outside a cell. The values of the membrane potential reflect the different concentrations of the ions inside the cell versus outside the cell, and their relative ability to pass through the membrane, or *permeability*. E_{membrane} values typically range from -50 to -70 mV. The driving force $E_{\text{transport}}$ that pushes an ion across a cell membrane can be calculated from Equation 21.2:

We can derive an equation connecting the potential of an electrochemical cell to ΔG for the process, allowing us to calculate the change in free energy that accompanies the transport of ions, and determine whether the process is spontaneous:

CONNECTION The Nernst equation and the relationship between E and ΔG were introduced in Sections 18.6 and 18.4, respectively.

Ion channels, transporters, and pumps, and the ion concentrations they control, are a finely tuned system that regulates the membrane potential of cells. Rapidly multiplying normal cells such as fertilized eggs and differentiating stem cells have membrane potentials much less negative than the typical values and may be as low as 0 to -10 mV. It has recently been suggested that membrane potential plays a role in wound healing, and it is well established that some cancer cells have depolarized cell membranes and that their membrane potentials are also in the 0 to -10 mV range.

SAMPLE EXERCISE 21.1 Calculating E_{ion} for Ion Transport LO2

Nerve cells contain structures called axons whose function relies on concentration differences on opposite sides of a membrane. The concentration of Na^+ inside a squid axon is 0.050 M (50 mM), in comparison with $[Na^+] = 0.440\ M$ (440 mM) in the fluid surrounding the cell.

1. Calculate the equilibrium potential E_{ion} for the Na^+ ion at 280 K.
2. If the membrane potential $E_{\text{membrane}} = -0.050$ V, is the transport of Na^+ from inside to outside the cell membrane spontaneous?

Collect, Organize, and Analyze We are given the concentrations of Na^+ on opposite sides of a cell membrane, and we are asked to calculate E_{ion} for Na^+ and to determine whether the transport across the membrane is spontaneous. Equation 21.1 allows us to calculate the equilibrium potential that arises from an unequal concentration of an ion on either side of a permeable membrane. If $[Na^+{}_{\text{outside}}] > Na^+{}_{\text{inside}}]$, then the natural logarithm (ln) term in Equation 21.1 will be greater than 1 and E_{ion} will be positive. Using Equations 21.2 and 21.3, we can calculate the useful work done during transport: if ΔG is negative, the process is spontaneous; if positive, it is nonspontaneous.

Solve

1. Substitution into Equation 21.1 gives

$$E_{\mathrm{Na}^+} = \frac{RT}{nF}\ln\frac{[\mathrm{Na}^+_{\mathrm{outside}}]}{[\mathrm{Na}^+_{\mathrm{inside}}]} = \frac{[8.314\,\cancel{\mathrm{J}}/(\cancel{\mathrm{mol}}\cdot\cancel{\mathrm{K}})](280\,\cancel{\mathrm{K}})}{(1/\cancel{\mathrm{mol}})(96{,}500\,\cancel{\mathrm{J}}/\mathrm{V})}\ln\left(\frac{440\,\cancel{\mathrm{m}M}}{50\,\cancel{\mathrm{m}M}}\right)$$
$$= 0.052\ \mathrm{V}$$

2. Using Equation 21.2, we can calculate $E_{\mathrm{transport}}$, which is the driving force available to push the ions across the membrane:

$E_{\mathrm{transport}} = E_{\mathrm{membrane}} - E_{\mathrm{ion}} = -0.050\ \mathrm{V} - (0.052\ \mathrm{V}) = -0.102\ \mathrm{V}$

Substituting -0.102 V into Equation 21.3:

$$\Delta G_{\mathrm{transport}} = -nFE_{\mathrm{transport}} = -(1/\mathrm{mol})(96{,}500\ \mathrm{J}/\cancel{\mathrm{V}})(-0.102\ \cancel{\mathrm{V}}) = 9888\ \mathrm{J/mol}$$
$$= 9.88\ \mathrm{kJ/mol}$$

Because $\Delta G > 0$, the transport is not spontaneous.

Think About It The equilibrium potential for Na^+ under these conditions is positive, consistent with our prediction. The transport of Na^+ from the inside to the outside of the cell membrane is not spontaneous because it goes against the concentration gradient and the negative membrane potential.

Practice Exercise The concentration of K^+ inside a frog muscle cell is 124 mM, in comparison with $[\mathrm{K}^+] = 2.3$ mM in the fluid surrounding the cell. Calculate the equilibrium potential for the K^+ ion at 310 K. If the membrane potential E_{membrane} is -73 mV, how much useful work must be done to transport K^+ into the cell at 310 K?

(Answers to Practice Exercises are in the back of the book.)

CONCEPT TEST

Do ion pumps represent spontaneous or nonspontaneous processes?

(Answers to Concept Tests are in the back of the book.)

Magnesium and Calcium

The biological roles of Mg^{2+} and Ca^{2+} are more varied than those of Na^+ and K^+. Calcium is a major component of teeth and bones. A prolonged deficiency of calcium can lead to osteoporosis (a disease characterized by low bone density), whereas high concentrations of calcium in muscle cells contribute to cramps. Most kidney stones are made of calcium oxalate or calcium phosphate. Magnesium deficiencies can reduce physical and mental capacity because of the role of Mg^{2+} in the transfer of phosphate groups to and from ATP (Mg^{2+} binds to ATP); slowing this transfer diminishes the amount of energy available to cells. The cellular concentrations of Mg^{2+} and Ca^{2+} are maintained by ion pumps.

Magnesium is a component of chlorophyll (**Figure 21.7**), which is one of several molecules used by plants to collect and capture light energy across the visible portion (400 to 700 nm) of the electromagnetic spectrum. Chlorophylls from different plants vary slightly in composition, but all of them contain magnesium coordinated to four nitrogen atoms. The presence of magnesium in chlorophyll does not account for the green color of the molecule, nor does it play a direct role in absorption of sunlight. The function of the Mg^{2+} ion is to orient the molecules in positions that allow energy to be transferred to the reaction centers where H_2O is consumed and O_2 is produced during photosynthesis. Carotene and related compounds are responsible for the orange colors (but not yellow or red) of autumn leaves on deciduous trees when chlorophyll production ceases. Mg^{2+} ions play important roles in ATP hydrolysis and ADP phosphorylation. The many Mg^{2+}-mediated ATP → ADP processes include transferring phosphate to glucose in the conversion of glucose to pyruvate and driving Na^+–K^+ ion pumps.

To some extent, calcium ions can also mediate ATP hydrolysis, but these ions play other roles in the cell. They are necessary to trigger muscle contractions, for example—the calcium ions used for this purpose are stored in proteins. Recall that the action of Na^+–K^+ pumps is responsible for the generation of nerve impulses. One effect of nerve impulses is to trigger the release of Ca^{2+} ions from their storage proteins into the intracellular fluid. In a multistep process, muscle cells contract and relax as Ca^{2+} ions are released. Once the muscle action is complete, the ions are returned to their storage proteins in a process coupled to Mg^{2+}-mediated ATP hydrolysis.

CONNECTION The catabolism of glucose was described in Sections 17.9 and 20.5.

Of Na, K, Mg, and Ca—the alkali metal and alkaline earth metal major essential elements (see Figure 21.4)—only calcium plays a major role in the formation of teeth and bones. Mammalian bones are a *composite material*, defined as a material containing a mixture of different substances. About 30% of dry bone mass is elastic protein fibers. The rest of the mass consists of calcium compounds, including the mineral hydroxyapatite, $Ca_5(PO_4)_3(OH)$, which is also a principal component of teeth. Hydroxyapatite crystals are bound to the protein fibers in bone through phosphate groups.

CONNECTION The role of ATP and ADP in metabolism was described in Section 17.9.

The shells of marine organisms are mostly calcium carbonate ($CaCO_3$) in a matrix of proteins and polysaccharides. Some magnesium is incorporated into the calcium carbonate outer shell of marine organisms that are capable of photosynthesis, such as algae and phytoplankton.

Chlorine

Of all the halogens, only chlorine (as chloride ions) is present at high enough cocentrations to be considered a major essential element in humans. Chloride ions are the most abundant anions in the human body and are involved in many processes. The concentration of chloride ions in the human body (1.5 mg per gram of body mass) is slightly less than one-tenth of the concentration of Cl^- in seawater (19 mg per gram of water) but about 12 times greater than in Earth's crust (0.13 mg per gram of crust). Like the major essential cations, chloride ions are transported into and out of cells primarily via ion channels and ion pumps. To maintain electrical neutrality in a cell, the transport of alkali metal cations is accompanied by the transport of chloride anions. The *cotransport* of Na^+ and Cl^- is essential in kidney function, where the ions are reabsorbed by the body rather than eliminated with liquid waste products.

Malfunctioning chloride ion channels are the underlying cause of cystic fibrosis, a lethal genetic disease that causes patients to accumulate mucus in their airways such that breathing becomes difficult. The discovery of high concentrations of Na^+ and Cl^- in the sweat of cystic fibrosis patients led to an understanding of the role of chloride ion transport in patients with this disease.

Chloride ions also play a major role in the elimination of CO_2 from the body. Because it is nonpolar, carbon dioxide produced during glucose catabolism can pass from muscle cells (for example) into red blood cells, moving easily through the largely nonpolar cell membranes of these cells. Inside the red blood cells, CO_2 is converted to bicarbonate ion (HCO_3^-). When HCO_3^- is pumped out of the cell, Cl^- enters the cell through an ion channel to maintain charge balance.

Chloride ion concentrations are high in gastric juices because of the presence of hydrochloric acid, which catalyzes digestive processes in the stomach. In response to food in the digestive system, cells tap ATP for the needed energy to pump hydrochloric acid into the stomach.

SAMPLE EXERCISE 21.2 Calculating the Concentration of HCl in Stomach Acid LO3

Acid reflux (sometimes called heartburn, though the heart is not involved) affects many people. It results from acid in the stomach leaking into the esophagus and causing discomfort. Stomach acid is primarily an aqueous solution of HCl. (a) Calculate the molarity of hydrochloric acid in gastric juice that has a pH of 0.80. (b) One treatment for the symptoms of acid reflux is to take an antacid tablet. What volume of gastric juice can be neutralized by a 750 mg tablet of calcium carbonate (a typical size for an over-the-counter antacid)?

Collect and Organize We are given the pH of a solution and are asked to calculate the concentration of HCl that corresponds to that pH. As we explained in Section 15.4 (Equation 15.10), $\text{pH} = -\log[H_3O^+]$. Hydrochloric acid is a strong acid and ionizes completely to H_3O^+ and Cl^- in water:

$$HCl(aq) + H_2O(\ell) \rightarrow H_3O^+(aq) + Cl^-(aq)$$

We are also asked to calculate the volume of HCl solution that can be neutralized by a 750 mg tablet of calcium carbonate ($CaCO_3$). We need to write a balanced chemical equation for the neutralization reaction.

Analyze The equation describing the ionization of hydrochloric acid indicates that 1 mole of H_3O^+ ions is formed for every mole of HCl present. The pH of gastric juice falls between 1 and 0, so $[H_3O^+]$ will be between 10^{-1} $(= 0.1)$ M and 10^0 $(= 1)$ M.

The net ionic equation for the neutralization reaction is

$$CaCO_3(s) + 2\,H_3O^+(aq) \rightarrow Ca^{2+}(aq) + CO_2(g) + 3\,H_2O(\ell)$$

This equation indicates that 2 moles of H_3O^+ are consumed for every mole of $CaCO_3$. We are told that the tablet size is typical of an antacid tablet, so common sense suggests that the volume of acid this tablet can neutralize will not be excessively large (greater than 1 L) or small (less than 10 mL): too large a tablet would be a waste of antacid, and too small a tablet would not relieve the symptoms.

Solve

1. Substitution into Equation 15.10 gives

   $$\text{pH} = -\log[H_3O^+] = 0.80$$

   We take the antilog of both sides to solve for $[H_3O^+]$:

$[H_3O^+] = 10^{-0.80} = 0.16\ M\ H_3O^+$

Therefore, the concentration of HCl is

$$0.16\ M\ H_3O^+ \times \frac{1 \text{ mol HCl}}{1 \text{ mol } H_3O^+} = 0.16\ M\ \text{HCl}$$

2. First, we calculate the number of moles of $CaCO_3$ present in 750 mg:

$$0.750\ \cancel{\text{g } CaCO_3} \times \frac{1 \text{ mol } CaCO_3}{100.09\ \cancel{\text{g } CaCO_3}} = 7.49 \times 10^{-3} \text{ mol } CaCO_3$$

Next, we use the stoichiometry of the neutralization reaction to calculate the volume of 0.16 *M* HCl this quantity of $CaCO_3$ can neutralize:

$$7.49 \times 10^{-3}\ \cancel{\text{mol } CaCO_3} \times \frac{2\ \cancel{\text{mol } H_3O^+}}{1\ \cancel{\text{mol } CaCO_3}} \times \frac{1 \text{ L}}{0.16\ \cancel{\text{mol } H_3O^+}} = 9.36 \times 10^{-2} \text{ L}$$
$$= 94 \text{ mL of } 0.16\ M\ \text{HCl}$$

Think About It A concentration of 0.16 *M* seems reasonable because it is indeed within the range of values predicted for a solution with $\text{pH} < 1$. The volume of 0.16 *M* acid that a 750 mg tablet of $CaCO_3$ can neutralize is also reasonable; 94 mL represents about 3 ounces of gastric juice.

Practice Exercise Calculate the pH of a solution prepared by mixing 10.0 mL of 0.160 *M* HCl with 15.0 mL of water. How much antacid containing 4.00×10^2 mg of $Mg(OH)_2$ in 5.00 mL of water is needed to neutralize this volume of acid?

CONCEPT TEST

Taking an antacid tablet is often sufficient to treat an occasional case of mild acid reflux. Another remedy is a drug such as Prilosec, which inhibits a cell’s proton pumps by binding to the site of the pump and disabling it for more than 24 hours. Is the equilibrium constant for the binding of a proton pump inhibitor likely to be less than or greater than 1?

Nitrogen

Nitrogen is a major essential element found primarily in proteins but also in DNA and RNA. Nitrogen is available in the atmosphere as N_2, and soil and water contain nitrate ions, but neither of these forms of nitrogen can be directly incorporated into amino acids, the building blocks of proteins. The biosynthesis of amino acids requires ammonia or ammonium ions. For example, glycine (NH_2CH_2COOH), the simplest amino acid, is formed by reaction of CO_2 and NH_3 in the presence of the appropriate enzyme. Interconversion of nitrogen-containing compounds in the environment is described by the nitrogen cycle (**Figure 21.8**). Certain bacteria use enzymes called *nitrogenases* to convert N_2 to NH_3. Plants convert NO_3^- ions to NO_2^- and then to NH_3 by using enzymes called *reductases*. Ultimately, the chemical reactions in these organisms begin a food chain that supplies the essential amino acids for human diets.

The reactions in **Figure 21.9** are all redox reactions that illustrate the wide range of oxidation numbers found among nitrogen compounds in the nitrogen cycle. By definition, each atom in nitrogen gas (N_2) is assigned an oxidation number of zero. When N_2 is converted to NH_3, the oxidation number of N decreases to -3, a reduction. The oxidation numbers of N in nitrite (NO_2^-) and nitrate (NO_3^-) are $+3$ and $+5$, respectively, as a result of oxidation.

Modern agriculture depends heavily on the use of nitrogen-based fertilizers, which include ammonia and salts containing ammonium salts and nitrate ions. Most of the fertilizer used in the 21st century is derived from the high-temperature, high-pressure Haber–Bosch process. There is considerable research in progress to emulate the nitrogen cycle in Figure 21.8 and produce fertilizer more efficiently. In Chapter 13 we encountered a different cycle for nitrogen in the environment: the conversion of N_2 and O_2 to NO and NO_2 in the engines of automobiles. Dinitrogen monoxide (N_2O) is a greenhouse gas. The nitrogen atoms in these volatile nitrogen oxides are assigned oxidation numbers of +1, +2, and +4 for N_2O, NO, and NO_2, respectively.

CONNECTION The Haber–Bosch process for making ammonia was discussed in Chapter 14.

SAMPLE EXERCISE 21.3 Writing a Balanced Chemical Equation Describing the Reaction of Nitrate Reductases LO3

Nitrate ion can be reduced to ammonia by enzymes called nitrate reductases. The first step is conversion of nitrate ion to nitrite ion. Assign oxidation numbers to the elements in these ions, and write a balanced net ionic equation for the conversion of nitrate to nitrite in a basic solution:

$NO_3^-(aq) \rightarrow NO_2^-(aq)$

Collect, Organize, and Analyze We need to assign oxidation numbers according to the guidelines in Section 4.8. We know that the oxidation numbers of nitrogen and oxygen in each polyatomic ion must add up to the charge on the ion. Oxygen in compounds usually has an oxidation number of −2.

Solve The oxidation number of nitrogen is unknown, so we call it x. The oxidation number of nitrogen in NO_3^- is

$x + 3(-2) = -1$

$x = +5$

The oxidation number of nitrogen in NO_2^- is

$x + 2(-2) = -1$

$x = +3$

In the preliminary expression:

$NO_3^-(aq) \rightarrow NO_2^-(aq)$

The number of nitrogen atoms is balanced; we balance the number of oxygen atoms by adding water:

$NO_3^-(aq) \rightarrow NO_2^-(aq) + H_2O(\ell)$

Then we balance hydrogen by adding hydrogen ions:

$2\,H^+(aq) + NO_3^-(aq) \rightarrow NO_2^-(aq) + H_2O(\ell)$

We balance charge by adding electrons:

$2\,e^- + 2\,H^+(aq) + NO_3^-(aq) \rightarrow NO_2^-(aq) + H_2O(\ell)$

We switch to a basic solution by adding just enough OH^- ions to neutralize any hydrogen ions; we must add the same number of OH^- ions to both sides of the equation:

$2\,OH^-(aq) + 2\,e^- + 2\,H^+(aq) + NO_3^-(aq) \rightarrow NO_2^-(aq) + H_2O(\ell) + 2\,OH^-(aq)$

The hydrogen ions combine with the hydroxide ions to form water, and we cancel the species that are the same on both sides:

This gives us a final net ionic equation for the reduction half-reaction:

$2\,e^- + H_2O(\ell) + NO_3^-(aq) \rightarrow NO_2^-(aq) + 2\,OH^-(aq)$

Think About It Assigning oxidation numbers is a convenient way of identifying which element is reduced or oxidized in a half-reaction and of determining how many electrons are gained or lost. The balanced half-reaction confirms that electrons are added to nitrate to reduce it to nitrite ion.

Practice Exercise The reduction half-reaction catalyzed by one type of nitrogenase produces 1 mole of $H_2(g)$ for every 2 moles of $NH_4^+(aq)$ from molecular nitrogen under acidic conditions. Write a balanced equation for this half-reaction.

In humans and other mammals, excess nitrogen is converted to urea in the liver and excreted via the kidneys. Plants use urea as a source of ammonia by the action of *ureases* via the reaction:

Unlike reactions catalyzed by nitrogenases and nitrate reductases, the conversion of urea to ammonia and carbon dioxide is *not* a redox reaction. It is a hydrolysis reaction, similar to the reaction of nonmetal oxides with water described in Chapter 4. Acidic solutions are observed when NH_4^+, NO_2, and N_2O_5 dissolve in water:

$$NH_4^+(aq) + H_2O(\ell) \rightleftharpoons NH_3(aq) + H_3O^+(aq)$$

$$2\ NO_2(g) + H_2O(\ell) \rightarrow HNO_2(aq) + HNO_3(aq)$$

$$N_2O_5(g) + H_2O(\ell) \rightarrow 2\ HNO_3(aq)$$

Hydrolysis of nitrite ion, however, leads to weakly basic solutions:

$$NO_2^-(aq) + H_2O(\ell) \rightleftharpoons HNO_2(aq) + OH^-(aq)$$

Phosphorus and Sulfur

Phosphorus and sulfur are major essential elements found primarily in proteins and DNA, but they are also present in polyatomic anions prevalent in the environment. In comparison with the nitrogen cycle, the biological phosphorus cycle contains only a single major species: the phosphate ion (PO_4^{3-}) and its conjugate acids HPO_4^{2-} and $H_2PO_4^-$, along with phosphate esters. Reduction of phosphorus(V) in PO_4^{3-} to phosphine (PH_3) does occur in swamps. An oxygen-free environment is needed because PH_3 spontaneously ignites in humid air, yielding phosphoric acid:

$$PH_3(g) + 2\ O_2(g) \rightarrow H_3PO_4(\ell)$$

Gases analogous to those in the nitrogen cycle, such as NO and NO_2, are absent from the phosphorus cycle. Slow weathering of insoluble phosphate minerals by weak acids in soil introduces phosphate ion into the environment, where it is eventually taken up by plants. Some of this phosphate is incorporated into biominerals such as hydroxyapatite [$Ca_5(PO_4)_3(OH)$], as seen previously in our discussion of calcium.

CONCEPT TEST

Why are phosphates more likely to precipitate with cations from aqueous solution than are nitrates?

In the discussion of pH buffers (Section 16.3), we explained how phosphate ion is in equilibrium with its conjugate acid, HPO_4^{2-}, which hydrolyzes, in turn, to $H_2PO_4^-$:

$$PO_4^{3-}(aq) + H_2O(\ell) \rightleftharpoons HPO_4^{2-}(aq) + OH^-(aq)$$

$$HPO_4^{2-}(aq) + H_2O(\ell) \rightleftharpoons H_2PO_4^-(aq) + OH^-(aq)$$

Aqueous phosphate ion can be transported into cells, where it is incorporated into organic molecules such as ATP, ADP, glucose-6-phosphate, and nucleic acids (**Figure 21.10**). Notice the carbon–oxygen bond between the monosaccharide and the phosphate group in all four of the molecules in Figure 21.10. In glucose-6-phosphate and nucleic acids, this new bond forms through a condensation reaction of an –OH group on the sugar molecule and HPO_4^{2-} that produces water as a product. Adenosine diphosphate (ADP) is converted to ATP through a condensation reaction between HPO_4^{2-} and a phosphate group on ADP.

The processes in Figure 21.10 are all reversible; the P–O bond can be hydrolyzed, releasing HPO_4^{2-}. For ATP, this reaction is exothermic and provides the energy for many cellular processes. Given the importance of phosphorus to life, significant amounts of phosphates are used as fertilizer in agriculture. Agricultural runoff may stimulate rapid growth of algae in freshwater ponds and lakes. The explosive growth of algae can use up all the dissolved oxygen, killing other higher aquatic organisms.

The sulfur cycle in **Figure 21.11** illustrates the array of sulfur compounds found in the environment. We have already encountered volatile sulfur oxides, SO_2 and SO_3, in the context of acid rain on early Earth in Section 3.1. Like the nonmetal oxides of groups 14 and 15, SO_2 and SO_3 dissolve in water to produce the weak acid H_2SO_3 and the strong acid H_2SO_4, respectively. The sulfate ion produced by the dissociation of H_2SO_4 and H_2SO_3, the sulfate ions derived from minerals in soil, and the sulfate ions produced by the oxidation of H_2S are all absorbed by plants. Sulfuric acid, made by the reaction between SO_3 and water, is one of the most important industrial chemicals produced in the world.

CONNECTION The role of nitrogen and sulfur oxides in acid rain is discussed in Chapters 4, 8, and 15.

The enzyme ATP sulfurylase promotes the introduction of SO_4^{2-} into ATP as adenosine-59-phosphosulfate (APS^{2-}; **Figure 21.12**). The sulfur in APS^{2-} eventually finds its way into sulfur-containing amino acids (cysteine and methionine) and organic sulfur-containing compounds. It is also released to the environment as H_2S, the sulfur analog of water.

Compounds of hydrogen with oxygen, sulfur, and the other group 16 elements provide interesting contrasts with respect to molecular shape and properties. The data in **Table 21.7** show how different water is from the other compounds. Water is a liquid at ordinary temperatures and pressures, has a large negative enthalpy of formation, and has a much larger bond angle than the other three hydrides. We also know that water is odorless and is absolutely essential for life. The hydrides of sulfur (S), selenium (Se), and tellurium (Te) are all gases under standard conditions and are foul-smelling and poisonous. Hydrogen sulfide is responsible for the smell of rotten eggs. It is especially dangerous because it tends to very quickly fatigue the nasal sensory sites responsible for detecting it. This means that the intensity of the odor is a very poor indicator of the concentration of H_2S in the air. Headache and nausea begin at air concentrations of H_2S as low as 5 ppm, and exposure to 100 ppm leads to paralysis and may result in death.

TABLE 21.7 Comparison of the Properties of Group 16 Dihydrides

[illegible] (kJ/mol)
[illegible]
[illegible]
[illegible]
[illegible]

Similarly, organic compounds containing sulfur have properties that differ from those of their oxygen-containing counterparts. Many of them also have characteristic odors. Methanol is an alcohol with the formula CH_3OH. It is a liquid at room temperature and has an odor usually described as slightly alcoholic. Methanethiol (CH_3—SH) is a gas at room temperature and has the pungent odor of rotten cabbage. It is produced in the intestinal tract of animals by the action of bacteria on proteins and is one of the sulfur compounds responsible for the characteristic aroma of a feedlot or a barnyard.

If we consider compounds with two carbon atoms, ethanol (CH_3CH_2OH; beverage-grade alcohol) is a liquid at room temperature. The corresponding sulfur compound is a very low-boiling liquid called ethanethiol, which has a penetrating and unpleasant odor, like very powerful green onions. The human nose can detect the presence of ethanethiol at levels as low as 1 ppb (part per billion) in the air. This gives rise to its use as an odorant in natural gas. Natural gas has no odor, and natural gas leaks are such enormous fire hazards that ethanethiol is added to natural gas streams to make even small leaks detectable.

If we rearrange the atoms in ethanol and ethanethiol, we produce two new compounds. For ethanol we get dimethyl ether (CH_3—O—CH_3), a colorless gas used in refrigeration systems. Its counterpart, dimethyl sulfide (CH_3—S—CH_3), is one of the compounds responsible for the “low-tide” smell of ocean shorelines.

Three of the sulfur compounds described—hydrogen sulfide, methanethiol, and dimethyl sulfide—are referred to as volatile sulfur compounds (VSCs) by dentists. They are produced by bacteria in the mouth and are the principal compounds responsible for bad breath. One of the reasons the odors of these compounds differ from those of their oxygen counterparts is that their molecular sizes and shapes are slightly different. Also, their polarities differ because of the electronegativity difference between oxygen ($EN = 3.5$) and sulfur ($EN = 2.5$). Recall that we discussed the importance of molecular shape in determining the extent of interaction of a compound with receptors in nasal membranes in Section 9.5. In part, the vast differences in odor and sensory detectability of these compounds are due to their shapes and electron distributions.

Many sulfur compounds have an odor. The characteristic and unpleasant smell of urine produced by some people after eating asparagus results from the inability of their bodies to convert sulfur compounds (**Figure 21.13**) into odor-free sulfate ions. Not all people can convert the sulfur compounds in asparagus to sulfate, and not all people can smell the odiferous sulfur compounds. Apparently, genetic differences determine how we metabolize these compounds and how well we can sense their odors.

The odor of skunk is caused mostly by butanethiol (**Figure 21.14**), and the odor of well-used athletic shoes is caused primarily by the presence of sulfur compounds produced by bacteria. Not all sulfur compounds have aromas as unpleasant as these, however. A compound with the formula $C_{10}H_{18}S$ is responsible for the aroma of grapefruit. If the orientation of the substituents at the carbon atom circled in red in the molecule in **Figure 21.15a** is switched, the resulting molecule has the same Lewis structure but no aroma at all (**Figure 21.15b**). The carbon atom circled in red in Figure 21.15 is a chiral center, and the two compounds represent an enantiomeric pair (see Section 20.2).

SAMPLE EXERCISE 21.4 Drawing Lewis Structures for Molecules in the Sulfur Cycle LO3

Dimethyl sulfide (CH_3SCH_3) is one of the products of the sulfur cycle in Figure 21.11. In marine environments, dimethyl sulfide can be oxidized by bacteria to dimethyl sulfoxide [$(CH_3)_2SO$].

1. Draw Lewis structures for CH_3SCH_3 and $(CH_3)_2SO$, and determine the molecular geometry about the S atom in each.
2. Methanethiol (CH_3SH) is the simplest of the thiols and has a boiling point of 6°C. Dimethyl sulfide has a boiling point of 38°C. Explain the difference in boiling point between CH_3SH and CH_3SCH_3.
3. Which hybrid orbitals does sulfur use in bonding to carbon in CH_3SCH_3 and CH_3SH?

Collect and Organize We need to draw Lewis structures for two sulfur compounds, determine their geometry, and compare their boiling points. Guidelines for drawing Lewis structures were introduced in Section 8.2. We are also asked to describe the hybrid orbitals of S in these compounds. Hybrid orbitals were described in Section 9.4. The effect of structure on boiling points was discussed in Section 10.2.

Analyze The Lewis structure for a molecule depends on the total number of valence electrons available, distributed over the atoms so that each atom has a complete octet (except H, which has a duet). Atoms with *Z*\$ 13 may have an expanded octet if such an arrangement leads to lower formal charges on the atoms. The arrangement of the bonding and lone pairs on the central atom allow us to predict intermolecular forces such as dipole–dipole interactions, hydrogen bonds, and dispersion forces, all of which can affect the boiling point of a substance. We can account for observed molecular geometries by combining *s* and *p* orbitals to form hybrid atomic orbitals such as sp, sp^2, and sp^3.

Solve (a) CH_3SCH_3 has a total of 20 valence electrons: 6 from the S atom, 6 from the H atoms, and 8 from the C atoms. These electrons can be distributed in six C—H single bonds and two S—C single bonds, with 4 electrons remaining as 2 nonbonding pairs on S. $(CH_3)_2SO$ has an oxygen atom bonded to sulfur, which brings an additional 6 valence electrons to the molecule, giving $(CH_3)_2SO$ a total of 26 valence electrons. Sharing one of the S lone pairs with O will complete the octets of both S and O but will leave O with a formal charge of -1 and sulfur with a formal charge of $+1$. Forming a S□O double bond makes the formal charges on both S and O equal to zero but requires that sulfur have an expanded octet. The two structures for $(CH_3)_2SO$ represent resonance forms:

(b) CH_3SH has 14 valence electrons: 6 from the S atom, 4 from the H atoms, and 4 from the C atom. The electrons are distributed in three C—H single bonds, one C—S single bond, and one S—H single bond. As in CH_3SCH_3, there are 2 nonbonding pairs left on S. Both CH_3SCH_3 and CH_3SH contain a sulfur atom surrounded by 2 bonding pairs and 2 nonbonding pairs of electrons for a total of 4 electron pairs. The electron-pair geometry is tetrahedral, and the molecular geometry is bent:

Both CH_3SH and CH_3SCH_3 are polar as a result of their molecular geometry and experience dipole–dipole interactions. Both molecules interact through dispersion forces as well. One might expect that the stronger dipole–dipole forces in CH_3SH would lead to a higher boiling point than for CH_3SCH_3, but we observe the opposite. We conclude that the dispersion forces in CH_3SCH_3 have a greater effect than the dipole–dipole interactions in CH_3SH, leading to CH_3SCH_3 boiling at a temperature about 32°C higher than CH_3SH.

(c) The similar geometry for CH_3SCH_3 and CH_3SH, with each molecule's central sulfur atom having 2 bonded atoms and 2 lone pairs, is consistent with sp^3 hybrid orbitals on the sulfur atom in both cases.

Think About It Methanethiol and dimethyl sulfide differ only in that CH_3SCH_3 has a CH_3 group in place of a hydrogen atom. (This relationship between thiols and sulfides corresponds to the relationship between alcohols and ethers.) Sulfur does not expand its octet in these compounds because using the lone pairs on S to form multiple bonds is not needed. The boiling points of CH_3SCH_3 and CH_3SH reveal an important observation: many weaker bonds (dispersion forces) in CH_3SCH_3 can outweigh a few stronger forces (dipole–dipole forces) in CH_3SH.

Practice Exercise The nitrogen cycle in Figure 21.8 involves both neutral compounds such as NO_2 and polyatomic ions such as NO_2^-. Draw Lewis structures for both species and determine whether they have the same molecular geometry about nitrogen. Identify which hybrid orbitals contain nitrogen lone pairs in NO_2 and NO_2^-.

Glossary

ion channel

a group of helical proteins that penetrate cell membranes and allow selective transport of ions.

ion pump

a system of membrane proteins that exchange ions inside the cell with those in the intercellular fluid.

membrane potential, E_{membrane}

a weighted average of the equilibrium (reversal) potentials of the major ions based on concentration and permeability of the individual ions.

equilibrium (reversal) potential, E_{ion}

an electrochemical potential that results from a concentration gradient of a particular ion on opposite sides of a cell membrane.

equilibrium (reversal) potential, E_{ion}

an electrochemical potential that results from a concentration gradient of a particular ion on opposite sides of a cell membrane.

Endnotes

- H_2Po is excluded; too little is known of its chemistry.

Polonium has no stable isotopes and is present on Earth only in very small quantities.Return to reference a

21.4 Trace and Ultratrace Essential Elements

Figure 21.16 shows the DRI values of four main group essential elements: silicon, selenium, fluorine, and iodine. Silicon, fluorine, and iodine are present in the body in average concentrations between 1 and 1000 μg of element per gram of body mass and are considered trace elements. Selenium is considered ultratrace, meaning that it is present in an average concentration of less than 1 μg of element per gram of body mass.

Selenium

The volatile selenium analog to water, H_2Se, is toxic; however, selenium is considered an ultratrace essential element. The average concentration of Se in the human body is 0.3 μg per gram of body mass. Mounting scientific evidence points to a need for a minimum daily dose of approximately 55 μg of selenium. The effects of selenium toxicity, however, are apparent in people who ingest more than 500 μg per day. Most of the selenium we need is obtained from selenium-rich produce such as garlic, mushrooms, and asparagus, or from fish. Selenium occurs in the body as the amino acid selenocysteine (**Figure 21.17**) and is incorporated into enzymes.

Selenocysteine is an antioxidant. Our bodies need oxygen to survive, yet living in an oxygen-rich atmosphere can lead to the formation of potentially dangerous oxidizing agents in cells. For example, metabolism of fatty acids forms oxidizing agents called alkyl hydroperoxides, which can attack the lipid bilayer of cell membranes. It is believed that aging is related to the inability of the body to inhibit oxidative degradation of tissue. Selenocysteine participates in a series of reactions that result in the decomposition of these alkyl hydroperoxides.

Fluorine and Iodine

Fluorine is a trace essential element, and fluoride ions have significant benefits for dental health. Tooth enamel is composed of the mineral hydroxyapatite, $Ca_5(PO_4)_3(OH)$, which is essentially insoluble in water:

When hydroxyapatite comes into contact with weak acids in your mouth, this equilibrium shifts to the right as the acid reacts with the hydroxide ions. This shift effectively increases the solubility of hydroxyapatite, so that your tooth enamel becomes pitted, and dental caries form. Fluoride ions reduce the likelihood of caries by displacing the OH^- ions in hydroxyapatite to form fluorapatite:

The solubility of fluorapatite depends less on pH than the solubility of hydroxyapatite, so changing tooth enamel to fluorapatite makes your teeth more resistant to decay. This is why toothpaste contains fluoride compounds and why fluoride is added to drinking water in many communities in North America and Europe.

CONNECTION The solubility product (K_{sp}) was introduced in Section 16.8. Le Châtelier’s principle was discussed in Section 14.7.

Of all the trace essential elements, iodine may have the best-defined role in human health. The body concentrates iodide ions in the thyroid gland, where they are incorporated into two hormones—thyroxine and 3,5,39-triiodothyronine (**Figure 21.18**)—whose role is to regulate energy production and use. The conversion of thyroxine to 3,5,39-triiodothyronine is catalyzed by selenocysteine-containing proteins. A deficiency of iodine or of either hormone can cause fatigue or feeling cold and can ultimately lead to an enlarged thyroid gland, a condition known as goiter. To help prevent iodine deficiency, table salt sold in the United States and many other countries is “iodized” with a small amount of sodium iodide. An excess of either hormone can cause a person to feel hot and is linked to Graves’ disease, an autoimmune disease. The immune system in a patient with Graves’ disease attacks the thyroid gland and causes it to overproduce the two hormones.

Silicon

The role of silicon in biological systems is less clear than for selenium and the halides. In mammals, a lack of the trace essential element silicon stunts growth. The presence of silicon as silicic acid, $Si(OH)_4$, is believed to reduce the toxicity of Al^{3+} ions in organisms by precipitating the aluminum as aluminosilicate minerals. Amorphous silica, SiO_2, is found in the exoskeletons of diatoms and in the cell membranes of some plants, such as the tips of stinging nettles.

21.5 Nonessential Elements

The ten elements listed in Table 21.2 are found in the human body but are classified as nonessential. In Section 21.5 we discuss how some of these elements may end up in our bodies, working our way from left to right across the periodic table.

Rubidium and Cesium

Rubidium is generally regarded as nonessential in humans, yet it is the 15th most abundant element in the body. It is believed that Rb^+ is retained by the body because of the similarity of its size and chemistry to that of K^+. Like the other cations of group 1, cesium ions (Cs^+) are also readily absorbed by the body. Cesium cations have no known function, although they can substitute for K^+ and interfere with potassium-dependent functions. Usually, the concentration of cesium in the environment is low, so exposure to Cs^+ is not a health concern. The nuclear accident at Chernobyl in 1986, however, released significant quantities of radioactive ^{137}Cs into the environment. The ability of Cs^+ to substitute for K^+ led to the incorporation of $^{137}Cs^+$ into plants, which rendered crops grown in the immediate area unfit for human consumption because of the radiation hazard posed by this long-lived ($t_{1/2} < 30$ yr) β emitter.

Strontium and Barium

Some single-celled organisms build exoskeletons made with $SrSO_4$ and $BaSO_4$, but the human body appears to have no use for Sr^{2+} and Ba^{2+} ions. These ions do find their way into human bones, where they replace Ca^{2+} ions. At the low concentrations of Sr^{2+} and Ba^{2+} that are typically present in the human body, these elements appear to be benign. As with radioactive ^{137}Cs, however, incorporation of ^{90}Sr ($t_{1/2} = 29$ yr) in bones can lead to leukemia. Atmospheric testing of nuclear weapons over the Pacific Ocean and in sparsely populated regions of the American West in the 1950s released ^{90}Sr into the environment. The full extent of the toxic effects of the fallout from these tests did not become apparent for several decades.

CONNECTION The biological effects of different types of nuclear radiation were described in Section 19.6.

CONNECTION We discussed the St. Louis Baby Tooth Survey and the effect of nuclear testing on children’s teeth in Section 2.1.

Germanium

Germanium is a nonessential element and is barely detectable in the human body. Bis(carboxyethyl)germanium sesquioxide (**Figure 21.19**) has been touted as a nutritional supplement, but its efficacy remains in doubt.

Antimony

The role of antimony is also poorly understood. Most antimony compounds are toxic because they cause liver damage. However, ultratrace amounts of antimony may have a stimulatory effect, and selected antimony compounds have been used medically as antiparasitic agents, as discussed in Section 21.6.

Bromine

Bromine has no known function in the human body but is consumed in foods such as grains, nuts, and fish in amounts ranging from 2 to 8 mg per day, leading to average concentrations of Br^- in blood of about 6 mg/L. Bromide ion has sedative and anticonvulsive properties but becomes toxic at concentrations around 100 mg/L, limiting its use to veterinary medicine. Bromide ion concentrations in seawater typically range from 65 to 80 mg/L. A select group of aquatic species can metabolize Br^- into bromomethane (CH_3Br) and other brominated organic compounds.

CONCEPT TEST

Looking at groups 1, 2, 14, 15, and 17, what periodic trend do you see in the location of the nonessential elements compared with the essential elements in the same group?

21.6 Elements for Diagnosis and Therapy

So far we have talked about the biological roles of several essential and nonessential main group elements found in our bodies. Some of these elements are also useful in diagnosing or treating diseases, as are some of the other elements in groups 1, 2, and 13–18 that we have not mentioned (**Figure 21.20**). In this section we describe some of the applications of radioactive isotopes in the diagnosis of diseases. We also explore how compounds of essential and nonessential elements have found application in the treatment of a wide variety of illnesses.

Any diagnostic or therapeutic compound that is injected intravenously must be sufficiently soluble in blood to be delivered to the target. While in transit, the compound must be stable enough not to undergo chemical reactions that result in its precipitation or rapid elimination from the body. A medicinal chemist can also take advantage of substances that occur naturally in the body, such as antibodies, to carry a diagnostic or therapeutic metal ion to its target. We focus here on the main group elements and their compounds (groups 1, 2, and 13–18). Medical applications of compounds containing the transition elements (groups 3–12) are described in Chapter 22.

Diagnostic Applications

Physicians in the 21st century have an array of imaging agents to help in diagnosing disease. Some methods use radionuclides with short half-lives that emit easily detectable gamma rays. Examples include the use of iodine-131 to image the thyroid gland (**Figure 21.21**) and of neutron-poor isotopes such as carbon-11 and fluorine-18 for positron emission tomography (PET). Not all imaging depends on radionuclides, however. In magnetic resonance imaging (MRI), for instance, which can diagnose soft-tissue injuries, stable isotopes of gadolinium (a lanthanide) are heavily used as contrast agents to enhance images despite their toxicity to kidneys.

Imaging with Radionuclides The radionuclides used in medicine have short half-lives to limit the patient’s exposure to ionizing radiation. If the half-life is too short, however, the nuclide may either decay before it can be administered or not reach the target organ rapidly enough to provide an image. Emission of relatively low-energy γ rays is essential to preventing collateral tissue damage.

Nuclide selection is also governed by the toxicity of both the parent element and the daughter nuclide. The speed at which the imaging agent is eliminated from the body can help mitigate toxic effects. The cost and availability of a particular nuclide also factor into its usefulness in a clinical setting.

CONNECTION Chapter 19 gives a more detailed discussion of nuclear chemistry and nuclear medicine, including an assessment of the effects of different types of radiation on living tissue.

CONCEPT TEST

Why is it important to consider the nature of the decay products—α, β, or γ particles, or positrons—when choosing a radionuclide for medical imaging?

Gallium, Indium, and Thallium Gallium-66, gallium-67, gallium-68, and indium-111 are used as imaging agents for tumors and leukemia. All four nuclides decay by electron capture, and the γ radiation emitted in this nuclear reaction produces the images. All three gallium isotopes also decay by positron emission, which makes compounds containing these isotopes attractive for positron-emission tomography. Their half-lives range from just over 1 h for gallium-68 to 78 h for gallium-67. The indium-111–containing compound Zevalin is currently used to treat some forms of non-Hodgkin's lymphoma. It is formed by reacting indium(III) chloride with the molecule in Figure 21.22. The indium 3+ ion acts as a Lewis acid and forms coordinate bonds of the type described in Section 16.6. Ibritumomab in Figure 21.22 is an antibody used to transport the radioactive indium to its target.

The use of the γ emitter thallium-201 ($t_{1/2} = 73$ h) in diagnosing heart disease presents an interesting case for balancing the risks and benefits of using a particular isotope in medicine. Although thallium compounds are among the most toxic metal-containing compounds known, the nanogram quantities required for diagnosis pose few, if any, health hazards, meaning that the benefits outweigh the risks.

SAMPLE EXERCISE 21.5 Calculating Quantities of Radioactive Isotopes LO5

Indium-111 ($t_{1/2} = 2.805$ d) and gallium-67 ($t_{1/2} = 3.26$ d) are both used in radioimaging to diagnose chronic infections. Which isotope decays faster? If we start with 10.0 mg of each isotope, how much of each remains after 24 h (1 d)?

Collect and Organize We are given the half-lives of two radionuclides and asked to predict which one will decay faster and to calculate how much of each isotope remains after 24 h of decay.

Analyze An isotope with a shorter half-life decays faster. Radioactive decay follows first-order kinetics. Quantitatively, the relationship between half-life and the amount of material remaining is described by the following equation from Section 19.5:

Here N_0 and N_t refer to the amount of material present initially and the amount at time *t*, respectively. If our prediction for the relative decay rates of the two isotopes is correct, then more of the isotope with the longer half-life should remain after 24 h. We need to complete two calculations to determine the amount of each sample present after 24 h.

Solve Indium-111 has the shorter half-life, so it should decay faster.

For the amount of indium-111 remaining after 24 h, we have

Taking the antilog of both sides, we get

For gallium-67:

Think About It We predicted that indium-111 would decay faster, which means that after 24 h the quantity of this isotope should be less than the quantity of gallium-67, and it is.

Practice Exercise Two radioactive isotopes of bismuth are used to treat cancer. The half-lives are 61 min for bismuth-212 and 46 min for bismuth-213. If we start with 25.0 mg of each isotope, how much of each sample remains after 24 h?

CONNECTION Tritium is produced in nuclear reactors by bombarding ^{6}Li and ^{7}Li with high-energy neutrons. The reactions involved (Equations 19.13 and 19.14) are discussed in Section 19.9.

Imaging with Noble Gases and MRI None of the noble gas elements are essential to the human body, although the World Anti-Doping Agency (WADA) has added both Xe and Ar to the list of banned substances for athletes at Olympic and other sporting events since 2014. Apparently, in addition to behaving as an anesthetic, xenon increases the oxygen-carrying capacity of blood, providing an advantage in aerobically demanding sports. Similar effects are believed to occur with argon.

The lack of chemical reactivity of the group 18 elements and their ease of introduction into the body by inhalation, however, make selected isotopes of the noble gases—including helium-3, krypton-83, and xenon-129—attractive as agents for enhancing MRI images, particularly of the lungs. Krypton-83 provides greater sensitivity than xenon-129, allowing for better resolution in the images and, in principle, requiring the use of less gas.

Helium-3 has no known side effects and is preferable to xenon-129 for MRI, but it is present in only trace natural abundance. This isotope is obtained from β decay of tritium (^{3}H):

Neon-19 has been used in PET despite its short half-life (17.5 s). A patient positioned in a PET scanner breathes air containing a small amount of this isotope. Positron emission from the neon is recorded, and an image is created.

Therapeutic Applications

We next examine therapeutic agents that contain metallic and heavier main group elements in addition to carbon, hydrogen, nitrogen, oxygen, and sulfur.

Lithium, Boron, Aluminum, and Gallium The similar size of Li^+ (76 pm) and Mg^{2+} (72 pm) means that lithium ions can compete with magnesium ions in biological systems. The substitution of lithium for magnesium may account for its toxicity at high concentrations. Nevertheless, lithium carbonate is used to treat bipolar disorder, and other lithium compounds have been used to treat hyperactivity. In all cases, however, the use of lithium-containing drugs must be carefully monitored.

Of the elements of group 13, only boron and aluminum have been detected in humans. The role of boron in our bodies is not fully understood, but it appears to play a role in nucleic acid synthesis and carbohydrate metabolism. Selected boron compounds appear to concentrate in human brain tumors. This property has opened the door to a treatment known as boron neutron-capture therapy (BNCT). Once a suitable boron compound has been injected and has made its way to a tumor, irradiation of the tumor with low-energy neutrons leads to the nuclear reaction

The α particles generated in the reaction have a short penetration depth but high relative biological effectiveness (RBE), so they can kill the tumor cells without harming surrounding tissue. The identification of compounds suitable for BNCT remains an area of active research.

CONNECTION The relative biological effectiveness (RBE) of radioactive particles is a factor that accounts for the differences in physical damage caused by different types of radiation. It was introduced in Section 19.6.

Aluminum is found in some antacids as aluminum hydroxide, $Al(OH)_3$, or aluminum carbonate, $Al_2(CO_3)_3$. Some brands of baking powder contain sodium aluminum sulfate, $NaAl(SO_4)_2 \cdot 12\ H_2O$. Most of the aluminum in the human body can be traced to these sources. Aluminum is not considered essential to humans, but low-aluminum diets have been observed to harm goats and chickens. High concentrations of aluminum are clearly toxic; the effects are most noticeable in patients with impaired kidney function. The role of aluminum in Alzheimer’s disease has been extensively debated but remains unresolved.

Simple gallium compounds such as gallium(III) nitrate and gallium(III) chloride, either alone or in combination with other drugs, have shown activity on bladder and ovarian cancers. The similar ionic radii of Ga^{3+} (62 pm) and Fe^{3+} (64.5 pm) allow gallium to block DNA synthesis by replacing iron in a protein called transferrin and in other enzymes. Because gallium compounds accumulate in tumors at a higher rate than in healthy tissue, the disruption of DNA synthesis in the tumor cells inhibits tumor growth.

Antimony and Bismuth Antimony compounds are generally considered toxic. It has been reported, for instance, that exposure of infants to antimony compounds used as fire retardants in mattresses may contribute to sudden infant death syndrome (SIDS). However, this element does appear to have a medical use. Leishmaniasis, an insect-borne disease characterized by the formation of boils or skin lesions, is resistant to most treatments, but some patients have been successfully treated with sodium stibogluconate, one of the few applications of antimony compounds in human health.

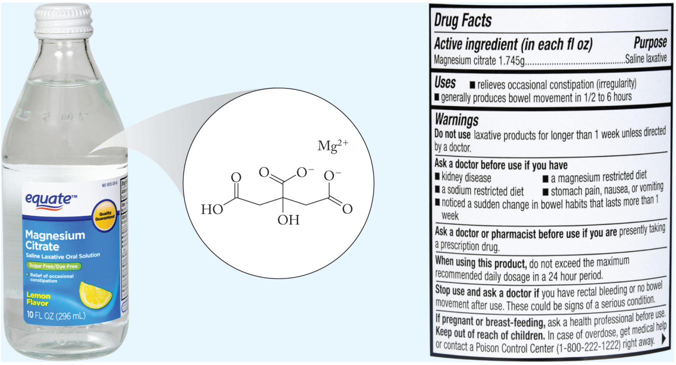
Popular over-the-counter remedies for indigestion, diarrhea, and other gastrointestinal disorders contain bismuth subsalicylate (**Figure 21.23**). The bismuth in these compounds acts as a mild antibacterial agent that reduces the number of bacteria that cause diarrhea.

The human body requires about 30 elements to function properly. To manage the problems of disease and injury, scientists, physicians, engineers, and scores of other people have turned to the properties of these and many other elements in the periodic table to develop treatments and to enhance quality of life. In this chapter we have briefly introduced the roles of the main group elements in establishing and maintaining living systems.

SAMPLE EXERCISE 21.6 Integrating Concepts: Colonoscopy

Many patients undergoing gastrointestinal medical procedures, such as a colonoscopy to screen for colon cancer, must drink about 230 mL of a magnesium citrate solution ($MgC_6H_6O_7$; $\mathcal{M} = 214.41$ g/mol), which serves as a laxative that clears the large intestine. Magnesium citrate (**Figure 21.24**) is an electrolyte composed of magnesium(II) ions and citrate ions.

1. As indicated on the label in Figure 21.24, the solution contains 1.745 g magnesium citrate per fluid ounce (fl oz). What is the molarity of this solution? (There are 29.57 mL in 1.000 fl oz.)
2. What is the osmotic pressure (Π) of the solution at 37°C? Its van ’t Hoff factor (i) is 1.09.
3. Most electrolytes composed of $2+$ cations and $2-$ anions have van ’t Hoff factors closer to 2 than to 1 at the concentration calculated in part (a). Propose a reason why the i value for sodium citrate is so low. In developing your answer, consider the structure of citrate ions and how they might interact with Mg^{2+} ions in aqueous solutions.
4. The walls of the small intestine act as a semipermeable membrane, allowing water to pass from the cells of the tissues surrounding the small intestine into the fluid within it or in the reverse direction from inside the small intestine into the cells of the surrounding tissues. If the osmotic pressure in these cells is about 3.5 atm, in which direction will osmosis occur if the fluid passing through the small intestine has an osmotic pressure near that of the solution in the bottle?



Drug Facts

Active ingredient (in each fl oz) — **Purpose**

Magnesium citrate 1.745g .... Saline laxative

Uses ■ relieves occasional constipation (irregularity) ■ generally produces bowel movement in 1/2 to 6 hours

Warnings

Do not use laxative products for longer than 1 week unless directed by a doctor.

Ask a doctor before use if you have
- ■ kidney disease
- ■ a magnesium restricted diet
- ■ a sodium restricted diet
- ■ stomach pain, nausea, or vomiting
- ■ noticed a sudden change in bowel habits that lasts more than 1 week

Ask a doctor or pharmacist before use if you are presently taking a prescription drug.

When using this product, do not exceed the maximum recommended daily dosage in a 24 hour period.

Stop use and ask a doctor if you have rectal bleeding or no bowel movement after use. These could be signs of a serious condition.

If pregnant or breast-feeding, ask a health professional before use.
Keep out of reach of children. In case of overdose, get medical help or contact a Poison Control Center (1-800-222-1222) right away.

FIGURE 21.24 Structure of magnesium citrate.

Collect and Organize We are asked to calculate the molar concentration and osmotic pressure of a solution of magnesium citrate. These two properties of the solution are related by the equation $\Pi = iMRT$. We are also asked if water will flow into or out from the small intestine if the fluid in the small intestine has nearly the same osmotic pressure as the $MgC_6H_6O_7$ solution. The osmotic pressure of the fluid in the cells of the surrounding tissues is about 3.5 atm.

Analyze We first need to convert the concentration of the $MgC_6H_6O_7$ solution from g/fl oz into molarity. There are nearly 2 g $MgC_6H_6O_7$/fl oz in the solution; there are about 30 mL in 1 fl oz, and $MgC_6H_6O_7$ has a molar mass near 200 g/mol. Therefore, the molarity of the solution should be about 2 g/fl oz × 1 fl oz/30 mL × 1000 mL/L × 1 mol/200 g = 0.3 mol/L. The van 't Hoff factor i is about 1, and the temperature is 37 + 273 = 310 K, so the value of Π should be about 0.3 mol/L × 0.08 L · atm/(mol · K) × 300 K = 7 atm. This value is about twice that of the fluids surrounding the small intestine.

Solve

1. Calculating the molarity of the $MgC_6H_6O_7$ solution:

$$\frac{1.745\ \cancel{\text{g}}}{1\ \cancel{\text{fl oz}}} \times \frac{1.000\ \cancel{\text{fl oz}}}{29.57\ \cancel{\text{mL}}} \times \frac{1000\ \cancel{\text{mL}}}{1\ \text{L}} \times \frac{1\ \text{mol}}{214.41\ \cancel{\text{g}}} = 0.2752\ \text{mol/L}$$

2. Calculating the osmotic pressure of this solution:

$$\Pi = iMRT = 1.09 \times 0.2752\ \frac{\cancel{\text{mol}}}{\cancel{\text{L}}} \times 0.08206\ \frac{\cancel{\text{L}} \cdot \text{atm}}{\cancel{\text{mol}} \cdot \cancel{\text{K}}} \times 310\ \cancel{\text{K}} = 7.63\ \text{atm}$$

3. The molecular structure of the citrate ion includes two carboxylate groups, which means it could form $2+/2-$ ion pairs with Mg^{2+} ions. In addition, the lone pairs of electrons on the O atoms in these and other groups in the citrate ions may form multiple coordinate bonds with Mg^{2+} ions, which, as we discussed in Chapter 16, could lead to the formation of complex ions that would further reduce the number of independent solute particles in solution.
4. The osmotic pressure of the $MgC_6H_6O_7$ solution is more than twice that in the cells of the tissues surrounding the walls of the small intestine. This means water will spontaneously flow from those cells into the small intestine if the fluid inside the small intestine has nearly the same osmotic pressure as the $MgC_6H_6O_7$ solution.

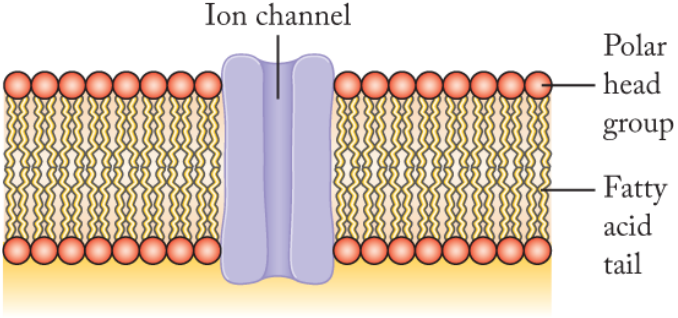
Think About It Osmotic laxatives such as magnesium citrate work by drawing water into the intestines. This softens the waste in the large intestine, which makes bowel movements easier, and it also stimulates muscle action that helps speed up the clearance process.

Learning Objectives

- Describe the health hazards posed by some radioactive isotopes of main group elements and the use of others in medical diagnosis and therapy **Return to Sample Exercise 21.5**

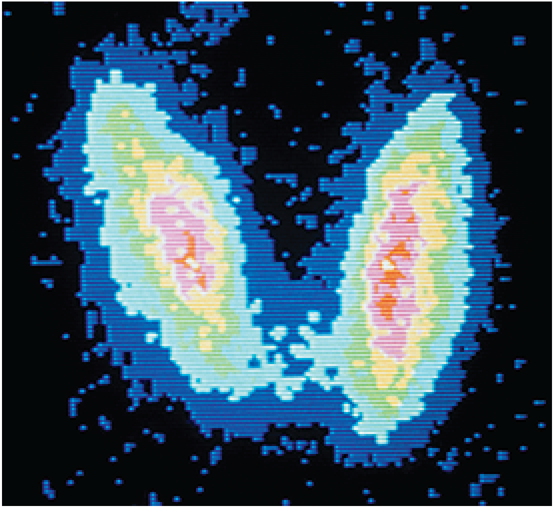
SUMMARY

LO1 Essential elements have a physiological function in the body. Nonessential elements are present in the body but have no known functions. Some may have stimulatory effects. Essential elements are categorized as major, trace, or ultratrace essential elements depending on their concentrations in the body. (Sections 21.1 and 21.2)



- LO2 Transport of Na^+ and K^+ across cell membranes involves ion pumps or selective transport through ion channels. Chloride ion is the most abundant anion in the human body, facilitating transport of alkali metal cations and elimination of CO_2. Differences in concentrations of ions inside and outside cell membranes give rise to a membrane potential, which determines the permeability of ions through the membrane. (Section 21.3)
- LO3 Acid–base chemistry and redox reactions are of great significance in living systems. The principles of structure and electron distribution in molecules apply to interactions *in vivo* just as they do in the laboratory. (Sections 21.3, 21.4, and 21.5)
- LO4 The most abundant elements in the human body include seven nonmetals (C, H, O, Cl, S, P, and N) and four metals (Ca^{2+}, K^+, Na^+, and Mg^{2+}). Nonessential elements from groups 1 and 2 may be absorbed into cells or substituted into bone or other tissues because they are similar in size and

charge to essential elements. Some nonessential elements are used in nutritional supplements, whereas others have therapeutic properties in low concentrations but are toxic at higher levels. (Sections 21.3, 21.4, and 21.5)



- LO5 Radionuclides with short half-lives that emit low-energy γ rays are used in assessing function and diagnosing disease. The selection of a radionuclide for medical use is governed by the toxicities of the element and its daughter nuclides, its radioactive half-life, and the speed at which it is eliminated from the body. (Section 21.6)
- LO6 Main group elements beyond the essential elements are useful in a wide variety of compounds with therapeutic value. Lithium salts are used in treating depression, whereas aluminum compounds find use as antacids. Fluoride in toothpaste helps prevent cavities. (Section 21.6)

PARTICULATE PREVIEW WRAP-UP

From left to right, the ions are Ca^{2+}, Na^+, H_3O^+, and K^+. The H_3O^+ ion is most likely to undergo selective transport through the sodium ion channel as a result of its similar charge and size. None of the other three ions is likely to pass through the K^+ ion channel because those ions differ in size from the K^+ ion.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts and Equations	Sample Exercises
Calculating equilibrium potential (E_{ion}) for ions and ΔG for ion transport	Calculate E_{ion} by using the Nernst equation: $E_{ion} = \frac{RT}{nF}\ln\left(\frac{[M^{x+}_{outside}]}{[M^{x+}_{inside}]}\right)$ (21.1) Calculate ΔG by using the relationships between ΔG and E: $E_{transport} = E_{membrane} - E_{ion}$ (21.2) $\Delta G_{transport} = -nFE_{transport}$ (21.3)	21.1
Calculating an acid concentration from its pH	Relate the pH of a solution to its $[H_3O^+]$ by the pH equation $pH = -\log[H_3O^+]$ (15.10)	21.2
Assigning oxidation numbers and writing half-reactions	Use the guidelines in Section 4.8.	21.3
Drawing Lewis structures for molecules	Use the guidelines in Sections 8.2 and 9.4.	21.4
Calculating quantities of radioactive isotopes	Use the equation $\ln\frac{N_t}{N_0} = -0.693\frac{t}{t_{1/2}}$ where N_0 and N_t are the amounts of material present initially and at time t, respectively.	21.5

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

Which part of Figure P21.1 best describes the periodic trend in monatomic cation radii moving up or down a group or across a period in the periodic table? (Arrows point in the direction of *increasing* radii.)

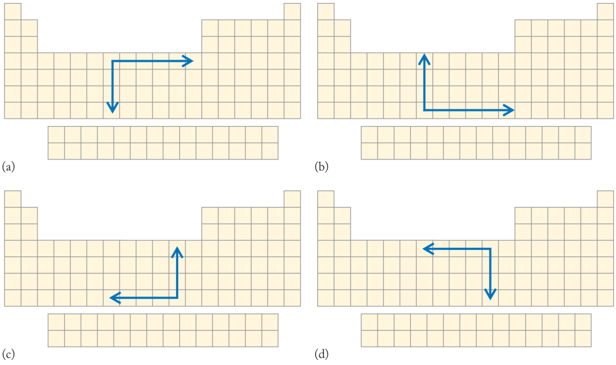


FIGURE P21.1

Which part of Figure P21.1 best describes the periodic trend in monatomic anion radii moving up or down a group or across a period in the periodic table? (Arrows point in the direction of *increasing* radii.)

Which of the two groups highlighted in the periodic table in Figure P21.3 typically forms ions that have *larger* radii than those of the corresponding neutral atoms?

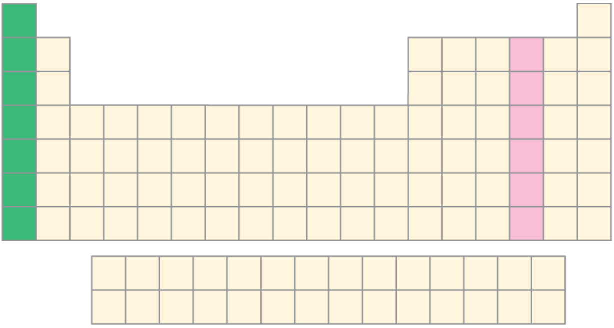

FIGURE P21.3

Which of the two groups highlighted in the periodic table in Figure P21.4 typically forms ions that have *smaller* radii than those of the corresponding neutral atoms?

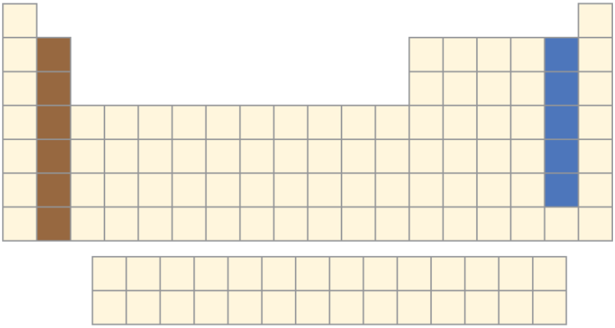

FIGURE P21.4

As we saw in Chapter 18, the free energy (ΔG) of a reaction is related to the cell potential by the equation $\Delta G = -nFE$. In Figure P21.5, two solutions of Na^+ of different concentrations are separated by a semipermeable membrane. Calculate ΔG for the transport of Na^+ from the side with higher concentration to the side with lower concentration.

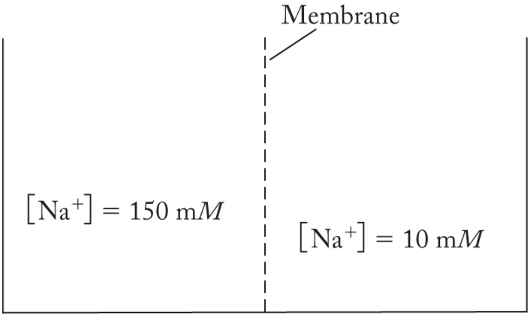

FIGURE P21.5

Two solutions of K^+ are separated by a semipermeable membrane in Figure P21.6. Calculate ΔG for the transport of K^+ from the side with lower concentration to the side with higher concentration.

QUESTIONS AND PROBLEMS

Main Group Elements and Human Health

Concept Review

What is the difference between an essential element and a nonessential element?

Are all essential elements major essential elements?

What is the main criterion that distinguishes major, trace, and ultratrace essential elements from one another?

Should trace essential elements also be considered to be stimulatory?

Problems

The concentrations of very dilute solutions are sometimes expressed as parts per million. Express the concentration of each of the following trace and ultratrace essential elements in parts per million:

1. Fluorine, 110 mg in 70 kg
2. Silicon, 5.25 mg/kg
3. Iodine, 0.043 g in 100 kg

In the human body, the concentrations of ultratrace essential elements are even lower than those of trace essential elements and therefore are sometimes expressed in parts per billion. Express the concentrations of each of the following elements in parts per billion:

1. Bromine, 6 mg/L
2. Boron, 0.014 g/100 kg
3. Selenium, 5.0 mg/70 kg

Which element in each of the following pairs is more abundant in the human body? (a) silicon or oxygen; (b) iron or oxygen; (c) carbon or aluminum

Which element in each of the following pairs is more abundant in the human body? (a) H or Si; (b) Ca or Fe; (c) N or Cr

Periodic Properties of Main Group Elements

Concept Review

In Chapter 2 we defined main group elements as those elements found in groups 1, 2, and 13–18 in the periodic table. Why do some chemists refer to these as the “*s*-block” and "*p*-block" elements, respectively?

Why do we classify the main group elements by group rather than by period?

Lithium oxide (Li_2O) and carbon monoxide (CO) have nearly the same molar mass. Why is Li_2O a solid with a high melting point, whereas CO is a gas?

The nonradioactive group 17 elements are found as diatomic molecules, X_2 (X = F, Cl, Br, I). Why is Br_2 a liquid at room temperature, whereas Cl_2 is a gas?

Which of the following properties can be used to distinguish a metallic element from a semimetallic element: atomic radius, electrical conductivity, and/or molar mass?

Which of the following cannot be measured: ionization energy, electron affinity, ionic radius, atomic radius, or electronegativity?

Why is Be^{2+} more likely than Ca^{2+} to displace Mg^{2+} in biomolecules?

PbS, $PbCO_3$, and PbCl(OH) have limited solubility in water. Which of them is/are more likely to dissolve in acidic solutions?

Problems

Which ion channel—K^+ or Na^+—must accommodate the larger cation?

Which ion is larger: Cl^- or I^-?

Place the following ions in order of increasing ionic radius: Mg^{2+}, Li^+, Al^{3+}, and Cl^-.

Place the following ions in order of increasing ionic radius: Br^-,

O^{2-}, K^+, and Ca^{2+}.

Place the following elements in order of increasing electronegativity: K, S, F, and Mg.

When we compare any two main group elements, is the element with the smaller atomic radius always more electronegative?

Why can we estimate the electron affinity of Cl atoms by measuring the ionization energy of a Cl^- anion?

Place the following ions in order of increasing ionization energy: Na^+, S^{2-}, F^-, and Mg^+.

Major Essential Elements

Concept Review

Ion Transport in Cells Describe three ways in which ions of major essential elements (such as Na^+ and K^+) enter and exit cells.

Which transport mechanism for ions requires ATP: diffusion, ion channels, or ion pumps?

Why is it difficult for ions to diffuse across cell membranes?

Why does Sr^{2+} substitute for Ca^{2+} in bones?

Which alkali metal ion is Rb^+ most likely to substitute for?

Why don’t alkaline earth metal cations substitute for alkali metal cations in cases where the ionic radii are similar?

Why might nature have selected calcium carbonate over calcium sulfate as the major exoskeleton material in shells?

Bromide ion and fluoride ion are nonessential elements in the body. Do you expect their concentrations to be more similar to the concentrations of major essential elements or to the concentrations of ultratrace essential elements?

Problems

Osmotic Pressure of Red Blood Cells One of the functions of the alkali metal cations Na^+ and K^+ in cells is to maintain the cells' osmotic pressure. The concentration of NaCl in red blood cells is approximately 11 m*M*. Calculate the osmotic pressure of this solution at body temperature (37°C).

Calculate the osmotic pressure exerted by a 92 m*M* solution of KCl in a red blood cell at body temperature (37°C).

Electrochemical Potentials across Cell Membranes Very different concentrations of Na^+ ions exist in red blood cells (11 m*M*) and the blood plasma (160 m*M*) surrounding those cells. Solutions with two different concentrations separated by a membrane constitute a concentration cell. Calculate the electrochemical potential created by the unequal concentrations of Na^+ at 310 K.

The concentration of K^+ in red blood cells is 92 m*M*, and the concentration of K^+ in plasma is 10 m*M*. Calculate the electrochemical potential created by the two concentrations of K^+ at 310 K.

Calcium Ion Pumps Transport of Ca^{2+} across cell membranes is critical for cardiac muscle cells. The $[Ca^{2+}]$ in these cells increases by $<10^2$ during contraction of the heart at 310 K. What electrochemical potential ($E°_{ion}$) does this difference in concentration correspond to?

Removing excess Na^+ from a cell by an ion pump requires energy. How many moles of ATP must be hydrolyzed to overcome a cell potential of -0.07 V? The hydrolysis of 1 mole of ATP provides 34.5 kJ of energy.

Genetic Engineering Plants require phosphate (PO_4^{3-}) to grow, and application of fertilizers that contain phosphate promotes the growth of the desired crops but also weeds, requiring the application of herbicides to kill the latter. In 2018 geneticists announced the development of a strain of cotton that could grow on *phosphite* (HPO_3^{2-}) rather than phosphate, while common weeds could not.

1. Draw Lewis structures for both anions and assign oxidation states to phosphorus in each. (The phosphite ion contains a P–H bond).
2. Why might phosphite-based fertilizers make it possible to use less herbicide?

Naming Molecular Ions The name “phosphite” for HPO_3^{2-} is misleading. By analogy to the nomenclature for polyoxoanions in Chapter 2, what molecular formula and charge does the term “phosphite” suggest? Draw a Lewis structure for this molecular ion.

Trace and Ultratrace Essential Elements; Nonessential Elements

Concept Review

What danger to human health is posed by ^{137}Cs ($t_{1/2} < 30$ yr)?

Why is ^{137}Cs ($t_{1/2} < 30$ yr) considered dangerous to human health, whereas naturally occurring ^{40}K ($t_{1/2} = 1.28 \times 10^6$ yr) is benign?

What are the likely signs of ΔS and ΔH for the dissolution of tooth enamel?

Why does fluorapatite resist acid better than hydroxyapatite if both are insoluble in water?

Why do superoxide ions (O_2^-) act as strong oxidizing agents?

Why are thyroxine and 3,5,39-triiodothyronine (Figure 21.18) considered amino acids? Why aren't they *essential* amino acids?

Problems

The Aroma of Coffee More than 1000 compounds have been identified in roasted coffee beans, many of which contribute to the aroma of brewed coffee when the beans are ground and extracted with water. Four sulfur compounds are included among the known aroma compounds in coffee (Figure P21.57).

1. Which compound do you expect to have the highest vapor pressure?
2. If we replaced the S with O, would you expect the vapor pressure of the resulting compounds to increase or decrease? Explain.

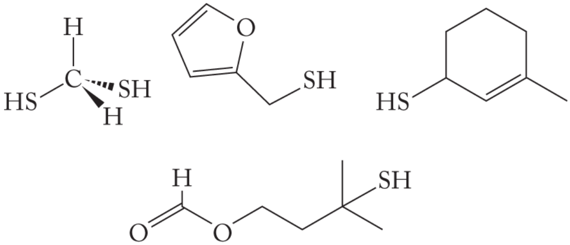

FIGURE P21.57

Identify the functional group that contains the sulfur in Figure P21.57 and determine whether any of these compounds are chiral. Are these compounds likely to be polar or nonpolar?

Calculate the pH of a $1.00 \times 10^{-3} M$ solution of selenocysteine ($pK_{a1} = 2.21$, $pK_{a2} = 5.43$).

Calculate the pH of a $1.00 \times 10^{-3} M$ solution of cysteine ($\mathrm{p}K_{a1} = 1.7$, $\mathrm{p}K_{a2} = 8.3$). Is selenocysteine a stronger acid than cysteine?

Composition of Tooth Enamel Tooth enamel contains the mineral hydroxyapatite. Hydroxyapatite reacts with fluoride ion in toothpaste to form fluorapatite. The equilibrium constant for the reaction between hydroxyapatite and fluoride ion is $K = 8.48$. Write the equilibrium constant expression for the following reaction. In which direction does the equilibrium lie?

$$\mathrm{Ca_3(PO_4)_3(OH)}(s) + \mathrm{F^-}(aq) \rightleftharpoons \mathrm{Ca_5(PO_4)_3(F)}(s) + \mathrm{OH^-}(aq)$$

Effects of Excess Fluoridation on Teeth Too much fluoride might lead to the formation of calcium fluoride according to the reaction

$$\mathrm{Ca_5(PO_4)_3(OH)}(s) + 10\ \mathrm{F^-}(aq) \rightleftharpoons 5\ \mathrm{CaF_2}(s) + 3\ \mathrm{PO_4^{3-}}(aq) + \mathrm{OH^-}(aq)$$

Write the equilibrium constant expression for the reaction. Given the K_{sp} values for the following two reactions, calculate K for the reaction between $\mathrm{Ca_5(PO_4)_3(OH)}$ and fluoride ion that forms $\mathrm{CaF_2}$.

$$\mathrm{Ca_5(PO_4)_3(OH)}(s) \rightleftharpoons 5\ \mathrm{Ca^{2+}}(aq) + 3\ \mathrm{PO_4^{3-}}(aq) + \mathrm{OH^-}(aq)$$

$$K_{\mathrm{sp}} = 2.3 \times 10^{-59}$$

$$\mathrm{CaF_2}(s) \rightleftharpoons \mathrm{Ca^{2+}}(aq) + 2\ \mathrm{F^-}(aq)$$

$$K_{\mathrm{sp}} = 3.9 \times 10^{-11}$$

Tooth enamel is actually a composite material containing both hydroxyapatite and a calcium phosphate, $\mathrm{Ca_8(HPO_4)_2(PO_4)_4 \cdot 6\ H_2O}$ ($K_{\mathrm{sp}} = 1.1 \times 10^{-47}$).

Is this calcium mineral more or less soluble than hydroxyapatite ($K_{\mathrm{sp}} = 2.3 \times 10^{-59}$)?

2. Calculate the solubility in moles per liter of hydroxyapatite [$Ca_5(PO_4)_3(OH)$], where $K_{sp} = 2.3 \times 10^{-59}$ in water at 25°C and pH = 7.00.
3. What is the solubility of hydroxyapatite at pH = 5.00?

The K_{sp} of actual tooth enamel is reported to be 1×10^{-58}.

1. Does this mean that tooth enamel is more soluble than pure hydroxyapatite ($K_{sp} = 2.3 \times 10^{-59}$)?
2. Does the measured value of K_{sp} for tooth enamel support the idea that tooth enamel is a mixture of hydroxyapatite [$Ca_5(PO_4)_3(OH)$] and a calcium phosphate, $Ca_8(HPO_4)_2(PO_4)_4 \cdot 6\ H_2O$ ($K_{sp} = 1.1 \times 10^{-47}$)?
3. Calculate the solubility in moles per liter of $Ca_8(HPO_4)_2(PO_4)_4 \cdot 6\ H_2O$ ($K_{sp} = 1.1 \times 10^{-47}$) in water at 25°C and pH = 7.00.

Lead in Drinking Water The municipal water systems of many older cities, including Flint, Michigan, still rely on water pipes made of lead or lead alloys. In principle, this is not as dangerous as it seems because lead corrodes, forming a protective coating of lead(II) carbonate ($PbCO_3$; Figure P21.65).

1. Calculate the molar solubility of $PbCO_3$.
2. The EPA limit for dissolved Pb^{2+} is 15 ppb. Does your answer to part (a) meet this standard?
3. How does the solubility of $PbCO_3$ depend on pH?

FIGURE P21.65

Removing Lead from Water To reduce the concentration of Pb^{2+} in drinking water, many treatment plants add phosphate ion (PO_4^{3-}) to the water to precipitate lead(II) phosphate.

1. Is $Pb_3(PO_4)_2$ ($K_{sp} = 3.0 \times 10^{-44}$) more or less soluble than $PbCO_3$?
2. Why does the addition of phosphate also regulate the pH of the solution?
3. Calculate the pH of a 0.125 *M* solution of Na_3PO_4.

All the group 16 elements form compounds with the generic formula H_2E (E = O, S, Se, or Te). Which compound is the most polar? Which compound is the least polar?

All the group 15 elements form compounds with the generic formula H_3E (E = N, P, As, Sb, and Bi). Which compound is the most polar? Which compound do you predict to have the smallest H–E–H bond angle?

Elements for Diagnosis and Therapy

Concept Review

When choosing an isotope for imaging, why is it important to consider the decay mode of the isotope as well as the half-life?

Why might an α emitter be a good choice for radiation therapy?

What advantage does a β emitter have over an α emitter for imaging?

Why do we sometimes use radioisotopes of toxic elements, such as thallium, for imaging?

Why does ^{213}Bi undergo β decay but ^{111}In decays by electron capture?

Several isotopes of arsenic are used in medical imaging. Which isotope, ^{72}As or ^{77}As, is more likely to be useful for PET imaging?

The World Anti-Doping Agency (WADA) added xenon and argon to the list of banned substances in 2014. Which intermolecular forces account for the solubility of Xe and Ar in blood?

Helium is used in SCUBA gear to prevent nitrogen narcosis. Do you expect the solubility of He in blood to be greater than or less than the solubility of Xe and Ar in blood?

Problems

PET Imaging with Gallium A patient is injected with a 5 μ*M* solution of gallium citrate containing ^{68}Ga ($t_{1/2} = 9.4$ h) for a PET study. How long is it before the activity of the ^{68}Ga drops to 5% of its initial value?

Iodine-123 ($t_{1/2} = 13.3$ h) has replaced iodine-131 ($t_{1/2} = 8.1$ d) for diagnosis of thyroid conditions. How long is it before the activity of ^{123}I drops to 5% of its initial value?

Like aqueous solutions of Fe^{3+} in Chapter 16, bismuth ions (Bi^{3+}) form acidic solutions with a $pK_a = 1.5$.

1. Write a balanced net ionic equation for the reaction of Bi^{3+} with water to form a dication, $Bi(H_2O)_5OH^{2+}$.
2. What is the pH of a 0.00364 *M* solution of Bi^{3+}?
3. Is this solution more or less acidic than an equimolar solution of vinegar? (*Note*: No calculation is necessary to answer this question.)

Some medicines used in treating depression contain lithium carbonate.

1. Draw the Lewis structure for Li_2CO_3.
2. Explain whether or not Li_2CO_3 hydrolyzes in water.
3. Calculate the solubility of Li_2CO_3 in water in moles/L.

Aluminum hydroxide is used in some antacids. Write a balanced net ionic equation for the reaction of aluminum hydroxide with HCl.

Aluminum carbonate is used in some antacids. Write a balanced net ionic equation for the reaction of aluminum carbonate with hydrochloric acid.

Maalox The antacid known as Maalox contains a mixture of magnesium and aluminum hydroxides.

1. Which substance will neutralize more acid on a per-mole basis?
2. Does the same substance also neutralize more acid on a per-gram basis?
3. How many grams of each are required to neutralize 115 mL of 0.75 *M* stomach acid?

Tums Sodium bicarbonate and calcium carbonate both act as antacids and are found in common stomach remedies such as Tums.

1. Which substance will neutralize more acid on a per-mole basis?
2. Does the same substance also neutralize more acid on a per-gram basis?
3. How many grams of each are required to neutralize 115 mL of 0.75 *M* stomach acid?

Il Campanello The 1836 opera *Il Campanello* by Gaetano Donizetti features the farcical troubles of a newly wed wealthy pharmacist and his much younger wife and her meddlesome old boyfriend. The pharmacist turns to a mixture of antimony(III) chloride and mercury(II) sulfide to solve his problems.

1. In which group of the periodic table is antimony found?
2. Draw a Lewis structure for antimony(III) chloride.
3. Is antimony(III) chloride more likely to behave as a Lewis acid or a Lewis base?

The chemistry of antimony(III) chloride is similar to that of the other elements in its group. Antimony(III) chloride can be converted to Sb_2O_3, which has been used as a flame retardant.

1. Write a balanced chemical equation for the reaction of antimony(III) oxide with water to form H_3SbO_3.
2. Write a balanced chemical equation for the reaction of antimony(III) oxide with sodium hydroxide to form $NaSbO_2$ and water.
3. Identify the role of Sb_2O_3 in parts (a) and (b) as either an acid or a base.

Glossary

essential element

an element present in tissue, blood, or other body fluids that has a physiological function.

nonessential element

an element present in humans that has no known function.

stimulatory effect

increased activity, growth, or other biological response to the presence of a nonessential element.

ultratrace essential element

an essential element present in the body in average concentrations less than 1 μg of element per gram of body mass.

ion pump

a system of membrane proteins that exchange ions inside the cell with those in the intercellular fluid.

ion channel

a group of helical proteins that penetrate cell membranes and allow selective transport of ions.

major essential element

an essential element present in the body in average concentrations greater than 1 mg of element per gram of body mass, resulting in gram quantities in the human body.

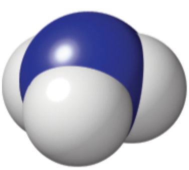
trace essential element

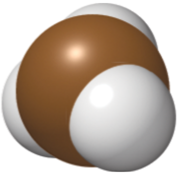
an essential element present in the body in average concentrations between 1 and 1000 μg of element per gram of body mass.

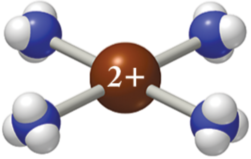
membrane potential,E_{membrane}

a weighted average of the equilibrium (reversal) potentials of the major ions based on concentration and permeability of the individual ions.

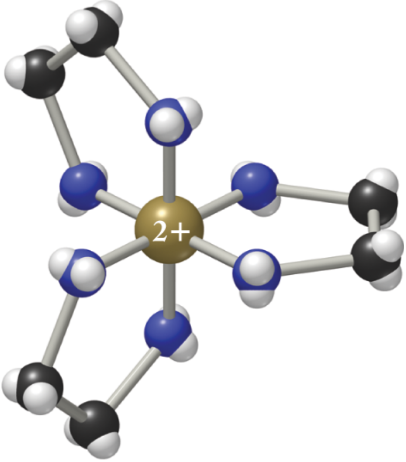
RED COLOR OF BLOOD The red color of blood comes from the heme group, a molecule containing a ring with four nitrogen atoms that bind to a central Fe^{2+} ion.







Cu^{2+} complex



Ni^{2+} complex

Transition Metals Biological and Medical Applications

PARTICULATE REVIEW

Lewis Acid or Lewis Base?

In Chapter 22 we discuss the bonding and structure of compounds and complex ions formed by transition metals and learn about their presence in biological systems and their applications to medicine. The compounds shown here are ammonia, borane, and water.

- Draw the Lewis structure for each compound.
- Which compound(s) has/have at least one lone pair of electrons on the central atom?
- Which compound(s) can function as a Lewis acid? Which can function as a Lewis base?

  (Review Chapters 4,8, and16 if you need help.)

(Answers to Particulate Review questions are in the back of the book.)

PARTICULATE PREVIEW

One Molecule, One Bond versus One Molecule, Two Bonds

Here are two complex ions that contain metal cations bonded to different molecules. As you read Chapter 22, look for ideas that will help you answer these questions:

- Two different molecules form coordinate bonds to Cu^{2+} and Ni^{2+} in the figure to the right. Which element coordinates to the metal?
- What molecule is bonded to the copper cation? How many of these molecules form coordinate bonds with the copper cation?
- What molecule is bonded to the nickel cation? How many of these molecules form coordinate bonds with the nickel cation?

Learning Outcomes

- LO1 Recognize complex ions and their counterions in chemical formulas

  Sample Exercise 22.1

- LO2 Interconvert the names and formulas of complex ions and coordination compounds

  Sample Exercise 22.2

- LO3 Explain the chelate effect and its importance

  Sample Exercise 22.3

- LO4 Explain the origin of the colors of transition metal compounds by using the spectrochemical series
- LO5 Describe the factors that lead to high-spin or low-spin electronic states of complex ions

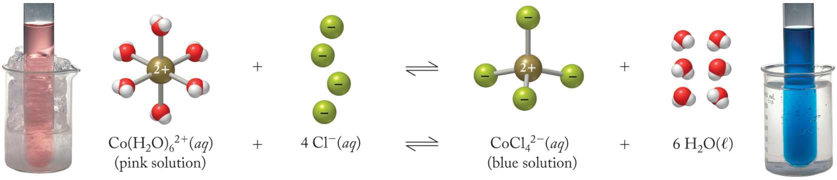
  Sample Exercise 22.4

- LO6 Identify geometric, linkage, and optical isomers of coordination compounds

  Sample Exercise 22.5

- LO7 Describe several of the roles of transition metal complexes in biochemistry and how they are used as diagnostic or therapeutic compounds

Sample Exercise 22.6



$Co(H_2O)_6^{2+}(aq) + 4\,Cl^-(aq) \rightleftharpoons CoCl_4^{2-}(aq) + 6\,H_2O(\ell)$

22.1 Transition Metals in Biology: Complex Ions

Many of the metallic elements in the periodic table are essential to good health. For example, copper, zinc, and cobalt play key roles in protein function. Iron is needed to transport oxygen from our lungs to all the cells of our body. These and other essential metallic elements, several of which we discussed in Chapter 21, should be present either in our diets or in the supplements many of us rely on for balanced nutrition. **Table 22.1** lists the transition metals essential to our bodies in trace and ultratrace concentrations. However, the mere presence of these elements is insufficient—they must be in a form that our cells can use. Swallowing an 18-mg steel pellet would not be a good way for you to get your recommended dietary allowance (Table 21.4) of iron. If we are to benefit from consuming essential metals in food and nutritional supplements, the metals need to be in compounds, not free elements, and the compounds must be bioavailable to the body.

TABLE 22.1 Essential Transition Elements Found in the Human Body

Trace (1–100 μg/g Body Mass)
Iron
Zinc

Ultratrace (<1 μg/g Body Mass)
Chromium
Cobalt
Copper
Manganese
Molybdenum
Nickel
Vanadium

All the metallic transition elements essential to human health occur in nature in ionic compounds, but not all ionic forms are absorbed equally well. For example, most of the iron in fish, poultry, and red meat is readily absorbed because it is present in a form called *heme iron*. The iron in plants, however, is mostly nonheme and is not as readily absorbed. Eating a meal that includes both meat and vegetables improves the absorption of the nonheme iron in the vegetables. Fruits, vegetables and other foods high in vitamin C increase the availability of iron, possibly by forming complex ions of the type described in Section 16.6. All these dietary factors work together at the molecular level to provide us with the nutrients we need to survive.

Interactions between transition metals and accompanying nonmetal ions and molecules influence the solubility of the metals, which is a key factor toward making them chemically reactive and biologically available to plants and animals. These interactions also influence other properties, including the wavelengths of visible light that the metals absorb and therefore the colors of their compounds and solutions. In this chapter we explore how the chemical environment of transition metal ions in solids and in solutions affects their physical, chemical, and biological properties. We answer questions such as why many, but not all, metal compounds have distinctive colors, and how, through the formation of complex ions with biomolecules, transition metals play key roles in many biological processes.

We begin by examining the interactions between transition metal ions and the other ions and molecules that surround them in solids and solutions. To understand these interactions, we need to review the definitions of Lewis acids and Lewis bases we first used in Section 16.5:

- A *Lewis base* is a substance that *donates* a lone pair of electrons in a chemical reaction.
- A *Lewis acid* is a substance that *accepts* a lone pair of electrons in a chemical reaction.

CONNECTION Lewis's pioneering theories of the nature of covalent bonding were described in Chapter 8, and the formation of complex ions between metal ions (Lewis acids) and ligands (Lewis bases) was discussed in Section 16.6.

In Section 10.3, we described how ions dissolved in water are *hydrated*, that is, surrounded by water molecules oriented with their positive dipoles directed toward anions and their negative dipoles directed toward cations (see Figure 10.6). When these ion–dipole interactions lead to the sharing of lone-pair electrons with empty valence-shell orbitals on the cations, they meet our definition of covalent bonds, and in this case are called *coordinate covalent bonds*, or simply *coordinate bonds*. Much of the chemistry of the transition metals is associated with their ability to form coordinate bonds with molecules or anions. Review Chapter 10 if you need help with these concepts.

As we saw in Section 16.6, molecules or anions that function as Lewis bases and form coordinate bonds with metal cations are called *ligands*. The resulting species, which are composed of central metal ions and the surrounding ligands, are called *complex ions* or simply *complexes*. Direct bonding to a central cation means that the ligands in a complex occupy the inner coordination sphere of the cation. Take another look at Sample Exercise 14.12, in which we discussed the equilibrium between two forms of cobalt(II), one pink and one blue (see Figure 14.11), in an aqueous solution of HCl (**Figure 22.1**). Both the pink and blue forms are complexes; the pink cobalt(II) species has six water ligands in its inner coordination sphere, whereas the blue species has four chloride ions. The charge on each complex ion is the sum of the charges of the metal ion and the ligands: $2+$ for $Co(H_2O)_6{}^{2+}$ because the charge of the cobalt ion is $2+$ and water molecules are neutral, and $2-$ for $CoCl_4{}^{2-}$

because the sum of the 2+ charge on the cobalt ion and four 1− charges on the chloride ions is 2− .

The foundation of our understanding of the bonding and structure of complex ions comes from the pioneering research of Swiss chemist Alfred Werner (1866–1919), for which he was awarded the Nobel Prize in Chemistry in 1913. Some of Werner's research addressed the unusual behavior of different compounds formed by dissolving cobalt(II) chloride in aqueous ammonia and oxidizing it to cobalt(III) by bubbling air through the solution. One of the redox reactions produces an orange compound (**Figure 22.2a**) that contains 3 moles of Cl^- ions and 6 moles of ammonia for every 1 mole of Co^{3+} ions. Another reaction produces a reddish purple compound (**Figure 22.2b**) that has the same proportions of Cl^- and Co^{3+} ions, but with only 5 moles of ammonia per mole of cobalt(III). Both compounds are water-soluble solids that react with aqueous solutions of $AgNO_3$, forming solid AgCl. However, 1 mole of the orange compound produces 3 moles of solid AgCl, whereas 1 mole of the reddish purple one produces only 2 moles of AgCl. Results like these inspired Werner to study the electrical conductivity of aqueous solutions of the two compounds. He found that the orange compound was the better conductor, indicating that it produced more ions in solution than the reddish purple one.

CONNECTION We discussed in Chapter 4 how the electrical conductivity of aqueous solutions depends on the concentrations of dissolved ions in the solutions.

Werner concluded that the differences in the two compounds' composition, in their capacities to react with Ag^+ ions, and in their electrolytic properties are all caused by the presence of two types of Co–Cl bonds inside them. He proposed that these bonds were all ionic in the orange compound, but that only two-thirds of them were ionic in the reddish purple compound. The remaining one-third are coordinate covalent bonds.

CONCEPT TEST

How would the electrical conductivity and freezing points of 0.010 *m* aqueous solutions of the two compounds in Figure 22.2 differ?

(Answers to Concept Tests are in the back of the book.)

This capacity to form two kinds of bonds means that Co^{3+} and other transition metal ions have two kinds of bonding capacity, or *valence*. The first kind involves ionic bonds and is based on the number of electrons that a metal atom loses when it forms an ion. This valence is equivalent to its oxidation number, which is $+3$ for cobalt in both the orange and reddish purple compounds. The second kind of valence is based on the capacity of metal ions to form coordinate bonds. This property corresponds to an ion's coordination number, the number of sites around a central metal ion where bonds to ligands form.

When the two compounds in Figure 22.2a and b dissolve in water, they form an orange and a reddish purple solution. The respective solutions contain the ions shown in **Figure 22.3**. The orange solution contains $[Co(NH_3)_6]^{3+}$ and three chloride ions, whereas the reddish purple solution contains $[Co(NH_3)_5Cl]^{2+}$ and two chloride ions. Notice how brackets in the formulas of these coordination compounds set off the complex ions from the ionically bonded chloride counterions, which balance the charges on the complex ions: $3+$ for the orange one (Figure 22.3a), but only $2+$ for the reddish purple one because it contains a negatively charged Cl^- ion within its inner coordination sphere (Figure 22.3b).

The release of 3 moles of chloride ions from the orange compound, but only 2 from the reddish purple compound, explains the compounds' chemical and electrolytic properties.

Werner proposed, correctly, that the six ligands in the inner coordination sphere of cobalt(III) ions are arranged in an octahedral geometry, as shown in the structures in Figure 22.3. This geometry is consistent with the formation of six bonds to a central atom (or central ion in this case), as we learned in Chapter 9 (see Table 9.1). Many other transition metal ions form six coordinate bonds and octahedral complex ions. Some are listed in **Table 22.2**, as are complex ions that have only two or four ligands. Those with two have linear structures, whereas those with four may be tetrahedral or square planar. Both geometries occur in cobalt(II) ions: $CoCl_4^{2-}$ is tetrahedral, whereas $Co(CN)_4^{2-}$ is square planar.

CONCEPT TEST

In the coordination compound $Na_3[Fe(CN)_6]$, which ions occupy the inner coordination sphere of the Fe^{3+} ion and which ions are counterions? Of the four cobalt complexes described in this section, which would have conductivity in aqueous solution similar to that of $Na_3[Fe(CN)_6]$?

TABLE 22.2 Common Coordination Numbers and Shapes of Complex Ions

Coordination Number	Shape	Examples	
6	Octahedral	$Fe(H_2O)_6^{3+}$ $Ni(H_2O)_6^{2+}$ $Co(H_2O)_6^{3+}$	4	Square planar	$Pt(NH_3)_4^{2+}$	4	Tetrahedral	$Zn(H_2O)_4^{2+}$	2	Linear	$Ag(NH_3)_2^{+}$	
SAMPLE EXERCISE 22.1 Assigning Oxidation States in Coordination Compounds LO1

The first modern synthetic color, Prussian blue, was made in 1704 in Berlin, Germany. It was heavily used in the 19th-century Japanese woodblock print *The Great Wave off Kanagawa* (**Figure 22.4**), and it continues to be popular with artists worldwide. The formula for the insoluble pigment is $Fe_4[Fe(CN)_6]_3$.

1. What is the formula of the complex ion in this compound and what is its charge if the counterion is Fe^{3+}?

2. What is the oxidation state of iron in the complex ion?

Collect, Organize, and Analyze We have the formula of a coordination compound and are asked to identify the complex ion and the counterion. The complex ion is contained in brackets, the four Fe^{3+} counterions are outside the brackets, and the compound must be electrically neutral.

Solve

1. The combined charge of four Fe^{3+} is $12+$. To achieve electrical neutrality, the combined charge of the three complex anions must be $12-$. Therefore, the charge of each anion is $(12-)/3 = 4-$, and the formula for the anion is $[Fe(CN)_6]^{4-}$.
2. Six cyanide ligands, CN^-, occupy the inner coordination sphere for a total charge of $6-$. Therefore, the oxidation state of Fe must be $2+$ for the charge on the complex ion to equal $4-$.

Think About It Complex ions may have positive or negative charges. Correspondingly, counterions will have charges opposite to those of the complex ions to ensure electrical neutrality.

Practice Exercise A coordination compound of ruthenium, $[Ru(NH_3)_4Cl_2]Cl$, has shown some activity against leukemia in animal studies. Identify the complex ion, determine the oxidation number of the metal, and identify the counterion.

(Answers to Practice Exercises are in the back of the book.)

Glossary

inner coordination sphere

the ligands that are bound directly to a metal via coordinate bonds.

coordination number	the number of sites occupied by ligands around a metal ion in a complex.
coordination compound	a compound made up of at least one complex ion.
counterion	an ion whose charge balances the charge of a complex ion in a coordination compound.

Learning Objectives

- Recognize complex ions and their counterions in chemical formulas **Return to Sample Exercise 22.1**

22.2 Naming Complex Ions and Coordination Compounds

The names of complex ions and coordination compounds tell us the identity and oxidation state of the central ion, the names and numbers of ligands, the charge in the case of complex ions, and the identity of counterions. To convey all this information, we need to follow some naming rules.

Complex Ions with a Positive Charge

1. Start with the identities of the ligand(s). Names of common ligands appear in **Table 22.3**. If there is more than one kind of ligand, list the names alphabetically.
2. Use the usual prefix(es) in front of the name(s) written in step 1 to indicate the number of each type of ligand (**Table 22.4**).
3. Write the name of the metal ion with a Roman numeral indicating its oxidation state.

TABLE 22.4 Common Prefixes Used in the Names of Complex Ions

Number of Ligands	Prefix
2	di-
3	tri-
4	tetra-
5	penta-
6	hexa-

Examples:

It may seem strange to have two *a*'s together in these names, but it is consistent with current naming rules. Prefixes are ignored in determining alphabetical order, which is why *ammine* comes before *aqua* rather than *di* before *tetra* in tetraamminediaquacopper(II).

The ligands are all electrically neutral in these three examples. This makes determining the oxidation state of the central metal ion a simple task because the charge on the complex ion is the same as the charge on the metal ion, which is the oxidation state of the metal. When the ligands are anions, determining the oxidation state of the central metal ion requires us to account for these charges.

Complex Ions with a Negative Charge

1. Follow the steps for naming positively charged complexes.
2. Add *-ate* to the name of the central metal ion to indicate that the complex ion carries a negative charge (just as we use *-ate* to end the names of oxoanions). For some metals, the base name changes, too. The two most common examples are iron, which becomes *ferrate*, and copper, which becomes *cuprate*.

Examples:

In the first two examples we must determine the oxidation state of Fe. We start with the charge on the complex ion and then take into account the charges on the ligand anions to calculate the charge on the metal ion. For example, the overall charge of the aquapentacyanoferrate(II) ion is $3-$. It contains five CN^- ions. To reduce the combined charge of $5-$ from these cyanide ions to an overall charge of $3-$, the charge on Fe must be $2+$. The most common ionic charges for some transition metals are shown in **Figure 22.5**.

CONCEPT TEST

What is the name of the complex anion with the formula $PtCl_4{}^{2-}$?

Coordination Compounds

1. If the counterion of the complex ion is a cation, the cation's

name goes first, followed by the name of the anionic complex ion.

2. If the counterion of the complex ion is an anion, the name of the cationic complex ion goes first, followed by the name of the anion.

Examples:

A key to naming coordination compounds is to recognize from their formulas that they are coordination compounds. For help with this, look for formulas that have the atomic symbols of a metallic element and one or more ligands, all in brackets, either followed by the atomic symbol of an anion, as in $[Co(NH_3)_5(H_2O)]Br_2$, or preceded by the symbol of a cation, as in $K_3[Fe(CN)_6]$.

SAMPLE EXERCISE 22.2 Naming Coordination Compounds LO2

Name the coordination compounds (a) $Na_4[Co(CN)_6]$ and (b) $[Co(NH_3)_5Cl](NO_3)_2$.

Collect and Organize We are asked to write a name for each compound that unambiguously identifies its composition. The formulas of the complex ions appear in brackets in both compounds. Because cobalt, the central metal ion in both, is a transition metal, we express its oxidation state by using Roman numerals. The names of common ligands are given in Table 22.3.

Analyze It is useful to take an inventory of the ligands and counterions:

LIGAND
[illegible]
$Na_4[Co(CN)_6]$
$[Co(NH_3)_5Cl](NO_3)_2$
Chloro

The oxidation state of each cobalt ion can be calculated by setting the sum of the charges on all the ions in both compounds equal to zero:

1. Ions: (4 Na^+ ions) + (1 Co^x ion) + (6 CN^- ions)

   Charges: $4+ + x + 6- = 0$

   $x = 2+$

2. Ions: (1 Co^x ion) + (1 Cl^- ion) + (2 NO_3^- ions)

   Charges: $x + 1- + 2- = 0$

   $x = 3+$

Solve

1. Because the counterion, sodium, is a cation, its name comes first. The complex ion is an anion. To name it, we begin with the ligand cyano, to which we add the prefix *hexa-* and write *hexacyano*. This is followed by the name of the transition metal ion: hexacyano*cobalt*. We add *-ate* to the ending of the name of the complex ion because it is an anion: hexacyanocobalt*ate*. We then add a Roman numeral to indicate the oxidation state of the cobalt: hexacyanocobaltate(*II*). Putting it all together, we get sodium hexacyanocobaltate(II).
2. The complex ion is the cation in this compound, and we begin by naming the ligands directly attached to the metal ion in alphabetical order: ammine and chloro. We indicate the number (5) of NH_3 ligands with the appropriate prefix: *penta*amminechloro. We name the metal next and indicate its oxidation state with a Roman numeral: pentaamminechloro*cobalt(III)*. Finally, we name the anionic counterion: *nitrate*. Putting it all together, we obtain the name: pentaamminechlorocobalt(III) nitrate.

The structures of the complex ions in the named coordination compounds are shown in **Figure 22.6**.

Think About It Naming coordination compounds requires us to write a name for each compound that unambiguously identifies its composition. The names sodium hexacyanocobaltate(II) and pentaamminechlorocobalt(III) nitrate are unique to the compounds

$Na_4[Co(CN)_6]$ and $[Co(NH_3)_5Cl](NO_3)_2$, respectively.

Practice Exercise Identify the ligands and counterions in (a) $[Zn(NH_3)_4]Cl_2$ and (b) $[Co(NH_3)_4(H_2O)_2](NO_2)_2$, and name each compound.

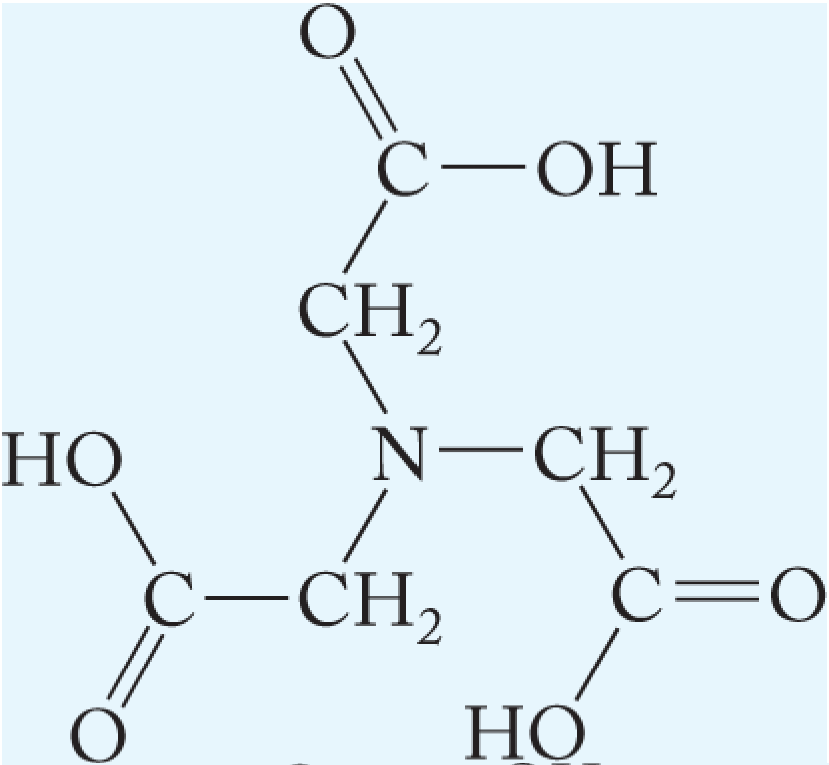
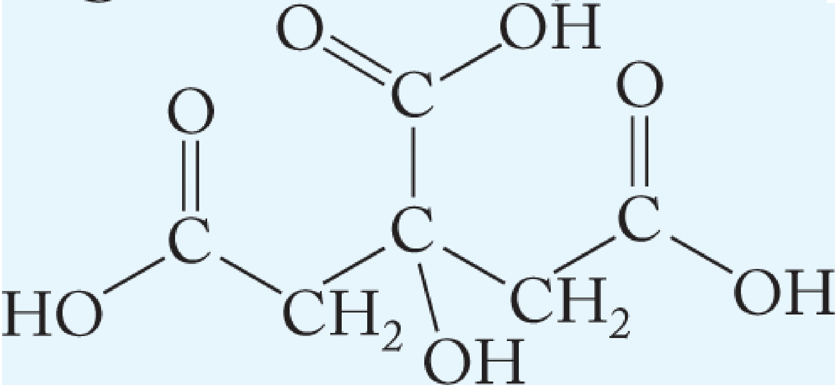
FIGURE 22.10 (a) In the hexadentate ligand EDTA, the six donor groups are the two amine groups and the four carboxylic acid groups. The acid groups ionize to form carboxylate anions. (b) All six Lewis base groups in ionized EDTA can form a coordinate bond with the same metal ion, such as Co^{3+} (the gold sphere) shown here. In the process they form four 5-membered rings.





22.3 Polydentate Ligands and Chelation

Ligands are electron-pair donors—that is, Lewis bases. Let’s explore the strengths of several ligands as Lewis bases by considering their affinity for $Ni^{2+}(aq)$ ions. Suppose we dissolve crystals of nickel(II) chloride hexahydrate, $NiCl_2 \cdot 6\ H_2O$ (**Figure 22.7a**), in water. The dot connecting the two halves of the formula and the prefix *hexa* indicate that each Ni^{2+} ion in crystals of nickel(II) chloride is surrounded by six water molecules. Lime green crystals of $NiCl_2 \cdot 6\ H_2O$ form green aqueous solutions (**Figure 22.7b**). The solid and its solution have the same color, which tells us that the same arrangement of water molecules around Ni^{2+} ions occurs in both solid $NiCl_2 \cdot 6\ H_2O$ and aqueous solutions of Ni^{2+} ions. Thus, the Ni^{2+} ion in a solution of nickel(II) chloride is most likely $Ni(H_2O)_6{}^{2+}$. The hydrated ion $Ni(H_2O)_6{}^{2+}$ can also be expressed as $Ni^{2+}(aq)$.

Now let’s bubble colorless ammonia gas through a green solution of $Ni(H_2O)_6{}^{2+}$ ions. As shown in the middle beaker in Figure 22.7b, the green solution turns blue. The color change means that different ligands are bonded to the Ni^{2+} ions. We may conclude that NH_3 molecules have displaced at least some H_2O molecules around the Ni^{2+} ions. If all the molecules of H_2O are displaced, the complex $Ni(NH_3)_6{}^{2+}$ is formed. The following chemical equation describes this change:

This *ligand displacement* reaction illustrates that Ni^{2+} ions have a greater affinity for molecules of NH_3 than for molecules of H_2O. Many other transition metal ions also have a greater affinity for ammonia than for water. We may conclude that ammonia is inherently a better electron-pair donor and hence a stronger Lewis base than water. This conclusion is reasonable because we saw in Chapter 15 that ammonia was also a stronger Brønsted–Lowry base than H_2O.

Next we add the compound ethylenediamine (see Table 22.3) to the blue solution of $Ni(NH_3)_6{}^{2+}$ ions. The solution changes color again, from blue to purple (Figure 22.7b), indicating yet another change in the ligands surrounding the Ni^{2+} ions. Molecules of ethylenediamine displace ammonia molecules from the inner coordination sphere of Ni^{2+} ions. This affinity of Ni^{2+} ions for ethylenediamine molecules is reflected in the large formation constant for $Ni(en)_3^{2+}$ (where “en” represents ethylenediamine):

This value is more than 10^9 times the K_f value for $Ni(NH_3)_6^{2+}$. Why should the affinity of Ni^{2+} ions for ethylenediamine be so much greater than their affinity for ammonia? After all, in both ligands the coordinate bonds are formed by lone pairs of electrons on N atoms. To answer this question, we need to look at the differences between ligands such as ammonia, which occupy only one site on a metal ion, and ligands such as ethylenediamine, which occupy two or more sites.

Many ligands in Table 22.3 can donate only one pair of electrons to a single metal ion. Even atoms with more than one lone pair usually donate only one pair at a time to a given metal ion because the other lone pair or pairs are oriented away from the metal ion. Because these ligands have effectively only one donor group, they are called monodentate ligands, which literally means “single-toothed.”

Certain molecules larger than ammonia and water may be able to donate more than one lone pair of electrons and therefore form more than one coordinate bond to a central metal ion. Ligands in this category are called polydentate ligands, or more specifically *bidentate*, *tridentate*, and so on. One group of polydentate ligands is the polyamines, which include ethylenediamine, a bidentate ligand that has the structure:

The lone pairs on the two $–NH_2$ groups are separated from each other by two $–CH_2–$ groups. This combination means that a molecule of ethylenediamine can partially encircle a metal ion so that both lone pairs can bond to the same metal ion.

The structure of an ethylenediamine complex of $Ni^{2+}(aq)$ is shown in **Figure 22.8a**. The two orbitals that share the lone pairs of electrons from a molecule of ethylenediamine must be on the same side of the Ni^{2+} ion. However, two more ethylenediamine molecules can bond to other pairs of bonding sites, displacing additional pairs of water molecules and forming a complex in which the Ni^{2+} ion is surrounded by three bidentate ethylenediamine molecules, as shown in **Figure 22.8b**.

Each ethylenediamine molecule forms a five-atom ring with the metal ion. If the ring were a regular pentagon (meaning all bond lengths and bond angles were exactly the same), each of its bond angles would be 108°. These pentagons are not perfect, but each ring's preferred octahedral bond angles of 90° for the N–Ni–N bond, and of 107° to 109° for all the other bonds, are accommodated with only a little strain on the ideal bond angles. The compound in Figure 22.8b is also chiral, a topic we address in Section 22.6.

An even larger ligand, diethylenetriamine ($H_2NCH_2CH_2NHCH_2CH_2NH_2$), is shown in **Figure 22.9a**. The lone pairs of electrons on its three nitrogen atoms give diethylenetriamine the capacity to form three coordinate bonds to a metal ion, meaning this is a tridentate ligand (**Figure 22.9b**).

The interaction of a metal ion with a ligand having multiple donor atoms is called chelation (pronounced *key-LAY-shun*). The word comes from the Greek *chele*, meaning "claw." The polydentate ligands that take part in these interactions are called *chelating agents*.

When we added ethylenediamine to the blue solution of $Ni(NH_3)_6{}^{2+}$ ions in Figure 22.7b, molecules of ethylenediamine (en) displaced ammonia molecules from the inner coordination sphere of Ni^{2+} ions as described in the following chemical equation:

The color change tells us that this reaction as written is spontaneous. As we discussed in Chapter 17, spontaneous reactions are those in which free energy decreases (i.e., $\Delta G < 0$). Furthermore, under standard conditions the change in free energy ΔG° is related to the changes in enthalpy and entropy that accompany the reaction:

$$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$$

The displacement of NH_3 by ethylenediamine is exothermic, but only slightly ($\Delta H^\circ = -12$ kJ/mol). More important, $\Delta S^\circ = +185$ J/mol · K. At 25°C, then,

There is such a large increase in entropy because there are 4 moles of reactants but 7 moles of products in Equation 22.1. Nearly doubling the number of moles of aqueous products over reactants translates into a large gain in entropy. It is this positive ΔS°, more than the negative ΔH° value, that drives the reaction and makes it spontaneous. Entropy gains drive many complexation reactions that involve polydentate ligands. The entropy-driven affinity of metal ions for polydentate ligands is called the chelate effect.

CONNECTION The molecule nonactin in Figure 21.6 acts as a chelating ligand when it forms a complex ion with K^+.

Many chelating agents have more than one kind of electron-pair–donating group. *Aminocarboxylic acids* represent one family of such compounds. The most important of them is ethylenediaminetetraacetic acid (EDTA), which is shown in **Figure 22.10a**. One molecule of EDTA contains two amine (nitrogen-containing) groups and four carboxylic acid (–COOH) groups. When the acid groups release their H^+ ions, they form four carboxylate anions, $-COO^-$, in which either of the O atoms can donate a pair of electrons to a central metal ion. When O atoms on all four groups do so and the two amine groups do as well, six octahedral bonding sites around the metal ion can be occupied, as shown in **Figure 22.10b**.

EDTA forms very stable complex ions and is used as a metal ion *sequestering agent*—that is, as a chelating agent that binds metal ions so tightly that they are “sequestered” and prevented from reacting with other substances. For example, EDTA is used as a preservative in many beverages and prepared foods because it sequesters iron, copper, zinc, manganese, and other transition metal ions often present in these foods that can catalyze the degradation of ingredients in the foods. Many foods are fortified with ascorbic acid (vitamin C), which is particularly vulnerable to metal-catalyzed degradation because it is also a polydentate ligand and is more likely to be oxidized when chelated to one of the above metal ions. EDTA effectively shields vitamin C from these ions. EDTA is also a common additive to shampoos because it can remove metal cations from hard water.

CONNECTION Hard water is discussed in Section 11.5.

SAMPLE EXERCISE 22.3 Identifying the Potential Electron-Pair–Donor Groups in a Molecule LO3

How many donor groups does nitrilotriacetic acid (NTA) have?

Collect, Organize, and Analyze We need to examine the molecular structure of this polydentate ligand to find electron pairs that can be donated. Because there are three single bonds around the N atom, the atom's fourth *sp*^{3} orbital must contain a lone pair of electrons. When all three carboxylic acid groups are ionized, there are three carboxylate groups in the molecule, and each carboxylate group can donate one nonbonding pair of electrons from one of its oxygen atoms to a metal atom.

Solve The central N atom and an O atom from each of the three carboxylate groups form a total of four coordinate bonds. Therefore, NTA is potentially a tetradentate ligand with four donor groups. If we also consider the lone pairs on the oxygen atoms of the $C=O$ group, NTA could coordinate a total of six oxygens to a transition metal cation, making NTA a hexadentate ligand. If we coordinate the nitrogen in NTA through its lone pair, one can imagine a seven-coordinate, heptadentate NTA ligand. The three carboxylate groups, though, are all bonded to a single N through a CH_2 group, so the bond distances and bond angles in NTA may prevent coordination numbers greater than four.

Think About It The tetradentate capacity of NTA is reasonable because, like EDTA, it is an aminocarboxylic acid. It has one fewer amino group and one fewer carboxylic acid group than the hexadentate EDTA.

Practice Exercise How many potential donor groups are there in citric acid, a component of citrus fruits and a widely used preservative in the food industry?

CONNECTION In Section 7.3 we first used the equation $E = h\nu = hc/\lambda$ when discussing the energy of light in the electromagnetic spectrum (Figure 7.7).

Glossary

monodentate ligand

a species that forms only a single coordinate bond to a metal ion in a complex.

polydentate ligand

a species that can form more than one coordinate bond per molecule.

chelation

the interaction of a metal with a polydentate ligand (chelating agent); pairs of electrons on one molecule of the ligand occupy two or more coordination sites on the central metal.

chelate effect

the greater affinity of metal ions for polydentate ligands than for monodentate ligands.

Learning Objectives

- Explain the chelate effect and its importance **Return to Sample Exercise 22.3**

(b) The lobes of the higher-energy orbitals (d_{xy}, d_{yz}, and d_{xz}) are closer to the ligands at the four corners of the tetrahedron than the lobes of the lower-energy orbitals ($d_{x^2-y^2}$ and d_{z^2}) are. (One of the four corners of the tetrahedron is hidden in these drawings.)

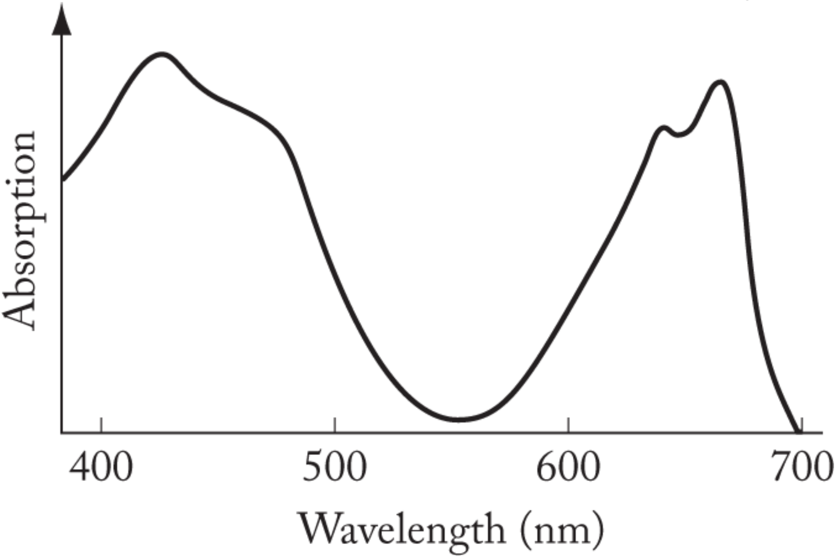

FIGURE 22.18 Absorption spectrum.

22.4 Crystal Field Theory

Why does the formation of complex ions change the color of solutions of transition metals? The colors of transition metal compounds and ions in solution result from transitions of *d*-orbital electrons. Let's explore these transitions by using Cr^{3+} as our model transition metal ion (**Figure 22.11**).

A Cr^{3+} ion has the electron configuration $[Ar]3d^3$in the gas phase. When a Cr^{3+} ion (or any atom or ion) is in the gas phase, all the orbitals in a given subshell have the same energy (**Figure 22.12a**). However, when a Cr^{3+} ion is in an aqueous solution and surrounded by an octahedral array of water molecules in $Cr(H_2O)_6{}^{3+}$, the energies of its 3*d* orbitals are no longer all the same. The $3d_{xy}$, $3d_{yz}$, and $3d_{xz}$ orbitals experience some increase in energy, but the energies of the $3d_{x^2-y^2}$and $3d_{z^2}$orbitals increase even more (**Figure 22.12b**) because the lobes of the $3d_{x^2-y^2}$and 3 d_{z^2}orbitals point directly toward the H_2O molecules' oxygen atoms at the corners of the octahedron formed by the ligands and are repelled by the electrons on those O atoms (**Figure 22.12c**). The energies of the $3d_{xy}$, $3d_{yz}$, and $3d_{xz}$ orbitals are not raised as much because the lobes of these three orbitals do not point directly toward the corners of the octahedron, so the electron repulsion they experience is weaker.

This process of changing degenerate (equal-energy) *d* orbitals into orbitals with different energies is known as crystal field splitting, and the difference in energy created by crystal field splitting is called crystal field splitting energy (Δ). The name was originally used to describe splitting of *d*-orbital energies in minerals, but the theory is also routinely applied to species in aqueous solutions.

An energy level diagram for the lower energy d orbitals to higher energy d orbitals is shown. An upward arrow labeled energy is shown on the left. A diagram labeled (a) shows the ground state of chromium 3 plus ion that consists of no electrons in the first cell (d subscript x square minus y squared and d subscript z squared) and contains 3 single electrons in the second cell (d subscript x y, d subscript y z, and d subscript x z). The diagram at the right labeled (b) shows excited state of chromium 3 plus ion, that consists of a single electron in the cell d subscript x squared minus y squared and no electron in d subscript z squared in the first cell and 2 single electrons in the second cell (d subscript x y, d subscript y z, and d subscript x z). The ground state yields (h v) excited state.

In a $Cr(H_2O)_6{}^{3+}$ ion, three electrons are distributed among five 3*d* orbitals. According to Hund's rule, each of the three electrons should occupy one of the three lower-energy orbitals, leaving the two higher-energy orbitals unoccupied, as shown in **Figure 22.13a**. The energy difference between the two subsets of orbitals is symbolized by Δ_o, where the subscript "o" indicates that the energy split was caused by an *o*ctahedral array of electron repulsions.

What if an aqueous Cr^{3+} ion absorbs a photon whose energy is exactly equal to Δ_o? As the photon is absorbed, a 3*d* electron moves from a lower-energy orbital to a higher-energy orbital (**Figure 22.13b**). The wavelength l of the absorbed photon is related to the energy difference between the two groups of orbitals—in other words, to the crystal field splitting energy—as follows:

The energy and wavelength of a photon are inversely proportional to each other (see Equation 7.3 in Section 7.3). Therefore, the larger the crystal field splitting in a complex ion, the shorter the wavelength of the photons the ion absorbs.

CONNECTION Crystal field theory is an example of molecular orbital theory, which was introduced in Section 9.6.

The size of the energy gap between split *d* orbitals often corresponds to radiation in the visible region of the electromagnetic spectrum. This means that the colors of solutions of metal complexes depend on the strengths of metal–ligand interactions that affect Δ_o. When white light (which contains all colors of visible light) passes through a solution containing complex ions, the ions may absorb energy corresponding to one or more colors. So, the light leaving the solution and reaching our eyes is missing some colors.

The color we perceive for any transparent object is not the color it absorbs but rather the color(s) that it transmits. To relate the color of a solution to the wavelengths of light it absorbs, we need to consider complementary colors as defined by a simple color wheel (**Figure 22.14**). For example, red and green are complementary colors, so a solution that absorbs green light appears red to us.

Aqueous solutions of Cu^{2+} (Figure 18.1) are blue because $Cu(H_2O)_6{}^{2+}$ absorbs orange light, the color that is complementary to blue. A solution of $Cu(NH_3)_4{}^{2+}$ ions also has a distinctive deep blue color (**Figure 22.15**). The spectrum of a solution containing $Cu(NH_3)_4{}^{2+}$ features a rather broad absorption band between 580 and 590 nm that spans yellow, orange, and red wavelengths. Once again, the complementary color is in the blue-violet region. If more than one color is absorbed, then our brain processes the bands of transmitted colors and signals to us as the average of these colors. The violet color of the solution containing $Cr^{3+}(aq)$ in Figure 22.11 is the result of color averaging, as are the colors of the aqueous Ni^{2+}, $Ni(NH_3)_6{}^{2+}$, and $Ni(en)_3{}^{2+}$ solutions in Figure 22.7.

The nickel(II) and chromium(III) complexes we have examined up to this point were octahedral, and their central ions had a coordination number of 6. In the solution of $Cu(NH_3)_4{}^{2+}$, however, the copper(II) ion has a coordination number of 4. This means that the deep blue color of this complex ion is caused by a different crystal field.

Four ligands around a central metal have either a tetrahedral arrangement or a square planar arrangement (Table 22.2). Square planar geometries tend to be limited to the transition metal ions with nearly filled valence-shell *d* orbitals, particularly those with d^8or d^9electron configurations. Cu^{2+} has the electron configuration $[Ar]3d^9$, and the $Cu(NH_3)_4{}^{2+}$ complex is square planar—which means that the strongest interactions occur between the 3*d* orbitals on the central ion and the nitrogen atom lone pairs at the four corners of the equatorial plane of the octahedron, as shown in **Figure 22.16**. The $d_{x^2-y^2}$orbital has the strongest interactions and the highest energy because its lobes are oriented directly at the four corners of the plane. The d_{xy} orbital has slightly less energy because its lobes, although in the *xy* plane, are directed 45° away from the corners. Electrons in the three *d* orbitals with most of their electron density out of the *xy* plane (i.e., d_{z^2},d_{xz}, and d_{yz}) interact even less with the lone pairs of the ligand and thus have even lower energies.

Finally, let’s consider the *d* orbital crystal field splitting that occurs in a tetrahedral complex (**Figure 22.17a**). In this geometry, the greatest electron–electron repulsions are experienced in the d_{xy}, d_{yz}, and d_{xz} orbitals because the lobes of these orbitals are oriented most directly to the corners of the tetrahedron, which are occupied by ligand electron pairs (**Figure 22.17b**). The two other *d* orbitals ($d_{x^2-y^2}$and d_{z^2}) are less affected because their lobes do not point toward the corners. The difference in energy between the two subsets of *d* orbitals in a tetrahedral geometry is labeled Δ_t.

Before ending this discussion on the colors of transition metal ions, let's revisit the color changes we saw in Figure 22.7, when first ammonia and then ethylenediamine were added to a solution of $Ni^{2+}(aq)$ ions. A green solution of $Ni^{2+}(aq)$ ions absorbs at red light (725 nm) as shown in **Table 22.5**. Similarly, a blue solution of $Ni(NH_3)_6{}^{2+}$ or a violet solution of $Ni(en)_3{}^{2+}$ absorbs yellow light (570 nm) or green light (545 nm), respectively. Notice how the colors these three solutions absorb run from longest to shortest wavelength. Radiant energy is inversely proportional to wavelength (Equation 22.2); therefore, the crystal field splitting of the *d* orbitals of Ni^{2+} ions is en > NH_3 > H_2O. Table 22.5 summarizes the observed colors of these Ni^{2+} ion complexes and the meaning we can infer from their colors.

Chemists use the parameter *field strength* to describe the relative magnitude of the split in the energies of the *d* orbitals in metal ions, ranking ligands in what is called a spectrochemical series. **Table 22.6** contains one such series. As the field strength of the ligand increases from the bottom to the top of Table 22.6, the crystal field splitting energy (Δ) increases. Consequently, high-field-strength ligands form complexes that absorb short-wavelength, high-energy light, whereas complexes of low-field-strength ligands absorb long-wavelength, low-energy light. The refinements of crystal field theory that have been made to better explain the spectrochemical series are beyond the scope of this book.

Glossary

crystal field splitting

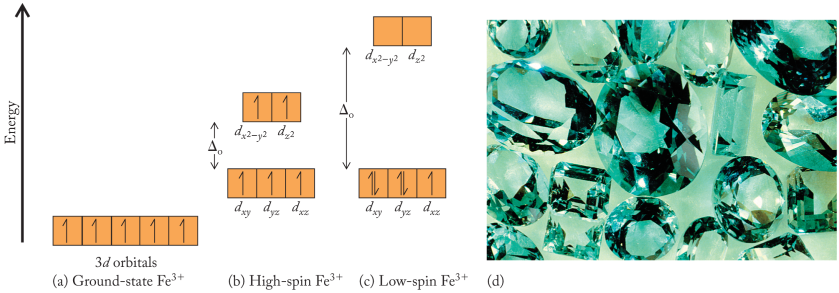
the separation of a set of *d* orbitals into subsets with different energies as a result of interactions between electrons in those orbitals and lone pairs of electrons in ligands.

crystal field splitting energy (δ)

the difference in energy between subsets of *d* orbitals split by interactions in a crystal field.

spectrochemical series

a list of ligands rank-ordered by their ability to split the energies of the *d* orbitals of transition metal ions.



(a) Ground-state Fe^{3+} (b) High-spin Fe^{3+} (c) Low-spin Fe^{3+} (d)

FIGURE 22.19 Low-spin and high-spin complexes. (a) The ground state of a free Fe^{3+} ion has a degenerate, half-filled set of 3*d* orbitals. (b) A weak octahedral field ($\Delta_o <$ electron-pairing energy) produces the high-spin state: five unpaired electrons, each in its own orbital. (c) In a strong octahedral field ($\Delta_o >$ electron-pairing energy), the energies of the 3*d* orbitals are split enough to produce the low-spin state: two sets of paired electrons, one unpaired electron, and two empty, higher-energy orbitals. (d) The Fe^{3+} ions in crystals of aquamarine are high spin.

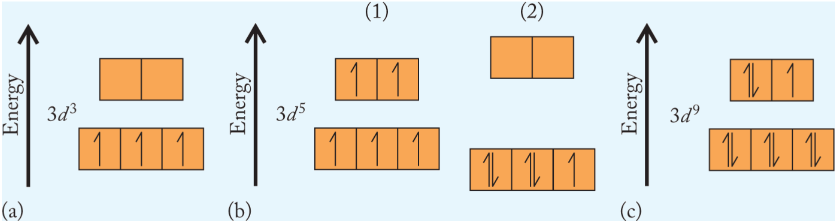


FIGURE 22.20 Options for electron distribution.

22.5 Magnetism and Spin States

In addition to contributing to the color of transition metal ions, crystal field splitting influences their magnetic properties because these properties depend on the number of unpaired electrons in the valence shell *d* orbitals. The more unpaired electrons, the more paramagnetic the ion. For example, an Fe^{3+} ion has five 3*d* electrons (**Figure 22.19a**). In an octahedral field there are two ways to distribute the five 3*d* electrons among these orbitals. One arrangement conforms to Hund's rule and has a single electron in each orbital, leaving them all unpaired (**Figure 22.19b**) and giving rise to the green color in aquamarine (**Figure 22.19d**). However, when Δ_o is large, as shown in **Figure 22.19c**, all five electrons occupy the three lower-energy orbitals. This pattern of electron distribution occurs when the energy of repulsion between two electrons in the same orbital is less than the energy needed to promote an electron to a higher-energy orbital. In this configuration, only one electron is unpaired.

CONNECTION We introduced the magnetic behavior of matter in Section 9.6 in our discussion of molecular orbital theory.

The configuration with all five electrons unpaired is called the *high-spin state* because the spin on all five electrons is in the same direction, resulting in the maximum magnetic field produced by the spins. The configuration with only one electron unpaired is called the *low-spin state*. Both configurations are paramagnetic because both have at least one unpaired electron, but material containing high-spin iron(III) ions would be more strongly attracted to an external magnet than a material containing low-spin iron(III) ions.

Not all transition metal ions can have both high-spin and low-spin states. A Cr^{3+} ion in an octahedral field, for instance, has only three 3*d* electrons (Figure 22.13), so each electron is unpaired whether the orbital energies are split a lot or only a little. Therefore, Cr^{3+} ions and any ion with less than four *d* electrons will have only one spin state. Metal ions with eight or more electrons in *d* orbitals also have only one spin state because there cannot be more than one or two unpaired electrons in these orbitals no matter how the electrons are distributed.

SAMPLE EXERCISE 22.4 Predicting Spin States LO5

Determine which of the following ions can have high-spin and low-spin configurations when surrounded by six Lewis bases in an octahedral complex: (a) Mn^{4+}; (b) Mn^{2+}; (c) Cu^{2+}.

Collect and Organize Mn and Cu are in groups 7 and 11 of the periodic table, so their atoms have 7 and 11 valence electrons, respectively. In an octahedral field, a set of five *d* orbitals splits into a low-energy subset of three orbitals and a high-energy subset of two orbitals.

Analyze To determine whether high-spin and low-spin states are possible, we need to determine the number of *d* electrons in each ion. Then we need to distribute them among sets of *d* orbitals split by an octahedral field to see whether it is possible for the ions to have different spin states. The electron configurations for manganese and copper atoms are $[\mathrm{Ar}]3d^{5}4s^{2}$for Mn and $[\mathrm{Ar}]3d^{10}4s^{1}$, respectively. When the transition metals Mn and Cu form cations, their atoms lose their 4*s* electrons first and then their 3*d* electrons. Therefore, the numbers of *d* electrons in the ions are 3 in Mn^{4+}, 5 in Mn^{2+}, and 9 in Cu^{2+}. It is likely that the ion with the fewest *d* electrons (Mn^{4+}) and the one with nearly the most *d* electrons possible (Cu^{2+}) will each have only one spin state.

Solve

1. Mn^{4+}: Following Hund's rule and putting three electrons into the lowest-energy 3*d* orbitals available and keeping them as unpaired as possible gives this orbital distribution of electrons (**Figure 22.20a**). There is only one spin state for Mn^{4+}.
2. Mn^{2+}: There are two options for distributing 5 electrons among the five 3*d* orbitals (**Figure 22.20b**). Thus, Mn^{2+} can have a high-spin (on the left) or a low-spin (on the right) configuration in an octahedral field.
3. Cu^{2+}: The 9 3*d* electrons fill the lower-energy orbitals and nearly fill the higher-energy ones. Only one arrangement is possible, so Cu^{2+} has only one spin state (**Figure 22.20c**).

Think About It In an octahedral field, metal ions with 4, 5, 6, or 7 *d* electrons can exist in high-spin and low-spin states. Those ions with 3 or fewer *d* electrons have only one spin state, in which all the electrons are unpaired and in the lower-energy set of orbitals. Ions with 8 or more *d* electrons have only one spin state because their lower-energy set of orbitals is filled. The magnitude of the crystal field splitting energy, Δ_{o}, determines which spin state an ion with 4, 5, 6, or 7 *d* electrons occupies.

Practice Exercise Which of the following ions can have high-spin and low-spin configurations when part of an octahedral complex: (a) V^{4+}; (b) Cr^{3+}; (c) Ni^{3+}? Are any of the possible spin configurations diamagnetic?

If the energy needed to promote an electron to a higher-energy orbital (Δ_o) is greater than the energy from the repulsion experienced by two electrons sharing the same lower-energy orbital, a low spin state is observed. If Δ_o is less than the energy of repulsion, a high spin state is observed. Several factors affect the size of Δ_o. We have already discussed a major one in the context of the spectrochemical series shown in Table 22.6: the different field strengths of different ligands. Because molecules containing nitrogen atoms with lone pairs of electrons are stronger field-splitting ligands than H_2O molecules, hydrated metal ions (small Δ_o) are more likely to be in high-spin states, and metals surrounded by nitrogen-containing ligands (large Δ_o) are more likely to be in low-spin states. Another factor affecting spin state is the oxidation state of the metal ion. The higher the oxidation number (and ionic charge), the stronger the attraction of the electron pairs on the ligands for the ion. Greater attraction leads to more ligand–*d* orbital interaction and therefore to a larger Δ_o.

Complexes of transition metals in the fifth and sixth rows tend to be low spin because their 4*d* and 5*d* orbitals extend farther from the nucleus than do 3*d* orbitals. These larger *d* orbitals overlap more and interact more strongly with the lone pairs of electrons on the ligands, leading to greater crystal field splitting.

Our discussion of high-spin and low-spin states has focused entirely on *d* orbitals split by octahedral fields. What about spin states in tetrahedral fields? Almost all tetrahedral complexes are high spin because tetrahedral fields are weaker than octahedral fields. Weaker field strength means less *d*-orbital splitting—not enough to offset the energies associated with pairing two electrons in the same orbitals. Therefore, Hund’s rule is obeyed.

CONCEPT TEST

Explain the following:

1. $Mn(py)_6{}^{2+}$ is a high-spin complex ion, but $Mn(CN)_6{}^{4-}$ is low spin.
2. $Fe(NH_3)_6{}^{2+}$ is high spin, but $Ru(NH_3)_6{}^{2+}$ is low spin.

22.6 Isomerism in Coordination Compounds

The coordination compound $Pt(NH_3)_2Cl_2$ was first described in 1849 and is now widely used as a chemotherapeutic agent to treat several types of cancer. Both molecules of ammonia and the two chloride ions are coordinately bonded to the Pt^{2+} ion, so the name of the compound is diamminedichloroplatinum(II). No counterions are present because the sum of the charges on the ligands and the platinum is zero and the complex is neutral. The compound is square planar, and when we draw it, there are two ways to arrange the ligands about the central metal ion: the two chloride ions and the two ammonia ligands can be at adjacent corners of the square (**Figure 22.21a**) or at opposite corners (**Figure 22.21b**). Coordination compounds like these two that have the same composition and the same connections between parts but differ in the three-dimensional arrangement of those parts are stereoisomers.

CONNECTION We discussed constitutional isomers, which have the same molecular formula but different connections between their atoms, in Sections 3.1 and 20.2.

The two molecules in Figure 22.21 have different physical and chemical properties, and we must find a way to distinguish between them when we name them. Isomer (a), with two members of each pair of ligands at adjacent corners, is called *cis*-diamminedichloroplatinum(II). Isomer (b), with pairs of ligands at opposite corners, is *trans*-diamminedichloroplatinum(II). By analogy to the stereoisomers of alkenes we saw in Chapter 20, these types of stereoisomers are called cis–trans isomers.

To illustrate the importance of stereoisomerism in coordination compounds, consider this: *cis*-diamminedichloroplatinum(II) is a widely used anticancer drug with the common name *cisplatin*, but the trans isomer is much less effective in fighting cancer. The therapeutic power of cisplatin comes from its structurally specific reactions with DNA. During these reactions the two Cl^- ions of $Pt(NH_3)_2Cl_2$ are replaced by two nitrogen-containing bases on a strand of DNA in the nucleus of a cell, as shown in **Figure 22.22**. The ability of cisplatin to cross-link these bases distorts the molecular shape of the DNA (Figure 22.22d) and disrupts its normal function. Most important, this kind of cell DNA damage inhibits the ability of cancerous cells to grow and replicate. The trans isomer forms complexes with other intracellular compounds more readily than with DNA so it is much less effective as an anticancer agent.

CONNECTION We introduced the concept of isomers in Section 3.1 and again in Section 9.5 when we discussed chirality. Enantiomers, also called optical isomers, are one type of stereoisomer; they are molecules that are not superimposable on their mirror image and that rotate the plane of polarized light, as we saw in Section 20.2.

Cis–trans isomers are also possible in octahedral complexes containing more than one type of ligand. For example, there are two possible stereoisomers of $[Co(NH_3)_4Cl_2]Cl$ (**Figure 22.23**). The two chloro ligands in $[Co(NH_3)_4Cl_2]^+$ are either on the same side of the complex with a 90° Cl–Co–Cl bond angle (the cis isomer) or across from each other so that the Cl–Co–Cl angle is 180° (the trans isomer). *cis*-Tetraamminedichlorocobalt(III) chloride is violet, whereas *trans*-tetraamminedichlorocobalt(III) chloride is green.

Enantiomers and Linkage Isomers

In the octahedral cobalt(III) complex ion containing two ethylenediamine molecules and two chloride ions, there are two ways to arrange the chloride ions: on adjacent bonding sites (the cis isomer) or on opposite sides of the octahedron (the trans isomer). Although these two molecules are cis–trans isomers, the cis isomer (**Figure 22.24**) also illustrates another kind of stereoisomerism that is possible in complex ions and coordination compounds.

Figure 22.24 shows that *cis*-$Co(en)_2Cl_2^+$ is chiral: it has a mirror image that is not identical to the original. There is no way to rotate the mirror image so that its atoms align exactly with those in the original, therefore the two structures are not superimposable. We encountered this phenomenon in Chapters 9 and 20 and noted that such nonsuperimposable stereoisomers are called *enantiomers*. If you look closely at Figure 22.8b, you will recognize a similar situation. The arrangement of the three ethylenediamine ligands around Ni^{2+} makes this compound chiral, too.

Naming *cis*-$Co(en)_2Cl_2^+$ also requires an additional rule. The complex ion is named *cis*-dichlorobis(ethylenediamine)cobalt(III). Note the prefix *bis*- just before (ethylenediamine). In naming complex ions containing a polydentate ligand, we use *bis*- instead of *di*- to indicate that two molecules of the ligand are present and to avoid the use of two *di*- prefixes in the same ligand name. Other prefixes used in this fashion are *tris*- for three polydentate ligands and *tetrakis*- for four.

CONCEPT TEST

Would four different ligands arranged in a square planar geometry produce a chiral complex ion? What about four different ligands in a tetrahedral geometry?

A third kind of isomerism called *linkage isomerism* occurs in coordination compounds when a ligand can bind to a central metal ion by using either of two possible electron-pair–donating atoms. The two complexes of Co^{3+} shown in **Figure 22.25** are a pair of linkage isomers. One complex contains the thiocyanate (SCN^-) ion as a ligand in which the S atom covalently bonds to the metal (Figure 22.25a). The other contains the isothiocyanate (NCS^-) ion as a ligand in which the N atom forms the bond (Figure 22.25b). Another ligand that forms linkage isomers with metals is NO_2^-, called nitro when the N atom donates an electron pair and nitrito when an O atom is the donor. Because these pairs of molecules have different connectivities, linkage isomers are *not* stereoisomers. Instead, linkage isomers are a type of constitutional isomer.

SAMPLE EXERCISE 22.5 Identifying Isomers of Coordination Compounds LO6

Sketch the structures and name the isomers of $Ni(NH_3)_4(NO_2)_2$.

Collect and Organize We are given the formula and asked to name and draw the structures of the isomers of a coordination compound. The Ni^{2+} complexes we have seen so far in the chapter have all been octahedral. Ammonia molecules and NO_2^- ions are both monodentate ligands, but NO_2^- can bond to Lewis bases through either the lone pair on N or through one of the lone pairs on O.

Analyze The formula contains no brackets, so the NO_2^- ions are not counterions; they must be covalently bonded to the Ni ion. There are two NO_2^- ions, so the charge on Ni must be $2+$. There are a total of six ligands, which confirms that the compound is octahedral.

Solve There are two ways to orient the nitrite ions relative to the four ammonia ligands: opposite each other with a $O_2N–Ni–NO_2$ bond angle of 180° or on the same side of the octahedron with a $O_2N–Ni–NO_2$ bond angle of 90°:

The first case represents a *trans* arrangement of the NO_2^- ligands, whereas the second is a *cis* arrangement. The first isomer is *trans*-tetraamminedinitronickel(II); the second is *cis*-tetraamminedinitronickel(II). Both names include the word *nitro* to signify coordination of the NO_2^- group through N, but the nitrite ligand can also bond through the O, which changes the ligand name to *nitrito* and generates two additional linkage isomers for both the trans and cis isomers.

The names for these four isomers are *trans*-tetraammine(nitrito)(nitro)nickel(II), *trans*-tetraamminedinitritonickel(II); *cis*-tetraammine(nitrito)(nitro)nickel(II), and *cis*-tetraamminedinitritonickel(II), respectively.

Think About It We can draw other tetraamminedichloronickel(II) structures that do not look exactly like these two structures. If we flip or rotate them, however, they will match one of the two structures shown.

Practice Exercise Sketch the stereoisomers of $[CoBr_2(en)(NH_3)_2]^+$ and name them.

22.7 Coordination Compounds

in Biochemistry

In Section 22.1, we noted that metals essential to human health must be present in foods in forms the body can absorb. In this section we explore some biological polydentate ligands that help metal ions participate in processes that are essential to nutrition and good health. DRI/RDA values for trace essential elements, including iron and zinc, are in the range of 10–20 mg/d. There are DRI/RDA values for some, but not all, of the ultratrace essential elements, ranging from 45 μg/d for molybdenum up to 5 mg/d for manganese. Compounds of iron and zinc are present in the body in average concentrations between 1 and 1000 μg of element per gram of body mass and are considered to be trace elements. Other transition metals (chromium, cobalt, copper, manganese, molybdenum, nickel, and vanadium) are considered ultratrace, meaning essential elements present in the body in average concentrations less than 1 μg of element per gram of body mass. Here we survey the roles of some of the other ultratrace transition metals in biology.

Manganese and Photosynthesis

Let's begin with photosynthesis, a chemical process at the foundation of our food chain. Green plants can harness solar energy because they contain large biomolecules we collectively call *chlorophyll.* All molecules of chlorophyll contain ring-shaped tetradentate ligands called *chlorins* (**Figure 22.26a**). The structures of chlorins are similar to those of porphyrins, another class of tetradentate ligands found in biological systems (**Figure 22.26b**). We saw porphyrins in Section 20.4 as the Fe^{2+}-binding molecules in hemoglobin (Figure 20.29a). Chlorins and porphyrins are members of a larger category of polydentate compounds known as macrocyclic ligands. (*Macrocycle* means, literally, "big ring.")

Two of the four nitrogen atoms in porphyrins and chlorins are sp^3 hybridized and bound to hydrogen atoms, whereas the other two are sp^2 hybridized with no hydrogen atoms. When either compound forms coordinate bonds with a metal ion M^{n+} (**Figure 22.26c**), the two hydrogen atoms ionize, giving the ring a charge of $2-$ and the complex ion an overall charge of $(n-2)$. The lone pairs of electrons on the N atoms in the ionized structure are oriented toward the ring center. These lone pairs can occupy either the four equatorial coordination sites in an octahedral complex ion or all four coordination sites in a square planar complex ion. In octahedral complex ions, each central metal ion still has two axial sites available for bonding to other ligands. Depending on the charge of the central ion, the coordination compound may be either ionic (a complex ion) or electrically neutral.

CONNECTION Dietary reference intake (DRI) and recommended dietary allowance (RDA) were introduced in Section 21.1 in the discussion of essential elements in the human diet.

Porphyrin and chlorin rings are widespread in nature and play many biochemical roles. Their chemical and physical properties depend on

1. the identity of the central metal ion
2. the species that occupy the axial coordination sites of octahedral complexes
3. the number and identity of organic groups attached to the outside of the ring

The role of the major essential element Mg^{2+} in photosynthesis was described in Section 21.3. Another metal, the ultratrace essential element manganese, also plays a role in the production of oxygen during photosynthesis. To examine that role, let’s write an equation for photosynthesis that is slightly different from the equation we are used to seeing. Instead of writing the formula $C_6H_{12}O_6$ for glucose, we use the generic carbohydrate formula $(CH_2O)_n$ so that the coefficient is 1 for all other species in the reaction (rather than 6):

Writing the equation in this form makes it easier to see how the overall reaction between water and carbon dioxide involves electron transfer: photosynthesis is a redox reaction in which oxygen is oxidized and carbon is reduced.

This redox process requires manganese-containing enzymes in which Mn ions in the $+3$ and $+4$ oxidation states mediate the transfer of electrons from water in photosynthesis. Although the exact structure of these manganese compounds remains undetermined, it is believed that two manganese(III) ions and two manganese(IV) ions are present at the site of O_2 production. Copper-containing enzymes are also involved in the series of reactions that make up photosynthesis.

CONCEPT TEST

Manganese ions involved in photosynthesis are often surrounded by six ligands in an octahedral geometry. Is reduction of a manganese(IV) ion to manganese(III) in an octahedral complex (see Section 22.5) accompanied by a change in spin state of the Mn ion?

Transition Metals in Enzymes

Transition metal cations can form complexes by bonding to the nitrogen atoms of the amino acids in proteins and other Lewis bases in biological systems. Many of the enzymes in our bodies contain zinc or iron ions; these enzymes, along with others containing transition metal ions, are called *metalloenzymes*.

Zinc The enzyme carbonic anhydrase catalyzes the reaction between water and carbon dioxide to form bicarbonate ions:

$$H_2O(\ell) + CO_2(g) \rightleftharpoons HCO_3^-(aq) + H^+(aq)$$

The α form of carbonic anhydrase contains 260 amino acid residues and a zinc ion at the active site. Notice in **Figure 22.27** that the zinc ion is coordinately bonded to three nitrogen atoms on histidine side chains and to one molecule of water. The presence of these ligands and a fourth histidine nearby facilitates ionization of the water molecule. Ionization leaves a OH^- ion attached to the Zn^{2+} ion and a H^+ ion bonded to the side-chain nitrogen atom of the fourth histidine. In addition, a space just the right size and shape to accommodate a CO_2 molecule is next to the active site. When a CO_2

molecule in this space bonds to a hydroxide ion, a HCO_3^- ion forms. As the bicarbonate ion pulls away, another water molecule occupies the fourth coordination site on the Zn^{2+} ion, another CO_2 molecule enters, the histidine is protonated, and the catalytic cycle repeats. This reaction is important because it helps eliminate CO_2 from cells during respiration and mediates the uptake of CO_2 during photosynthesis in some plants.

Iron Iron-containing peroxidases and catalases are integral to the transfer of oxygen to biomolecules. For example, plants use a fatty acid peroxidase to catalyze the stepwise degradation of fatty acids, where R represents a long hydrocarbon chain. One $–CH_2–$ group at a time is removed from the fatty acid by using hydrogen peroxide:

Subsequent oxidation of the aldehyde back to a carboxylic acid yields a new fatty acid with one fewer $–CH_2–$ group:

Iron-containing enzymes also catalyze the reduction of nitrite (NO_2^-) and sulfite (SO_3^{2-}) ions:

In each case, the iron in the enzyme is oxidized, providing the electrons needed for reduction.

CONNECTION Fatty acids were described in Section 20.6.

Proteins called *cytochromes* also contain one or more heme groups (**Figure 22.28a**). Cytochromes mediate oxidation and reduction processes connected with energy production in cells. The heme group conveys electrons as the half-reaction

$$Fe^{3+} + e^- \rightleftharpoons Fe^{2+}$$

rapidly and reversibly consumes or releases electrons needed in the biochemical reactions that sustain life. Cytochromes catalyze electron transport in photosynthesis and the metabolism of glucose to CO_2 and water. Their role in electron transport makes them key participants in *in vivo* reactions that produce ATP, which is required for intracellular energy production and transfer in living things. As catalysts for oxidation and reduction, cytochromes are essential for the removal of toxic substances and for the process of programmed cell death, both of which are required for the health of multicellular organisms. Cytochrome *c* (**Figure 22.28b**) is a component of the electron transport chain in mitochondria that is ubiquitous in life forms ranging in complexity from microbes to human beings. Its amino acid sequence is very similar or the same across a spectrum of plants, animals, and many unicellular organisms. Consequently, studies of the cytochrome *c* molecule are seminal in evolutionary biology.

CONNECTION The role of adenosine triphosphate (ATP) as an energy source in biology is discussed in Section 17.9. The binding of oxygen (O_2) to hemoglobin is described in Section 20.4.

Many other kinds of cytochrome proteins have different substituents on the porphyrin rings and different axial ligands, each of which influences the function of the complex. This last point has been repeated several times in this chapter: the chemical properties and biological functions of transition metals that are essential to living organisms are linked to their molecular environments and to the formation of stable complex ions with ligands that are strong electron donors—that is, strong Lewis bases.

CONCEPT TEST

Which of the following small molecules could *not* function as a Lewis base and hence would not be expected to bond to iron in a heme protein? CO; H_2; NO_2; H_2S

Molybdenum and Vanadium Many metalloenzymes are involved in transformations of nitrogen. Molybdenum-containing reductases are responsible for converting NO_3^- ions to NO_2^- ions and then to NH_3 in the nitrogen cycle (see Figure 21.8). The active site of sulfite oxidase, which converts SO_3^{2-} ions to SO_4^{2-} ions in the sulfur cycle (see Figure 21.11), also contains molybdenum. Sometimes more than one type of transition metal is found in a metalloenzyme. For example, both molybdenum and iron are required by xanthine oxidase, an important enzyme along the pathway for degradation of excess nucleic acids (adenine and guanine) to xanthine and then to uric acid for elimination through the kidneys.

The combination of iron and vanadium is essential to the function of haloperoxidases, a class of enzymes found in some algae, lichens, and fungi that replace C—H bonds with carbon–halogen bonds. The reaction products are thought to function in the defense systems of these organisms.

Copper Copper-containing proteins perform several functions in both plants and animals, including oxygen transport in mollusks such as clams and oysters. Copper is also an essential element in the enzymes azurin and plastocyanin, which mediate electron transfer during photosynthesis.

Reactions catalyzed by xanthine oxidase may produce other reactive oxygen species besides H_2O_2. One of them is the superoxide ion, O_2^-. Superoxide ion is a strong oxidizing agent and must be eliminated to prevent cell damage. The removal of superoxide begins with the action of superoxide dismutases, which convert superoxide to hydrogen peroxide:

Researchers have isolated superoxide dismutases containing a variety of transition metals, including a copper–zinc enzyme. The hydrogen peroxide produced in this reaction is decomposed to water and oxygen by iron-containing catalase.

Nickel Ureases, the enzymes responsible for the conversion of urea to ammonia in plants, contain nickel(II). Nickel is also found with iron in enzymes called *hydrogenases*. Hydrogenases oxidize hydrogen gas to protons:

Nickel and iron also combine in CO dehydrogenase, an enzyme that catalyzes the formation of acetyl-CoA, which is a key component in the tricarboxylic acid cycle discussed in Section 20.5. Finally, nickel-containing enzymes are found among the enzymes responsible for methane generation by bacteria.

Cobalt and Coenzymes Many enzymes require the presence of a coenzyme, which is an organic compound that cocatalyzes a biochemical reaction. The coenzyme B_{12} (**Figure 22.29**) contains the ultratrace essential element cobalt(III) and is a derivative of vitamin B_{12}. The cobalt(III) in coenzyme B_{12} is easily reduced to cobalt(II) and even cobalt(I) in the course of enzyme-catalyzed redox reactions. The change in oxidation state of Co allows for facile transfer of methyl groups, as in the conversion of methionine to homocysteine:

Coenzyme B_{12} is also critical to the function of *mutases*, which are enzymes that catalyze the rearrangement of the skeleton of a molecule, as in the interconversion of glutamate and methylaspartate:

Chromium Chromium in the $+3$ oxidation state is an ultratrace essential element in our diets. It is involved in regulating glucose levels in the blood through a molecule called chromodulin. Chromodulin is a polypeptide containing only 4 of the 20 naturally occurring amino acids: glycine, cysteine, glutamic acid, and aspartic acid. Four Cr^{3+} ions are bound to the peptide chain. Cereals and grains contain enough chromium for our daily needs, but certain plants (such as shepherd’s purse) concentrate chromium and have been used as herbal remedies in diabetes treatment.

Chromium in the $+6$ oxidation state, as found in chromate ions ($CrO_4{}^{2-}$), is acutely toxic and also carcinogenic. Chromate ion enters cells through ion channels that transport $SO_4{}^{2-}$ ions. Once inside, $CrO_4{}^{2-}$ is reduced to Cr^{3+}, which binds to the phosphate backbone of DNA.

Glossary

porphyrin

a type of tetradentate macrocyclic ligand.

macrocyclic ligand

a ring containing multiple electron-pair donors that bind to a metal ion.

coenzyme

an organic molecule that, like an enzyme, accelerates the rate of biochemical reactions.

22.8 Coordination Compounds in Medicine

Transition metal coordination compounds are becoming important in both the diagnosis and treatment of diseases (**Figure 22.30**). Any diagnostic or therapeutic compound that is injected intravenously must be sufficiently soluble in blood to be delivered to the target. While in transit, the compound must be stable enough not to undergo chemical reactions that result in its precipitation or rapid elimination from the body. Occasionally, the compound can be in the form of a simple salt, but more often a metal ion is introduced as a coordination complex or coordination compound. Ligands used in forming biologically active coordination complexes include amino acids and simple anions such as the citrate ion. Chelating ligands such as diethylenetriaminepentaacetate ($DTPA^{5-}$; **Figure 22.31**) are often used in biological applications. A medicinal chemist can also take advantage of substances that occur naturally in the body, such as antibodies, to transport a diagnostic or therapeutic metal ion to its target.

CONNECTION Chapter 19 gave a more detailed discussion of nuclear chemistry and nuclear medicine, including an assessment of how different types of radiation affect living tissue.

Transition Metals in Diagnosis

As discussed in Section 19.7, radionuclides of main group elements with short half-lives that emit easily detectable γ rays are useful in positron emission tomography (PET). An equally wide array of transition metal isotopes is available for imaging. Magnetic resonance imaging (MRI), for instance, can be used to diagnose soft-tissue injuries and uses stable isotopes of gadolinium to enhance images.

Technetium and Rhenium Technetium, just below manganese in group 7 of the periodic table, is the most widely used radioactive isotope in imaging. Technetium is unusual in that it does not exist naturally on Earth in easily measurable amounts because it has no stable isotopes; in other words, all technetium isotopes are radioactive. These isotopes can be produced in nuclear reactors for use in medicine. The ^{99m}Tc used in hospitals for imaging is prepared in technetium generators in which a stable isotope of molybdenum, ^{98}Mo (23.78% natural abundance), is bombarded with neutrons. Technetium-99 has a half-life greater than 20,000 years; when it is produced in a nuclear reactor, however, its nucleus is in an excited state, called a *metastable* nucleus. The metastable state, designated by adding the letter “m” to the mass number, as in technetium-99m or ^{99m}Tc, has a half-life of 6 h and decays to the more stable technetium-99 nucleus.

Technetium-99m has been widely used as an imaging agent because it has a short half-life and emits low-energy g rays. Patients can be injected with a variety of technetium compounds, depending on the target organ. For imaging the heart, the coordination compounds shown in **Figure 22.32** are used.

The ability to target the delivery of radionuclides to a particular organ opens the possibility for selective irradiation of a tumor located in that organ. Therefore, some radionuclides can be used to not only image but also treat cancers. Certain tumors have highly selective receptor sites for particular molecules on their surfaces. Rhenium, for example, is being studied as both an imaging and a therapeutic agent for some tumors, including breast, liver, and skin cancer. Rhenium-186 and rhenium-188 undergo β decay with half-lives of 3.72 d and 17.0 h, respectively. By including a radioactive rhenium ion in a molecule that binds strongly and specifically to these receptors, physicians can deliver both an imaging agent and a therapeutic agent to the tumor. In principle, the β particles destroy the tumor. Several patents have been issued for the use of compounds containing rhenium isotopes, but therapies based on these compounds remain in the experimental stage. One example of a rhenium compound used in these applications is shown in **Figure 22.33**.

Scandium, Yttrium, and Lanthanide Elements Scandium, yttrium, and lanthanum are in group 3 in the periodic table, the first group in the transition metal series. Scandium-46 has been used to image the spleen, and scandium-47 shows promise in diagnosing breast cancer. Among the available radioactive isotopes of yttrium, yttrium-90 has been applied to imaging a variety of tumors, including intestinal, breast, and thyroid cancers. Chelating ligands are used to complex the $^{90}Y^{3+}$ cation and deliver it to the tumor, where it binds strongly to receptors on the surface of the tumor. Yttrium-90 agents for treatment of non-Hodgkin's lymphoma are currently in clinical trials.

Radioactive isotopes of the lanthanides have seen extensive use in scintigraphic imaging, a procedure that uses a scintillation counter (see Section 19.3) to measure the light emitted when radiation strikes a phosphor-coated screen in the instrument. The intensity of the emitted light is translated into a three-dimensional image of the organ of interest, a method similar to the PET technique described in Section 19.7. Among the nuclides used for this purpose are cerium-141, samarium-153, gadolinium-153, terbium-160, thulium-170, ytterbium-169, and lutetium-177. These nuclides are preferable to gallium isotopes because they have lower retention times in blood, which reduces the possibility of potentially harmful biological side effects. In some cases, lutetium-177 derivatives have replaced yttrium-90 compounds under investigation as radioactive antitumor agents.

As noted previously, the quality of an MRI scan (**Figure 22.34**) can be improved when gadolinium is used as a contrast agent. Before the procedure, the patient is injected with a gadolinium compound. Many ligands have been investigated for Gd^{3+} MRI contrast agents. The gadolinium used is a mixture of naturally occurring isotopes of gadolinium. Coordination compounds of other lanthanide ions (Dy^{3+} and Ho^{3+}) have been evaluated but do not work as well as those of gadolinium. The toxicity of gadolinium has spurred research into using manganese compounds suitable for MRI.

CONCEPT TEST

What is wrong with the statement, "A radioactive isotope with twice the half-life of another will allow an image to be collected in half the time"?

Transition Metals in Therapy

Like main group metal compounds described in Chapter 21, coordination compounds of the transition metals are finding their way into our expanding arsenal of useful therapeutic agents. We have already described the use of platinum compounds to treat cancer and the potential for chromium compounds to help mitigate diabetes. We now examine additional therapeutic agents that contain transition metal elements.

Iron The body must regulate the amount of iron in cells in order to produce enough hemoglobin to maintain good health. Deficiencies in iron lead to several diseases broadly classified as anemia. Mild forms of anemia are common among women of child-bearing age and are treated with oral iron supplements. A more serious genetic form of anemia, however, known as thalassemia, must be treated with blood transfusions that leave patients with too much iron in their blood. To remove the excess iron, these patients are treated with chelating ligands that complex some of the iron and transport it out of the red blood cells and eventually out of the body in what is known as chelation therapy. Chelation therapy relies on a large equilibrium constant for the reaction

$$\mathrm{FeL}(aq) + \mathrm{L9}(aq) \rightleftharpoons \mathrm{FeL9}(aq) + \mathrm{L}(aq)$$

where iron coordinated to ligand L (such as hemoglobin) in the blood is treated with ligand L9, which also binds iron. If the formation constant for the complex between iron and L9 is greater than for iron and L, then the equilibrium constant for the equation is greater than one, and formation of the iron–L9 complex is favored. The ligand L9 is chosen so that the complex formed between iron and L9 is eliminated from the body, thereby reducing the concentration of iron and relieving the symptoms caused by thalassemia treatments. Often the chelating ligand leads to chiral metal complexes of the kind described in Section 22.6. Chelation therapy is also the treatment of choice for heavy metal poisoning from toxic metals, including lead and mercury.

SAMPLE EXERCISE 22.6 Calculating the Equilibrium Constant of a Ligand Exchange Reaction LO7

The protein transferrin is involved in the transport of iron into cells.

Iron accumulation in the human body has been implicated in diseases such as Parkinson's, Alzheimer's, and thalassemia. The chelating ligand deferoxamine (DFO) is used to treat thalassemia; the complex between iron and DFO is eliminated from the body. Given the formation constants for the complexation of iron(III) by transferrin (Equation 1) and the reaction of DFO with iron (Equation 2), calculate the equilibrium constant for the ligand exchange reaction between DFO and transferrin (Equation 3).

Collect and Organize We are given the formation constants of two reactions involving iron and different ligands and are asked to calculate the equilibrium constant for the ligand exchange reaction. You may want to review Section 16.6 for calculations involving formation constants of complexes, as well as Chapters 14 and 15, where we manipulated equilibrium constants.

Analyze Transferrin is a reactant in Equation 1 and a product in the exchange reaction (3). Therefore, we need to reverse Equation 1 before adding it to Equation 2 to obtain Equation 3.

Reversing a reaction means taking the reciprocal of its equilibrium constant. Combining the reverse of Equation 1 with Equation 2 to obtain Equation 3 means multiplying $(1/K_{f,1})$ and $K_{f,2}$ together to obtain K_3. The reciprocal of $K_{f,1}$ has a value of about 10^{-20}. Therefore, the value of K_3 should be about $10^{-20} \times 10^{30}$, or about 10^{10}.

Solve Multiplying $(1/K_{f,1})$ by $K_{f,2}$ to obtain K_3:

Think About It The equilibrium constant for the ligand exchange between the Fe(transferrin)$^{3+}$ complex and DFO is indeed ~10^{10} and illustrates why DFO is an effective treatment for thalassemia—the large value for the equilibrium constant means that the equilibrium in Equation 3 lies toward the products (to the right), removing iron from the blood.

Practice Exercise The equilibrium constants for the reactions of penicillamine and methionine with methyl mercury are

Calculate the equilibrium constant for the exchange reaction:

$CH_3Hg(\text{methionine})^+ + \text{penicillamine} \rightleftharpoons CH_3Hg(\text{penicillamine})^+ + \text{methionine}$

Titanium, Vanadium, and Niobium Cancer Drugs Compounds of a surprisingly large number of transition metals demonstrate antitumor activity. Titanium(IV) complexes such as budotitane (**Figure 22.35**) show promise against colon cancer. Encouraging results against breast, lung, and colon cancers were observed with a series of compounds with formulas $(C_5H_5)_2TiCl_2$, $(C_5H_5)_2VCl$, and $(C_5H_5)_2NbCl_2$. The delivery of titanium and many other transition metal complexes to cells is believed to be mediated by the protein transferrin described in Sample Exercise 22.6. The precise way in which these compounds inhibit the growth of tumor cells is not yet understood. One working hypothesis proposes a mechanism similar to that for platinum compounds discussed in Section 22.6. Unfortunately, at therapeutically useful doses, the potential for liver damage outweighs the benefits of these compounds. These compounds contain carbon–metal bonds and belong to a class of substances called organometallic compounds.

Chromium, Vanadium, and Controlling Blood Sugar Insulin is a hormone needed for proper glucose metabolism and protein synthesis. People with diabetes either cannot produce insulin or produce the hormone but cannot use it effectively. The suggestion that vanadium plays a role in insulin production has prompted investigation of vanadium compounds as oral diabetes drugs. Redox activity and selective inhibition of enzymes at the insulin receptor site are possible modes of action for vanadium coordination compounds. Encouraging results from animal studies using bis(allixinato)oxovanadium(IV) (**Figure 22.36a**) have been reported, but the compound is not currently approved for use in humans. Chromium(III) compounds have been shown to lower fasting blood sugar levels and reduce the amount of insulin required by some diabetics (**Figure 22.36b**).

Platinum Group and Coinage Metals The period 5 and period 6 elements in groups 8, 9, and 10 (Ru, Rh, Pd, Os, Ir, and Pt) are often referred to as the *platinum group metals*. The group 11 elements of these two periods (Ag and Au) along with Cu are called the *coinage metals*. We now explore examples of soluble compounds of these metals used in medications for arthritis, cancer, and other diseases.

The serendipitous discovery in the 1960s that *cis*-diamminedichloroplatinum(II) (cisplatin in **Figure 22.37**) is effective in treating testicular, ovarian, and other cancers spurred the development of a host of cancer drugs based on both platinum group metals and coinage metals. The results of this research include a compound known as carboplatin that shows the same activity as cisplatin, whose mechanism of activity is shown in Figure 22.22, but has fewer side effects. In addition to platinum compounds, the antitumor activities of complexes of gold, rhodium, ruthenium, and silver have been explored. The effectiveness of all of these drugs lies in their ability to bind to the nitrogen-containing bases in DNA and inhibit cell replication. If their cells cannot divide, tumors cannot grow. The greater toxicity of rhodium compounds compared to compounds of platinum and ruthenium has limited their clinical application.

Selected osmium compounds reduce inflammation in joints resulting from arthritis, although the use of such compounds has diminished with the development of other anti-inflammatory agents. The therapeutic effects of aqueous solutions of osmium tetroxide (OsO_4) were first investigated in the 1950s. The use of osmium tetroxide was superseded by the use of glucose polymers containing osmium, known as osmarins. The use of osmarins reduces the toxic effects of osmium and illustrates how even toxic metals can be adapted to therapy.

Although the historic use of gold for medicinal purposes dates back millennia, the effective use of gold-containing pharmaceuticals originated with the discovery in the 1920s and 1930s that a gold thiosulfate compound, sanochrysin (**Figure 22.38a**), alleviates the symptoms of rheumatoid arthritis. The most commonly used gold drugs for the treatment of arthritis today are sold under the names myochrysine and auranofin (**Figure 22.38b, c**). Myochrysine is injected; auranofin can be taken orally.

Eye drops containing silver salts are used to treat eye infections. Silver sulfadiazine (**Figure 22.39**) is a broad-spectrum “sulfa” drug used to prevent and treat bacterial and fungal infections. It is also an active ingredient in creams used to treat thermal and chemical burns.

Although present in smaller amounts in the human body than the main group elements, the transition metals play crucial roles in our physiological system and in those of many organisms. Their rich and diverse chemistry has led to many applications of both essential and nonessential transition metal compounds to maintaining health and diagnosing and treating disease. Without a doubt, the smorgasbord of the periodic table will continue to provide us with useful substances and materials.

SAMPLE EXERCISE 22.7 Integrating Concepts: Water Quality in Swimming Pools

The diving competition at the 2016 Olympic Games in Rio de Janeiro was plagued by smelly green pool water (**Figure 22.40**). Several explanations were proposed including one based on the addition of copper(II) sulfate to kill the algae growing under the tropical conditions. The color in the water was attributed to the formation of green copper(II) chloride complexes and the odor from the conversion of sulfate to hydrogen sulfide by cytochromes. (The chloride ions were derived from ClO^- ions added to the water as a disinfectant.)

1. Aqueous solutions of copper(II) sulfate contain blue

$[Cu(H_2O)_6]^{2+}$ ions. How do the neutral water molecules bond to the Cu^{2+} ion?
2. Two possible copper(II) chloride complexes are $Cu(H_2O)_4Cl_2$ and $[Cu(H_2O)_5Cl]Cl$. How would we name these two coordination complexes?
3. How many isomers can be drawn for the copper(II) complexes in part (c)?
4. Are any of these complexes paramagnetic?
5. What is the origin of the blue color in solutions of $[Cu(H_2O)_6]^{2+}$?
6. Why does the color of the soluble copper complexes change from blue to green in the presence of chloride ion?
7. Does the conversion of $SO_4{}^{2-}$ to H_2S require a reducing agent or an oxidizing agent—perhaps cytochromes?

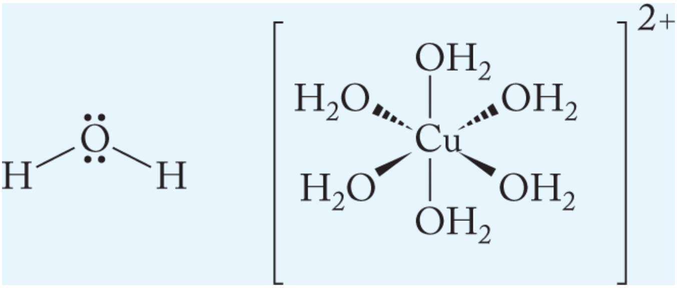
Collect and Organize We need to answer several questions about the structure and bonding in coordination compounds formed between transition metal cations and Lewis base ligands that may account for the color of the pool water. The transition metal ion is Cu^{2+} and the Lewis bases include water and chloride ions. We also need to consider the redox process that converts sulfate to hydrogen sulfide as a source of the foul odor associated with the green pool water. Reducing agents are themselves oxidized while oxidizing agents are reduced in the process (see Section 4.8). Cytochromes are a class of enzymes that mediate redox processes.

Analyze Transition metal cations act as Lewis acids, accepting electron pairs from Lewis bases. The Lewis bases have lone pairs available to share with Cu^{2+} in a coordinate covalent bond. The coordination number of copper equals 6 in each of the copper complexes. The number and identity of the ligands determines whether isomers are possible and provides clues to the color of the complexes. We will likely need to consult the *d*-orbital splitting in Figure 22.12 and the color wheel in Figure 22.14 when addressing questions about magnetism and color in copper complexes.

Solve

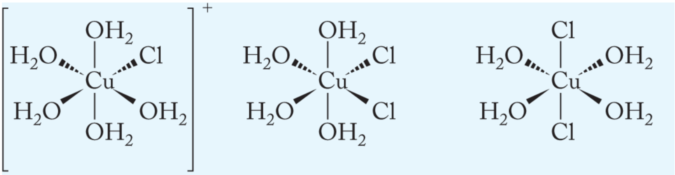
1. Based on the Lewis structure for water, each oxygen atom can share a lone pair of electrons with the Cu^{2+} ion to form a

coordinate covalent bond.



---

2. The two complexes, $Cu(H_2O)_4Cl_2$ and $[Cu(H_2O)_5Cl]Cl$, have different numbers of water and chloride ligands in their inner coordination sphere, which leads to different names. When naming coordination complexes containing two or more different ligands we list the names of the ligands in alphabetical order. We indicate how many of each ligand are present with the prefixes found in Table 22.4, and we include the oxidation state of the metal using a Roman numeral. The correct name for $Cu(H_2O)_4Cl_2$ is tetraaquadichlorocopper(II). The compound with the formula $[Cu(H_2O)_5Cl]Cl$ contains a complex ion with a positive charge and one chloride as a counterion. We name the complex cation before naming the anion: pentaaquachlorocopper(II) chloride.
3. The coordination number for copper in both $Cu(H_2O)_4Cl_2$ and $[Cu(H_2O)_5Cl]Cl$ is 6, suggesting an octahedral geometry about the copper cation. There are two ways to arrange four water molecules and two chloride ions around one Cu^{2+}: a cis and a trans arrangement. We can modify the name for $Cu(H_2O)_4Cl_2$ by adding the prefix *cis*- or *trans*- to indicate which isomer is present. Only one isomer is possible for $[Cu(H_2O)_5Cl]^+$.



Pentaquachloro-copper(II) *cis*-Tetraquadichloro-copper(II) *trans*-Tetraquadichloro-copper(II)

---

4. The magnetic properties of six-coordinate complexes can be

determined from the energy levels of the *d* orbitals of their central atoms (see Figure 22.12). The 9 valence electrons of Cu^{2+} fill the lower-energy d_{xy}, d_{xz}, and d_{yz} orbitals, but one of the two higher-energy orbitals, the d_{z^2} or $d_{x^2-y^2}$, contains a single, unpaired electron, which means that both Cu(II) complexes are paramagnetic.

5. The colors of six-coordinate complexes are also linked to their crystal field splitting energy Δ. The absorption of visible light of the proper wavelength by $[Cu(H_2O)_6]^+$ leads to promotion of an electron from one of the fully occupied lower-energy orbitals to the partially filled higher-energy orbital. The color we see is the complementary color to the wavelength absorbed by $[Cu(H_2O)_6]^+$ (see Figure 22.14). In this case, absorption of orange light accounts for the blue color.
6. The magnitude of Δ depends on the nature of the ligands that surround Cu^{2+}, as shown in the spectrochemical series (Table 22.6). Chloride is found below water in Table 22.6, which means that Δ for $Cu(H_2O)_4Cl_2$ and $[Cu(H_2O)_5Cl]^+$ will be less than for $[Cu(H_2O)_6]^+$. The result is that the energy of light required to move an electron from the d_{xy}, d_{xz}, and d_{yz} set of orbitals to the d_{z^2} or $d_{x^2-y^2}$ orbitals will be *less* for copper chloride complexes than for $[Cu(H_2O)_6]^+$. Lower-energy light corresponds to a *longer* wavelength, so copper chloride complexes will absorb the red region of the electromagnetic spectrum shown in Figure 22.14. The complementary color of red is green.
7. The conversion of sulfate (SO_4^{2-}) to hydrogen sulfide (H_2S) is a redox process because the oxidation number of sulfur changes from $+6$ in SO_4^{2-} to -2 in H_2S, a net gain of 8 electrons. The gain of electrons is defined as reduction, so one or more reducing agents must have been present in the pool. Cytochromes could provide the necessary electrons for the reduction of sulfate to hydrogen sulfide.

Think About It If copper sulfate was added to the diving pool water at the 2016 Olympic Games, the observed green color is consistent with the formation of copper(II) chloride complexes. The redox activity of cytochromes could account for the formation of H_2S, consistent with the hypothesis presented in this exercise. The data do not prove, however, that this was the origin of the green color.

Glossary

organometallic compound	a molecule containing direct carbon–metal covalent bonds.

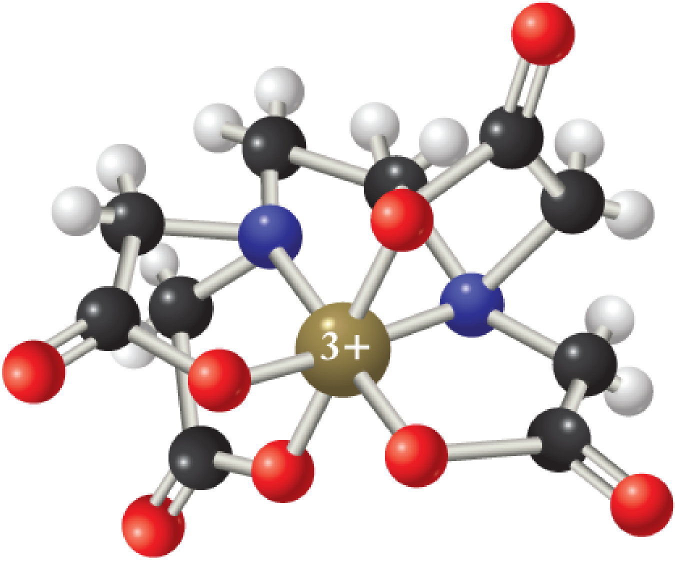
Learning Objectives

- Describe several of the roles of transition metal complexes in biochemistry and how they are used as diagnostic or therapeutic compounds **Return to Sample Exercise 22.6**

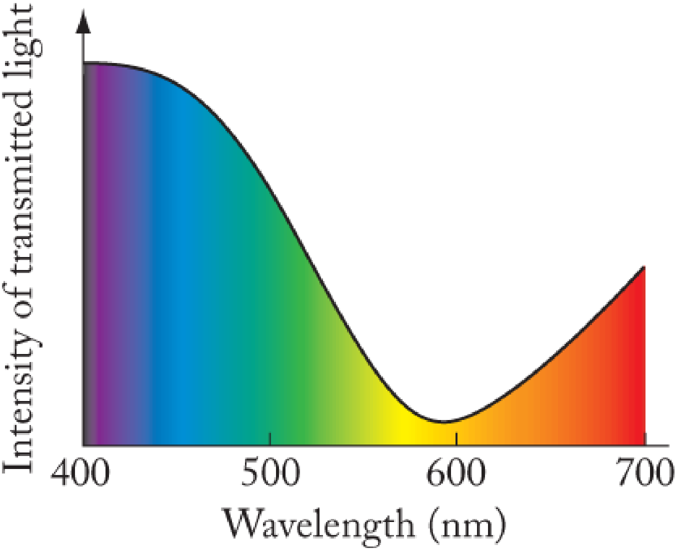
SUMMARY

LO1 Molecules or anions that function as Lewis bases and form coordinate bonds with metal cations are called *ligands*. The resulting species, which are composed of central metal ions and the surrounding ligands, are called *complex ions* or simply complexes. Direct bonding to a central cation means that the ligands in a complex occupy the inner coordination sphere of the cation. (Section 22.1)

- LO2 The names of complex ions and coordination compounds provide information about the identities and numbers of ligands, the identity and oxidation state of the central metal ion, and the identity and number of counterions. (Section 22.2)

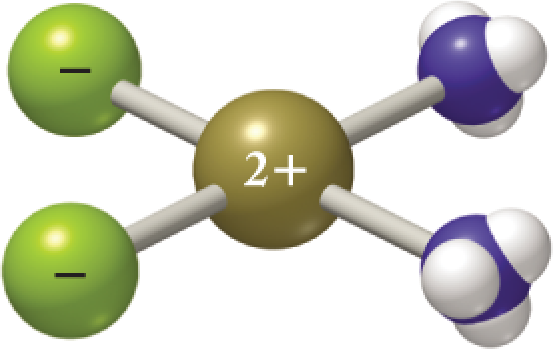


- LO3 A monodentate ligand donates one pair of electrons in a complex ion; a polydentate ligand donates more than one pair in a process called chelation. Polydentate ligands are particularly effective at forming complex ions. This phenomenon is called the chelate effect. EDTA is a particularly effective sequestering agent, which is a chelating agent that prevents metal ions in solution from reacting with other substances. (Section 22.3)



- LO4 The colors of transition metal compounds can be explained by the interactions between electrons in different *d* orbitals and the lone pairs of electrons on surrounding ligands. These interactions create crystal field splitting of the energies of the *d* orbitals. A spectrochemical series ranks ligands on the basis of their field strength and the wavelengths of electromagnetic radiation absorbed by their complex ions. (Section 22.4)
- LO5 Strong repulsions and large values of crystal field splitting energy can lead to electron pairing in lower-energy orbitals and an electron configuration called a low-spin state. Metals and their ions with their *d* electrons evenly distributed across all the *d* orbitals in the valence shell represent a high-spin state. (Section 22.5)
- LO6 Complex metal ions containing more than one type of ligand may form different kinds of isomers. When one type occupies two adjacent corners of a square planar complex, the complex is a *cis* isomer; when the same ligand occupies opposite corners, it is a *trans* isomer. When ligands contain two different Lewis base atoms, linkage isomers are possible. Octahedral complexes may form as a pair of enantiomers.

(Sections 22.6 and 22.7)



- LO7 Many enzymes contain transition metal ions. Soluble coordination compounds and organometallic compounds of the transition metals appear in enzymes. Such compounds are used for imaging and in medications for arthritis, cancer, and other diseases. (Section 22.8)

Nitrogen; ammonia, 4; ethylenediamine, 3.

PROBLEM-SOLVING SUMMARY

Type of Problem	Concepts and Equations	Sample Exercises
Interpreting and writing formulas of coordination compounds	Identify the ligands, counterions, and their charges. Determine the oxidation states of metals in complex ions. Use square brackets to represent a complex ion.	**22.1**
Naming coordination compounds	Follow the naming rules in Section 22.2.	**22.2**
Identifying the potential electron-pair donor groups in a molecule	Examine the molecular structure to find lone pairs that can be donated to a metal.	**22.3**
Predicting spin states	Sketch the orbital diagram based on crystal field splitting. Fill the lowest-energy orbitals with one valence electron each. If there are two ways of adding the remaining valence electrons to the diagram, then multiple spin states are possible.	**22.4**
Identifying isomers of coordination compounds	If ligands of one type are on the same side of the complex ion, it is a cis isomer. If ligands of one type are on opposite	**22.5**

sides, it is a trans isomer.		
22.6	**Calculating the equilibrium constant for a ligand exchange reaction**	Use the rules for equilibrium constants to calculate the equilibrium constant for a ligand exchange reaction.

VISUAL PROBLEMS

(Answers to boldface end-of-chapter questions and problems are in the back of the book.)

Figure P22.1 highlights six elements in the fourth row of the periodic table.

1. Which two of the highlighted elements have cations that form colored compounds with Cl^-?
2. Which of the highlighted transition metals form M^{2+} cations that cannot have high-spin and low-spin states?
3. Which of the highlighted transition metals have M^{2+} cations that form colorless tetrahedral complex ions?

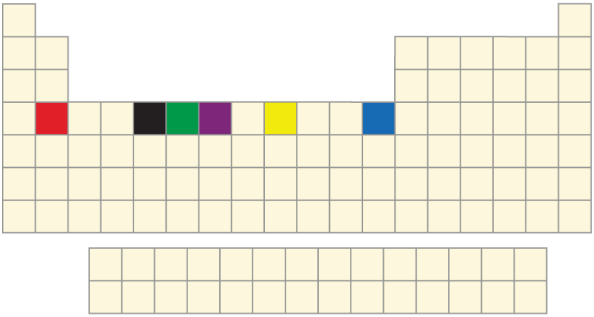

FIGURE P22.1

Predict the number of unpaired electrons for each of the transition metal complexes in Figure P22.2.

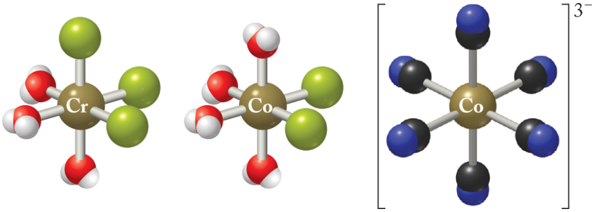

FIGURE P22.2

The presence of manganese impurities in crystals of silicon dioxide gives smoky quartz its distinctive lavender and purple colors. Which of the orbital diagrams in Figure P22.3 best describes the Mn^{2+} ion in a tetrahedral field?

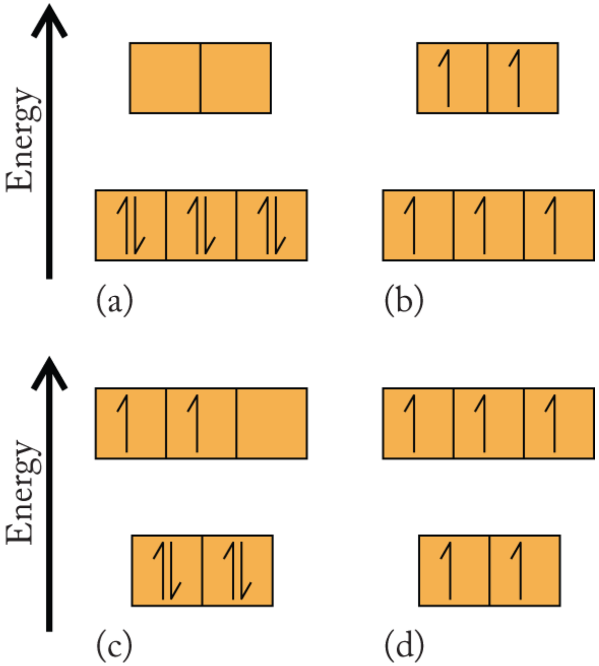

FIGURE P22.3

The nickel(II) complex $(PMePh_2)_2NiX_2$, where X = Cl, has no unpaired electrons, but it has two when X = Br. Which of the orbital diagrams in Figure P22.4 best explains the difference between the two complexes?

QUESTIONS AND PROBLEMS

Complex Ions

Concept Review

When NaCl dissolves in water, which molecules or ions occupy the inner coordination sphere around the Na^+ ions?

When $Cr(NO_3)_3$ dissolves in water, which of the following species are nearest the Cr^{3+} ions?

1. Other Cr^{3+} ions
2. NO_3^- ions
3. H_2O molecules with the O atoms closest to the Cr^{3+}
4. H_2O molecules with the H atoms closest to the Cr^{3+}

The coordination compound $Co_3[Cr(CN)_6]_2$ contains a Co^{2+} cation and a complex anion. What is the likely oxidation state for Cr in the anion?

The coordination compound $Fe_3[Fe(CN)_6]_3$ contains a Fe^{2+} cation and a complex anion. What is the likely oxidation state for Fe in the anion?

Problems

Use the following freezing point depression data to calculate the van ’t Hoff factor for $K_3[Fe(CN)_6]$.

ΔT (°C)	m (mol/kg)
0.0801	0.1
0.338	0.0740
0.807	0.160
1.197	0.24
1.588	0.3
1.914	0.40
2.435	0.51
3.064	0.6
3.454	0.73

Use the following data to calculate the van ’t Hoff factor for $K_4[Fe(CN)_6]$.

ΔT (°C)	m (mol/kg)
0.107	0.0222
0.380	0.0752
0.709	0.145
1.024	0.2
1.309	0.32

The accompanying table contains data from reactions of solutions of a series of octahedral platinum(IV) complexes with $AgNO_3(aq)$. The compounds have the general formula $Pt(NH_3)_xCl_4$, where $x = 6, 5, 4, 3,$ or 2. Write formulas for each compound.

Composition of Complex	Number of Moles of AgCl Produced per Mole of Complex Added
$Pt(NH_3)_6Cl_4$	4
$Pt(NH_3)_5Cl_4$	3
$Pt(NH_3)_4Cl_4$	2
$Pt(NH_3)_3Cl_4$	1

$Pt(NH_3)_2Cl_4$	0

The compositions of three compounds of chromium(III) and chloride ion are known: $Cr(H_2O)_6Cl_3$, $Cr(H_2O)_5Cl_3$, and $Cr(H_2O)_4Cl_3$. The following table summarizes their properties.

Compound	Color of Aqueous Solution	Number of Moles of AgCl Produced per Mole of Complex Added
A	Dark green	1
B	Blue-green	3
C	Green	2

Write the correct formulas for compounds A, B, and C.

Naming Complex Ions and Coordination Compounds

Problems

Name the complex ions of platinum(IV) in Problem 22.19.

Name the complex ions of chromium(III) in Problem 22.20.

What are the names of the following complex ions?

1. $Cr(NH_3)_6{}^{3+}$
2. $Co(H_2O)_6{}^{3+}$
3. $Ni(CN)_5{}^{3-}$

What are the names of the following complex ions?

1. $Cu(NH_3)_2{}^{+}$
2. $Ti(H_2O)_4(OH)_2{}^{2+}$
3. $Cr(en)(OH)_4{}^{-}$

What are the names of the following coordination compounds?

1. K_2CoBr_4
2. $NH_4[Zn(H_2O)(OH)_3]$

$[Fe(NH_3)_5Cl]Cl_2$ 3.

What are the names of the following coordination compounds?

Na_2CoI_4 1.
$BaCuCl_4$ 2.
$[Ni(NH_3)_4(H_2O)_2]SO_4$ 3.

What are the names of the following coordination compounds?

$[Zn(en)_2]SO_4$ 1.
$[Ni(NH_3)_5(H_2O)]Cl_2$ 2.
$K_4[Fe(CN)_6]$ 3.

What are the names of the following coordination compounds?

$(NH_4)_3[Co(CN)_6]$ 1.
$[Co(en)_2Cl](NO_3)_2$ 2.
$[Fe(H_2O)_4(OH)_2]Cl$ 3.

Polydentate Ligands and Chelation

Concept Review

What is meant by the term *sequestering agent*? What properties make a substance an effective sequestering agent?

The structures of two compounds that each contain two $–NH_2$ groups are shown in Figure P22.30. The one on the left is ethylenediamine, a bidentate ligand. Does the molecule on the right have the same ability to donate two pairs of electrons to a metal ion? Explain why you think it does or does not.

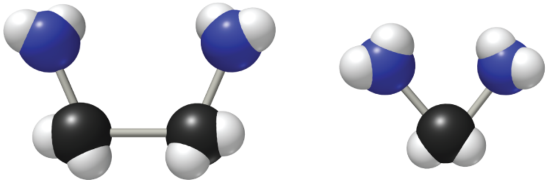

FIGURE **P22.30**

How does the chelating ability of an aminocarboxylic acid vary with changing pH?

Food Preservative The EDTA that is widely used as a food preservative is added to food, not as the undissociated acid, but rather as the calcium disodium salt: $Na_2[CaEDTA]$. This salt is actually a coordination compound with a Ca^{2+} ion at the center of a complex ion. Draw the structure of this compound.

Crystal Field Theory

Concept Review

Explain why the compounds of most of the first-row transition metals are colored.

Unlike the compounds of most transition metal ions, those of Ti^{4+} are colorless. Why?

Why is the d_{xy} orbital higher in energy than the d_{xz} and d_{yz} orbitals in a square planar crystal field?

On average, the *d* orbitals of a transition metal ion in an octahedral field are higher in energy than they are when the ion is in the gas phase. Why?

Problems

Aqueous solutions of one of the following complex ions of chromium(III) are violet; solutions of the other are yellow. Which is which? (a) $Cr(H_2O)_6{}^{3+}$; (b) $Cr(NH_3)_6{}^{3+}$

Which of the following complex ions should absorb the shortest wavelengths of electromagnetic radiation? (a) $CuCl_4{}^{2-}$; (b) $CuF_4{}^{2-}$; (c) $CuI_4{}^{2-}$; (d) $CuBr_4{}^{2-}$

The octahedral crystal field splitting energy Δ_o of $Co(phen)_3{}^{3+}$ is 5.21×10^{-19} J/ion. What is the color of a solution of this complex ion?

The octahedral crystal field splitting energy Δ_o of $Co(CN)_6{}^{3-}$ is 6.74×10^{-19} J/ion. What is the color of a solution of this complex ion?

Solutions of $NiCl_4{}^{2-}$ and $NiBr_4{}^{2-}$ absorb light at 702 nm and 756 nm, respectively. In which ion is the split of *d*-orbital energies greater?

Chromium(III) chloride forms six-coordinate complexes with bipyridine, including *cis*-$[Cr(bipy)_2Cl_2]^+$, which reacts slowly with water to produce *cis*-$[Cr(bipy)_2(H_2O)Cl]^{2+}$ and *cis*-$[Cr(bipy)_2(H_2O)_2]^{3+}$. In which of these complexes should Δ_o be the largest?

Magnetism and Spin States

Concept Review

What determines whether a transition metal ion is in a *high-spin* configuration or a *low-spin* configuration?

Would you expect a solution of a high-spin complex of a transition metal ion to be the same color as a solution of a low-spin complex? Why?

Problems

How many unpaired electrons are there in the following transition metal ions in an octahedral field? High-spin Fe^{2+}, Cu^{2+}, Co^{2+}, and Mn^{3+}

Which of the following cations can have either a high-spin or a low-spin electron configuration in an octahedral field? Fe^{2+}, Co^{3+}, Mn^{2+}, and Cr^{3+}

A solid compound containing iron(II) in an octahedral crystal field has four unpaired electrons at 298 K. When the compound is cooled to 80 K, the same sample appears to have no unpaired electrons. How do you explain this change in the compound’s properties?

The iron(II) compound $Fe(bipy)_2(SCN)_2$ is paramagnetic, but the corresponding cyanide compound $Fe(bipy)_2(CN)_2$ is diamagnetic. Why do these two compounds have different magnetic properties?

The manganese minerals pyrolusite (MnO_2) and hausmannite (Mn_3O_4) contain manganese ions surrounded by oxide ions.

1. What are the charges of the Mn ions in each mineral?
2. In which of these compounds could there be high-spin and low-spin Mn ions?

Dietary Supplement Chromium picolinate is an over-the-counter diet aid sold in many pharmacies. The Cr^{3+} ions in this coordination compound are in an octahedral field. Is the compound paramagnetic or diamagnetic?

Refining Cobalt One method for refining cobalt involves the formation of the complex ion $CoCl_4^{2-}$. This anion is tetrahedral. Is this complex paramagnetic or diamagnetic?

Why is it that $Ni(CN)_4^{2-}$ is diamagnetic, but $NiCl_4^{2-}$ is paramagnetic?

Isomerism in Coordination Compounds

Concept Review

What do the prefixes *cis*- and *trans*- mean in the context of an octahedral complex ion?

What do the prefixes *cis*- and *trans*- mean in the context of a square planar complex?

What is the minimum number of donor groups required in order to have stereoisomers of a square planar complex?

With respect to your answer to Problem 22.55, do all square planar complexes with this number of donor groups have stereoisomers?

Problems

Does the complex $Co(en)(H_2O)_2Cl_2$ have stereoisomers?

Does the complex ion $Fe(en)_3^{3+}$ have stereoisomers?

Sketch the stereoisomers of the square planar complex ion $CuCl_2Br_2^{2-}$. Are any of these isomers chiral?

Sketch the stereoisomers of the complex ion $Ni(en)Cl_2(CN)_2^{2-}$. Are any of these isomers chiral?

Coordination Compounds in Biochemistry

Concept Review

Enzymes are large proteins.

1. What is the function of enzymes?
2. Are all proteins enzymes?

Why is Cd^{2+} more likely than Cr^{2+} to replace Zn^{2+} in an enzyme such as carbonic anhydrase?

What effect does an enzyme have on the activation energy of a biochemical reaction?

Why might reductases also be described as reducing agents?

When a transition metal ion such as Cu^{2+} is incorporated into a metalloenzyme, is the formation constant likely to be much greater than one ($K >> 1$) or much less than one ($K << 1$)? $Cu^{2+} + \text{protein} \rightleftharpoons \text{metalloenzyme} \quad K = \frac{[\text{metalloenzyme}]}{[Cu^{2+}][\text{protein}]}$

Carbon monoxide poisoning derives from competitive binding of CO versus O_2 to the Fe^{2+} in the coordination sphere of hemoglobin. If CO can be displaced by breathing pure O_2, which of the following is likely to be correct under these conditions: $K_{O2}/K_{CO} < 1$ or $K_{O2}/K_{CO} > 1$?

What is the likely sign of ΔS for the reaction in Figure P22.67, which is catalyzed by carboxypeptidase?

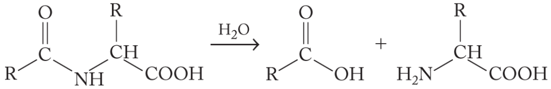

FIGURE P22.67

What is the likely sign of ΔG for the reaction in Problem 22.67?

Problems

The activation energy for the uncatalyzed decomposition of hydrogen peroxide at 20°C is 75.3 kJ/mol. In the presence of the enzyme catalase, the activation energy is reduced to 29.3 kJ/mol. By using the following form of the Arrhenius equation, RT In $(k_1/k_2) = E_{a1} - E_{a2}$, how much faster is the catalyzed reaction?

Enzymatic Activity of Urease Urease catalyzes the decomposition of urea to ammonia and carbon dioxide (Figure P22.70). The rate constant for the uncatalyzed reaction at 20°C and pH $= 8$ is $k = 3 \times 10^{-10}\ s^{-1}$. A urease isolated from the jack bean increases the rate constant to $k = 3 \times 10^{4}\ s^{-1}$. By using the RT In $(k_1/k_2) = E_{a1} - E_{a2}$ form of the Arrhenius equation, calculate the difference between the activation energies.

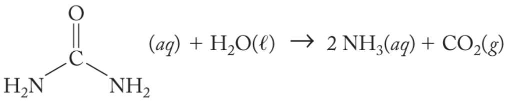

FIGURE P22.70

The initial rate of an enzyme-catalyzed reaction depends on the concentration of substrate as shown in Figure P22.71. What is the apparent reaction order at the far-right side of the graph?

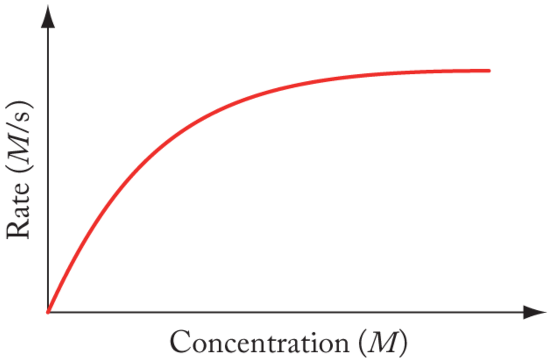

FIGURE P22.71

The rate of an enzyme-catalyzed reaction depends on the concentration of substrate. Which line in Figure P22.72 has the highest reaction rate?

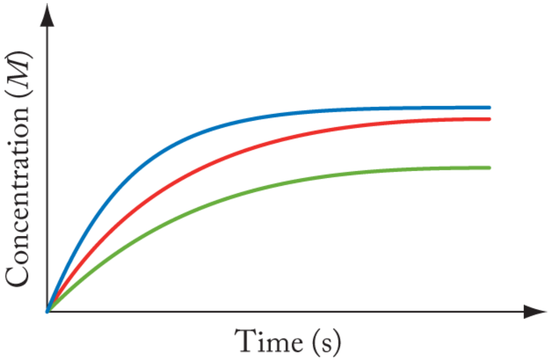

FIGURE P22.72

Coordination Compounds in Medicine

Concept Review

Under what circumstances might a coordination complex of a toxic metal be useful in medicine?

Cancer Treatment Brachytherapy is a cancer treatment that involves surgical implantation of a small capsule of ^{192}Ir into a tumor. Iridium-192 lies between two stable isotopes of iridium, ^{193}Ir and ^{191}Ir. How does this account for the fact that ^{192}Ir decays by β decay, electron capture, and positron emission?

Gadolinium-153 decays by electron capture. What type of radiation does ^{153}Gd produce that makes it useful for imaging?

Gadolinium-153 and samarium-153 both have the same mass number. Why might ^{153}Gd decay by electron capture, whereas ^{153}Sm decays by emitting β particles?

How do platinum- and ruthenium-containing drugs fight cancer?

Many transition metal complexes are brightly colored. Why might the titanium(IV) compound budotitane be colorless?

Is the glucose tolerance factor that contains chromium(III) paramagnetic or diamagnetic?

Coordination complexes containing paramagnetic transition metal ions make the best MRI contrast agents.

1. Which of the first-row transition metal cations with a $2+$ charge have the most unpaired valence electrons in the gas phase?
2. Which of the first-row transition metal cations with a $2+$ charge have the most unpaired valence electrons in octahedral coordination complexes?

Problems

The complexation of mercury(II) ion with methionine,

$$\mathrm{Hg}^{2+} + \text{methionine} \rightleftharpoons \mathrm{Hg(methionine)}^{2+}$$

has a formation constant of $\log K_\mathrm{f} = 14.2$, whereas the formation constant for the Hg^{2+} complex with penicillamine,

$$\mathrm{Hg}^{2+} + \text{penicillamine} \rightleftharpoons \mathrm{Hg(penicillamine)}^{2+}$$

is $\log K_\mathrm{f} = 16.2$. Calculate the equilibrium constant for the reaction,

$$\mathrm{Hg(methionine)}^{2+} + \text{penicillamine} \rightleftharpoons \mathrm{Hg(penicillamine)}^{2+} + \text{methionine}$$

The complexation of mercury(II) ion with cysteine in aqueous solution,

$$\mathrm{Hg}^{2+} + \text{cysteine} \rightleftharpoons \mathrm{Hg(cysteine)}^{2+}$$

has a formation constant of log $K_f = 14.2$, whereas the formation constant for the Hg^{2+} complex with glycine,

$$Hg^{2+} + \text{glycine} \rightleftharpoons Hg(\text{glycine})^{2+}$$

is log $K_f = 10.3$. Calculate the equilibrium constant for the reaction,

$$Hg(\text{cysteine})^{2+} + \text{glycine} \rightleftharpoons Hg(\text{glycine})^{2+} + \text{cysteine}$$

The equilibrium constant of the reaction,

$$CH_3Hg(\text{penicillamine})^{+}(aq) + \text{cysteine}(aq) \rightleftharpoons CH_3Hg(\text{cysteine})^{+}(aq) + \text{penicillamine}(aq)$$

is $K = 0.633$. Calculate the equilibrium concentrations of cysteine and penicillamine if we start with a 1.00 *M* solution of cysteine and a 1.00 m*M* solution of $CH_3Hg(\text{penicillamine})^{+}$.

The equilibrium constant of the reaction,

$$CH_3Hg(\text{glutathione})^{+}(aq) + \text{cysteine}(aq) \rightleftharpoons$$

$$CH_3Hg(\text{cysteine})^{+}(aq) + \text{glutathione}(aq)$$

is $K = 5.0$. Calculate the equilibrium concentrations of cysteine and glutathione if we start with a 1.20 m*M* solution of cysteine and a 1.20 m*M* solution of $CH_3Hg(\text{glutathione})^{+}$.

The two platinum compounds shown in Figure P22.85 have been studied in cancer therapy.

1. What is the difference between the two compounds?
2. Name the two complex ions.
3. Do both compounds have the same orbital diagram?
4. Sketch the *d* orbital diagram for the platinum compound(s), including the appropriate number of electrons.

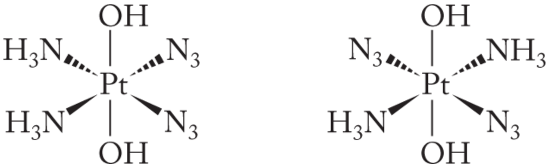

FIGURE P22.85

Anticancer treatments based on coordination complexes of ruthenium may have less severe side effects than cisplatin and other platinum-based medications. The complex shown in Figure P22.86 was tested against a colon cancer cell line with promising results.

1. Draw the other stereoisomer of $[Ru(py)_2Cl_4]^-$.
2. Name both isomers.
3. Sketch the orbital diagram for the ruthenium compound, including the appropriate number of electrons.

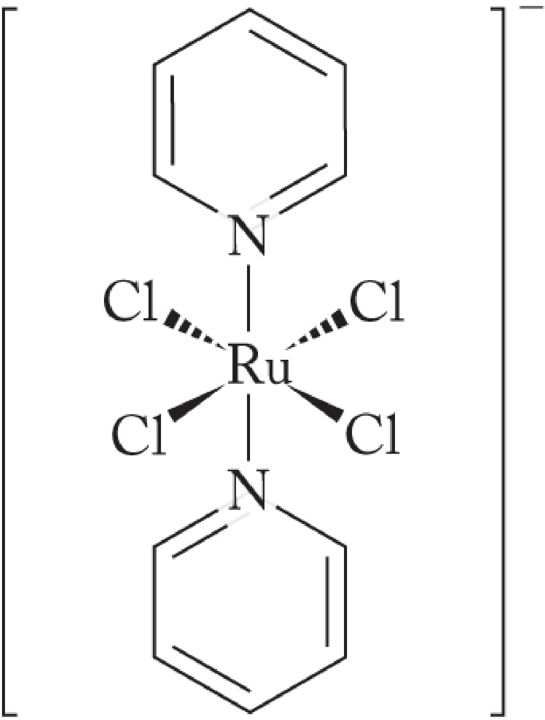

FIGURE P22.86

Two square planar gold and platinum complexes with medicinal properties are shown in Figure P22.87.

1. Do these two complexes have the same number of *d* electrons in their orbital diagram?
2. Are these compounds diamagnetic or paramagnetic?

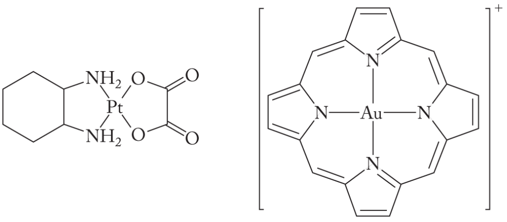

FIGURE P22.87

In Section 9.5 we saw that polycyclic aromatic compounds can intercalate into DNA. Compounds such as the rhodium and ruthenium complexes shown in Figure P22.88 behave in a similar fashion toward DNA.

1. What is the hybridization at the nitrogen and the carbon atoms in these ligands?
2. Why are these ligands planar?
3. Are these compounds diamagnetic or paramagnetic?

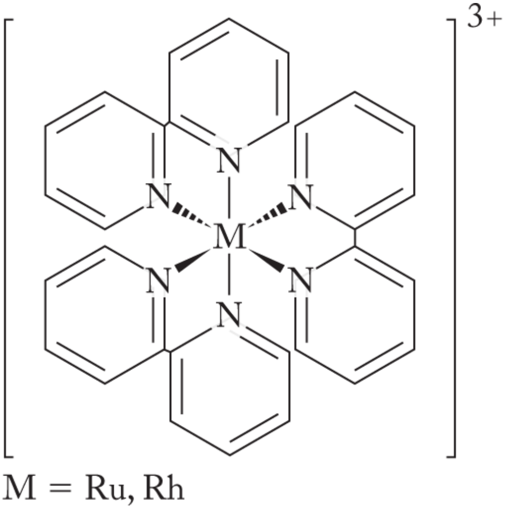

FIGURE P22.88

Additional Problems

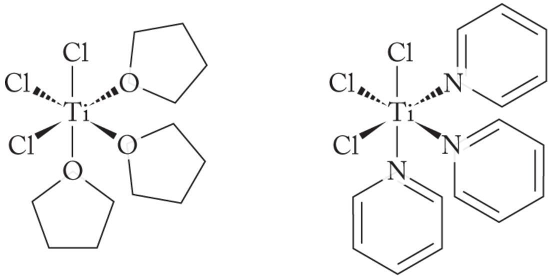
Dissolving cobalt(II) nitrate in water gives a beautiful red-purple solution. There are three unpaired electrons in this cobalt(II) complex. When cobalt(II) nitrate is dissolved in aqueous ammonia and oxidized with air, the resulting yellow complex has no unpaired electrons.

1. Which cobalt complex has the larger crystal field splitting energy Δ_o?
2. Draw orbital diagrams for the *d* orbitals of both complexes.

Adding pyridine to a solution of $TiCl_3(THF)_3$ (Figure P22.90) leads to a decrease in the wavelength at which the solution absorbs.

Is this consistent with the formation of $TiCl_3(py)_3$?

Figure P22.90 shows one possible arrangement of three chloride ligands and three THF or three pyridine ligands. Draw another geometric isomer of these compounds.



FIGURE

P22.90

When Ag_2O reacts with peroxodisulfate ($S_2O_8^{2-}$) ion (a powerful oxidizing agent), AgO is produced. Crystallographic and magnetic analyses of AgO suggest that it is not simply silver(II) oxide, but rather a blend of silver(I) and silver(III) in a square planar environment. The Ag^{2+} ion is paramagnetic but, like AgO, Ag^{+} and Ag^{3+} are diamagnetic. Explain why?

Two iron compounds (a) and (b) in Figure P22.92 both contain Fe^{2+} (R is a monoanion and the phosphorus ligands are neutral). Compound (a) has a tetrahedral geometry at iron and four unpaired electrons. Compound (b) has a square planar geometry at iron and two unpaired electrons. Account for the difference in magnetic properties.

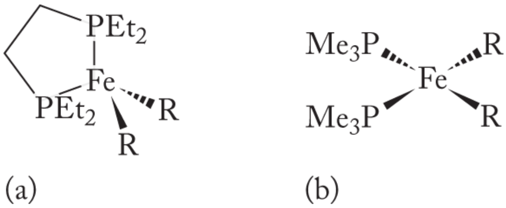


FIGURE P22.92

Ruthenium Drugs One of the earliest ruthenium compounds to be investigated for medicinal use was *trans*-$RuCl_2(DMSO)_4$, where DMSO represents dimethyl sulfoxide, $(CH_3)_2S$□O. When dissolved in water, some of the ligands are replaced by water to form $[RuCl(DMSO)_2(H_2O)_3]^+$.

trans-$RuCl_2(DMSO)_4 + H_2O \rightarrow [RuCl(DMSO)_2(H_2O)_3]Cl + 2$ DMSO

1. The product has an octahedral geometry (coordination number = 6) and can exist as two geometric isomers. Draw these isomers.
2. Why might the starting material and product have linkage isomers?

When the compound in Figure P22.94 is exposed to light at 400 nm, it undergoes linkage isomerism.

1. Draw the linkage isomer.
2. Are either or both of the isomers chiral?

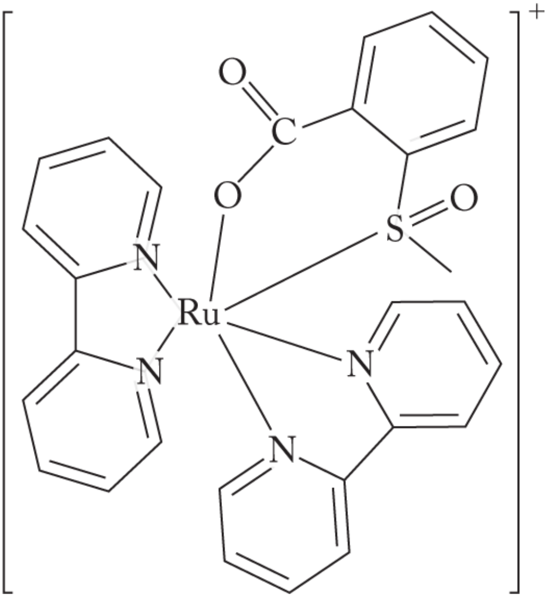

FIGURE P22.94

Manganese(II) chloride was one of the first compounds to be investigated as an MRI contrast agent. How many unpaired electrons does the complex have when $MnCl_2$ dissolves in water to form the coordination compound $MnCl_2(H_2O)_4$?

Gadolinium(III) ions are used in contrast agents for MRI because they have unpaired electrons. What is the electron configuration for Gd^{3+} and how many unpaired electrons does it have?

Glossary

inner coordination sphere
the ligands that are bound directly to a metal via coordinate bonds.

monodentate ligand
a species that forms only a single coordinate bond to a metal ion in a complex.

polydentate ligand

a species that can form more than one coordinate bond per molecule.

chelation

the interaction of a metal with a polydentate ligand (chelating agent); pairs of electrons on one molecule of the ligand occupy two or more coordination sites on the central metal.

chelate effect

the greater affinity of metal ions for polydentate ligands than for monodentate ligands.

crystal field splitting

the separation of a set of *d* orbitals into subsets with different energies as a result of interactions between electrons in those orbitals and lone pairs of electrons in ligands.

spectrochemical series

a list of ligands rank-ordered by their ability to split the energies of the *d* orbitals of transition metal ions.

organometallic compound

a molecule containing direct carbon–metal covalent bonds.

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

$$\begin{aligned} x &= \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} \\ &= \frac{-0.112 \pm \sqrt{(0.112)^2 - 4(1)(-1.2 \times 10^{-3})}}{2(1)} \\ &= \frac{-0.112 \pm \sqrt{0.01254 + 0.0048}}{2} \\ &= \frac{-0.112 \pm 0.132}{2} = +0.010 \text{ or } -0.122 \end{aligned}$$

$$\ln k = \ln A - \left(\frac{E_{\mathrm{a}}}{RT}\right)$$

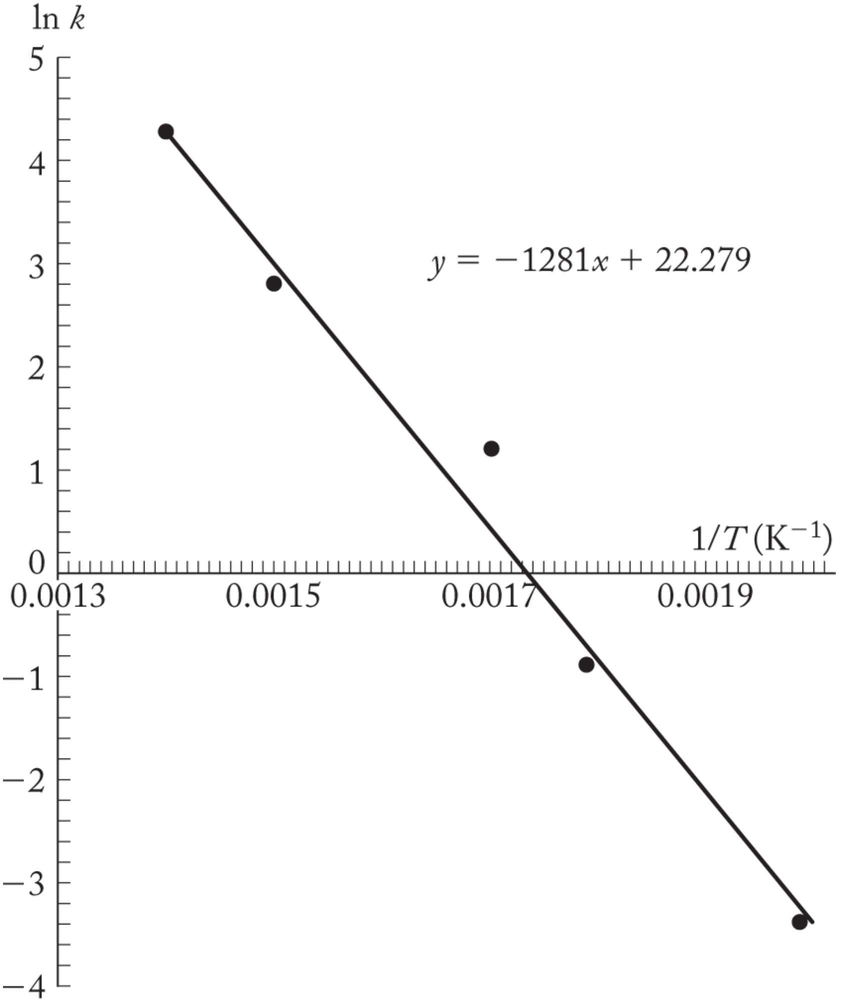

FIGURE A1.1

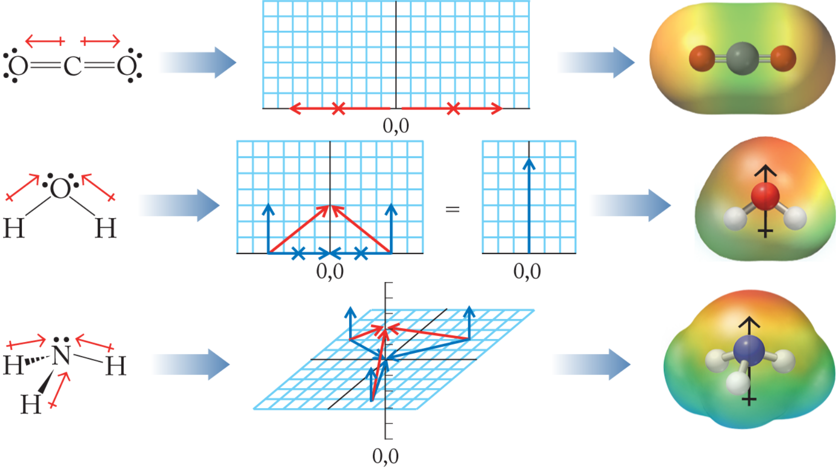
$$E_a = -(-1281\ \cancel{\text{K}})[8.314\text{ J/(mol} \cdot \cancel{\text{K}})]$$

$$= 10{,}650\text{ J/mol} = 10.65\text{ kJ/mol}$$

$$s = \sqrt{\frac{\sum_i (x_i - \bar{x})^2}{n - 1}}$$

$$\mu = \bar{x} \pm \frac{t\,s}{\sqrt{n}}$$



Appendix 1

Mathematical Procedures

Working with Scientific Notation

Quantities that scientists work with are sometimes very large, such as Earth's mass, and other times very small, such as the mass of an electron. It is easier to work with these values when they are expressed in scientific notation.

The general form of standard scientific notation is a value between 1 and 10 multipled by 10 raised to an integral power. According to this definition, 598×10^{22} kg (Earth's mass) is not in standard scientific notation, but 5.98×10^{24} kg is. It is good practice to use and report values in standard scientific notation.

1. **To convert an "ordinary" number to standard scientific notation,** move the decimal point to the left for a large number, or to the right for a small one, so that the decimal point is located after the first nonzero digit.

    1. For example, to express Earth's average density (5517 kg/m^3) in scientific notation requires moving the decimal point three places to the left. Doing so is the same as dividing the number by 1000, or 10^3. To keep the value the same we multiply it by 10^3. So, Earth's density in standard scientific notation is 5.517×10^3 kg/m^3.
    2. If we move the decimal point of a value less than 1 to the right to express it in scientific notation, then the exponent is a negative integer equal to the number of places we moved the decimal point to the right. For example, the value of R used in solving ideal gas law problems is 0.08206 L · atm/(mol · K). Moving the decimal point two places to the right converts the value of R to scientific notation: 8.206×10^{-2} L · atm/(mol · K).
    3. Another value of R, 8.314 J/(mol · K), does not need an exponent, though it could be written 8.314×10^0 J/(mol · K) because any value raised to the zero power is equal to 1.

2. **For calculations with numbers in scientific notation,** most calculators have a function key for entering the exponents of values expressed in scientific notation. In many calculators it is labeled "E" or "EE" or "Exp." To enter, for example, the speed of light in meters per second, 2.998×10^8, we enter the value before the exponent, 2.998, followed by the exponent key and then the value of the exponent (8). To enter a value with a negative exponent, use the sign-change key. Sometimes it is labeled "$(-)$" or "$+/-$" or "$\pm$."

Working with Logarithms

A logarithm to the base 10 has the following form:

$\log_{10}x = \log x = a$, where $x = 10^a$

We usually abbreviate the logarithm function “log” if the logarithm is to the base 10, which means the scale in which $\log 10 = 1$.

A logarithm to the base e, called a *natural logarithm*, has the following form:

loge $x = \ln x = b$, where $x = e^b$

Scientific calculators have LOG and LN keys, so it is easy to convert a number into its log or ln form. The directions below apply to most calculators.

Sample Exercise 1 Find the logarithm to the base 10 of 2.247 (log 2.247).

Solution In some calculators you enter 2.247 first and then press the LOG key. In others, such as the TI 84/89 series, you press the LOG key first followed by 2.247 and then the ENTER key. Either way, the answer should be 0.3516 (to four significant figures).

Sample Exercise 2 Find the natural logarithm of 2.247 (ln 2.247).

Solution Follow the same procedure as in Sample Exercise 1 except use the LN key. The answer

should be 0.8096. This answer is (0.8096/0.3516) = 2.303 times larger than log value. That is,

$$\ln x = 2.303 \log x$$

Sample Exercise 3 Find the log of 6.0221 × 10^{23}.

Solution Following the procedures described above for entering a value with an exponent into your calculator and then taking its log to the base 10, you should obtain the value 23.77974796. We know the original value to five significant figures; the log value should have the same precision, but how do we express it? You might think the log value should be 23.780; however, the 23 to the left of the decimal point reflects the value of the exponent in the original value, and exponents don't count in determining the number of significant figures in a value. Therefore, the value of the logarithm to five significant figures is 23.77975. To understand better why this is so, calculate the log of 6.0221. You should get 0.77975 to five significant figures. Note how the difference between the two log values (23.77975 and 0.77975) is simply the value of the exponent in the first value.

Combining Logs The following equations summarize how logarithms of the products or quotients of two or more values are related to the individual logs of those values:

$$\text{logarithm } (ab) = \text{logarithm } a + \text{ logarithm } b$$

and

$$\text{logarithm } (a/b) = \text{logarithm } a - \text{ logarithm } b$$

Converting Logarithms into Numbers

If we know the value of log x, what is the value of x? This question is frequently asked when working with pH, which is the negative log of the concentration of hydrogen ions, $[H_3O^+]$, in solution:

$$\text{pH} = -\log[H_3O^+]$$

Suppose the pH of a solution of a weak acid is 2.50. The concentration of H_3O^+ is related to this pH value as follows:

$$2.50 = -\log[H_3O^+]$$

or

$$-2.50 = \log[H_3O^+]$$

To find the value of $[H_3O^+]$, we enter 2.5 into the calculator and press the appropriate key to change its sign to −2.5. The next step depends on the type of calculator. If yours has a $\boxed{10^x}$ key (often accessible using a second function key), use it to find the value of $10^{-2.5}$, which is the value we are looking for. The corresponding keystrokes with many graphing calculators are $\boxed{10^x}$, $\boxed{(-)}$, 2.5, $\boxed{\text{ENTER}}$. Some calculators, including the virtual one in many Windows operating systems, have an $\boxed{x^y}$ key. We can use it for this problem by entering 10 and pushing the $\boxed{x^y}$ key, then entering 2.5 and pushing the $\boxed{+/-}$ key followed by the $\boxed{=}$ key. All of these approaches do the same calculation, taking 10 to the −2.50 power, and give the same answer, $[H_3O^+] = 3.2 \times 10^{-3}$ to two significant figures. (Remember, pH is a log value, so the digit before the decimal point is not significant.)

Solving Quadratic Equations

If the terms in an equation can be rearranged so that they take the form

$$ax^2 + bx + c = 0$$

they have the form of a quadratic equation. The value(s) of x can be determined from the values of the coefficients a, b, and c by using the equation

For example, if. the solution to a problem yields the following expression where x is the concentration of a solute:

$$x^2 + 0.112x - 1.2 \times 10^{-3} = 0$$

Then the value of x can be determined as follows:

In this example, the negative value for x satisfies the equation, but it has no meaning because we cannot have negative concentration values; therefore we use only the $+0.010$ value.

Expressing Data in Graphical Form

Fitting curves to plots of experimental data is a powerful tool in determining the relationships between variables. Many natural phenomena obey exponential functions. For example, the rate constant (k) of a chemical reaction increases exponentially with increasing absolute temperature (T). This relationship is described by the Arrhenius equation:

$$k = A\, e^{-E_a/RT}$$

where A is a constant for a particular reaction (called the frequency factor), E_a is the activation energy of the reaction, and R is the ideal gas constant. Taking the natural logarithms of both sides of the Arrhenius equation gives

This equation fits the general equation of a straight line ($y = mx + b$) if ($\ln k$) is the y-variable and ($1/T$) is the x-variable. Plotting ($\ln k$) versus ($1/T$) should give a straight line with a slope equal to $-E_a/R$. The slopes of these plots are negative because the activation energies, E_a, of chemical reactions are positive. The data for a reaction given in columns 2 and 4 of Table A1.1 are plotted in Figure A1.1. The program that generated the graph also gives us the equation of the straight line that best fits the data. The slope (-1281 K) of this line is used to calculate the value of E_a:

Expressing Precision and Accuracy

The precision in the results of a set of replicate measurements or analyses is determined by calculating the arithmetic mean ($\bar{x}$) of the data set and its standard deviation (s), which is a measure of the variation between the mean and the results of each measurement or analysis (x_i). The equation for calculating s is

TABLE A1.1 Rate Constant ***k*** as a Function of Temperature ***T***

[illegible]
[illegible]

where *n* is the number of data points. To calculate the confidence interval, which is the range that is predicted to contain the true mean value (μ) of the data set, we use this equation:

where *t* is a statistic that depends on the value of *n* and the degree of certainty, or *confidence level*, in the prediction. Table A1.2 contains values of *t* for confidence levels of 90.0, 95.0, 99.0, and 99.9%.

Combining Vector Quantities

Unequal sharing of the electrons in covalent bonds between atoms of different elements produces partial negative and positive charges on the ends of those bonds. This separation of partial charge creates a *bond dipole*. The quantity called a *dipole moment* assigns a value to the magnitude of the negative and positive charges that are separated and to the distance between the charges. Polar bonds have dipole moments and so, too, do polar molecules.

Dipole moments are *vector* quantities. A vector has two components: *magnitude*, which is the product of the partial charges times the distance between them, and *direction*, which is usually indicated by an arrow, +→, pointing toward the negative end of a polar bond, or toward the negative side of a polar molecule. Adding the dipole moments of all the polar bonds in a molecule allows us to predict whether the molecule itself is polar—that is, whether it has a permanent dipole.

For example, a molecule of CO_2 has two polar C□O bonds with dipole moments directed toward the oxygen atoms at each end of the molecule. The two dipole moments are equivalent because they involve the same kinds of atoms separated by the same kind of bond, as shown in the Lewis structure below. However, the linear shape of the molecule means that the direction of one C□O dipole is opposite the direction of the other, so the vectors corresponding to the two dipole moments offset each other, as shown in the graph in the middle image. As a result, a molecule of CO_2 has no permanent dipole, which means that carbon dioxide is a nonpolar compound.

On the other hand, a molecule of H_2O has a bent molecular geometry, as shown in the Lewis structure below. Therefore, the dipole moments of the two identical O–H bonds *do not completely* offset each other: their *x* components (shown in blue in the graph below) point directly toward each other, and they do offset each other. However, their *y* components (also shown in blue) are pointed in the same direction, and they add together as shown, giving the molecule a permanent dipole with a positive end centered between the H atoms and a negative pole in the O atom:

The above method of adding the *x* and *y* components of the vectors corresponding to dipole moments can be extended to three-dimensional molecular structures such as the trigonal pyramidal structure of NH_3. In the figure below, three: N–H bond dipoles are shown for a molecule of NH_3 drawn with its N atom at the top. Its three H atoms form a trigonal base in a two-dimensional plane as shown in the vector diagram. One component of each bond dipole vector is directed from the H atom toward the center of the base, directly below the N atom. All these vectors are spaced equally about the center and have the same magnitude. Therefore, they offset each other. However, the vertical components of all three dipole moments point in the same direction (upward), which means they are additive, giving NH_3 a permanent dipole centered between the three H atoms and pointing toward the N atom.

Endnotes

- The bond energy of C□O in CO_2 is 799 kJ/mol.Return to reference [a]
- Listed in descending order of critical temperature.Return to reference [a]
- Substances are arranged alphabetically by chemical formula within each class: (1) elements and monatomic ions; (2) polyatomic ions; (3) inorganic compounds (including CO and CO2); (4) organic compounds (hydrocarbon-based).Return to reference [a]
- Symbols denote standard enthalpy of formation ($\Delta H°$f), standard third-law entropy ($S°$), and standard Gibbs free energy of formation ($\Delta G°$f). Entropies in aqueous solution are referred to $S°[H^+(aq)] = 0$, not to absolute zero.Return to reference [b]

Appendix 5

Equilibrium Constants

TABLE A5.1 Ionization Constants of Selected Acids at 25°C

Acid	Formula	K_a	Aqueous Equilibrium[a]
Acetic acid	CH_3COOH	1.75×10^{-5}	$CH_3COOH(aq) + H_2O(\ell) \rightleftharpoons H3O^+(aq) + CH_3COO^-(aq)$
Arsenic acid	H_3AsO_4	5.5×10^{-3}	$H_3AsO_4(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + HAsO_4^-(aq)$
	$H_2AsO_4^-$	1.7×10^{-7}	$H_2AsO_4^-(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + HAsO_4^{2-}(aq)$
	$HAsO_4^{2-}$	5.1×10^{-12}	$HAsO_4^{2-}(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + AsO_4^{3-}(aq)$
Ascorbic acid	$H_2C_6H_6O_6$	8.0×10^{-5}	$H_2C_6H_6O_6(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + HC_6H_6O_6^-(aq)$
	$HC_6H_6O_6^-$	1.6×10^{-12}	$HC_6H_6O_6^-(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + C_6H_6O_6^{2-}(aq)$
Benzoic acid	C_6H_5COOH	6.25×10^{-5}	$C_6H_5COOH(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + C_6H_5COO^-(aq)$
Boric acid	H_3BO_3	5.4×10^{-10}	$H_3BO_3(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + H_2BO_3^-(aq)$
	$H_2BO_3^-$	[illegible] $\times 10^{-14}$	$H_2BO_3^-(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + HBO_3^{2-}(aq)$
Bromoacetic acid	$CH_2BrCOOH$	1.3×10^{-3}	$CH_2BrCOOH(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + CH_2BrCOO^-(aq)$
Butanoic acid	$CH_3CH_2CH_2COOH$	1.52×10^{-5}	$CH_3CH_2CH_2COOH(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + CH_3CH_2CH_2COO^-(aq)$

$Pb^{2+}(aq) + 2\ e^{-} \longrightarrow Pb(s)$	2	−0.126
$CrO_4^{2-}(aq) + 4\ H_2O(\ell) + 3\ e^{-} \longrightarrow Cr(OH)_3(s) + 5\ OH^{-}(aq)$	3	−0.13
$Sn^{2+}(aq) + 2\ e^{-} \longrightarrow Sn(s)$	2	−0.136
$AgI(s) + e^{-} \longrightarrow Ag(s) + I^{-}(aq)$	1	−0.152
$CuI(s) + e^{-} \longrightarrow Cu(s) + I^{-}(aq)$	1	−0.185
$N_2(g) + 5\ H^{+}(aq) + 4\ e^{-} \longrightarrow N_2H_5{}^{+}(aq)$	4	−0.23
$Ni^{2+}(aq) + 2\ e^{-} \longrightarrow Ni(s)$	2	−0.257
$PbSO_4(s) + H^{+}(aq) + 2\ e^{-} \longrightarrow Pb(s) + HSO_4^{-}(aq)$	2	−0.356
$Co^{2+}(aq) + 2\ e^{-} \longrightarrow Co(s)$	2	−0.277
$Ag(CN)_2^{-}(aq) + e^{-} \longrightarrow Ag(s) + 2\ CN^{-}(aq)$	1	−0.31
$Cd^{2+}(aq) + 2\ e^{-} \longrightarrow Cd(s)$	2	−0.403
$Cr^{3+}(aq) + e^{-} \longrightarrow Cr^{2+}(aq)$	1	−0.41
$Fe^{2+}(aq) + 2\ e^{-} \longrightarrow Fe(s)$	2	−0.447
$2\ CO_2(g) + 2\ H^{+}(aq) + 2\ e^{-} \longrightarrow H_2C_2O_4(s)$	2	−0.49
$Ni(OH)_2(s) + 2\ e^{-} \longrightarrow Ni(s) + 2\ OH^{-}(aq)$	2	−0.72
$Cr^{3+}(aq) + 3\ e^{-} \longrightarrow Cr(s)$	3	−0.74
$Zn^{2+}(aq) + 2\ e^{-} \longrightarrow Zn(s)$	2	−0.762
$Cd(OH)_2(s) + 2\ e^{-} \longrightarrow Cd(s) + 2\ OH^{-}(aq)$	2	−0.81
$2\ H_2O(\ell) + 2\ e^{-} \longrightarrow H_2(g) + 2\ OH^{-}(aq)$	2	−0.828
$SO_4^{2-}(aq) + H_2O(\ell) + 2\ e^{-} \longrightarrow SO_3^{2-}(aq) + 2\ OH^{-}(aq)$	2	−0.92
$N_2(g) + 4\ H_2O(\ell) + 4\ e^{-} \longrightarrow 4\ OH^{-}(aq) + N_2H_4(\ell)$	4	−1.16
$Mn^{2+}(aq) + 2\ e^{-} \longrightarrow Mn(s)$	2	−1.185
$Zn(OH)_2(s) + 2\ e^{-} \longrightarrow Zn(s) + 2\ OH^{-}(aq)$	2	−1.249
$Al^{3+}(aq) + 3\ e^{-} \longrightarrow Al(s)$	3	−1.662
$Mg^{2+}(aq) + 2\ e^{-} \longrightarrow Mg(s)$	2	−2.37
$Na^{+}(aq) + e^{-} \longrightarrow Na(s)$	1	−2.71

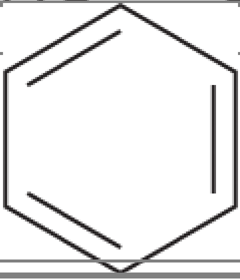
$Ca^{2+}(aq) + 2\,e^- \rightarrow Ca(s)$	−2.868
$Ba^{2+}(aq) + 2\,e^- \rightarrow Ba(s)$	−2.912
$K^{+}(aq) + e^- \rightarrow K(s)$	−2.925
$Li^{+}(aq) + e^- \rightarrow Li(s)$	−3.05

Appendix 7

Naming Organic Compounds

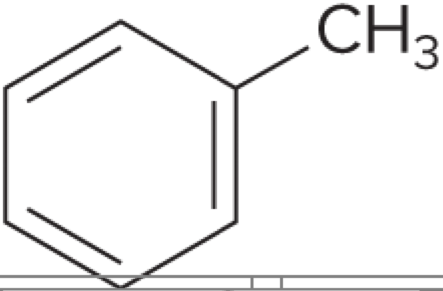
While organic chemistry was becoming established as a discipline within chemistry, many compounds were given trivial names that are still commonly used and recognized. We refer to many of these compounds by their nonsystematic names throughout this book, and their names and structures are listed in Table A7.1.

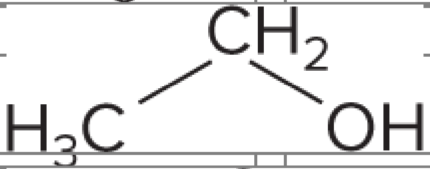
TABLE A7.1 Organic Compounds and Their Commonly Used Nonsystematic Names

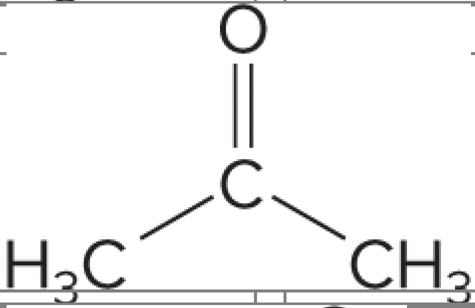
Name	Structure	Formula
		
	$HC\equiv CH$	
		


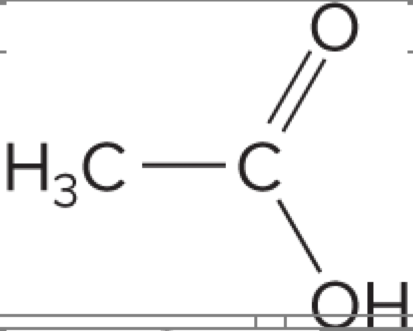
toluene		$C_6H_5CH_3$

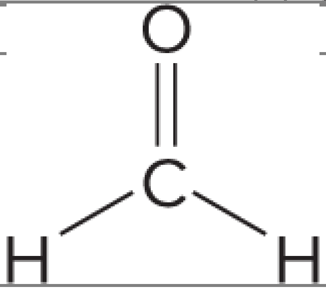
	
	
	
	
	











The International Union of Pure and Applied Chemistry (IUPAC) has proposed a set of rules for the systematic naming of organic compounds. When naming compounds or drawing structures based on names, we need to keep in mind that the IUPAC system of nomenclature is based on two fundamental ideas: (1) the name of a compound must indicate how the carbon atoms in the skeleton are bonded together, and (2) the name must identify the location of any functional groups in the molecule.

Alkanes

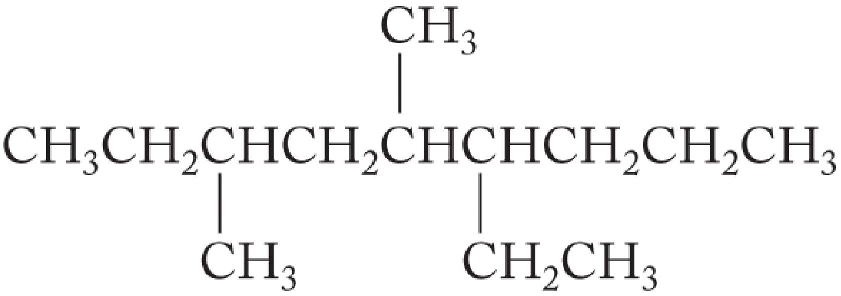
Table A7.2 contains the prefixes used for carbon chains ranging in size from C_1 to C_{20} and gives the names for compounds consisting of unbranched chains. The name of a compound consists of a prefix identifying the number of carbons in the chain and a suffix defining the type of hydrocarbon. The suffix *-ane* indicates that the compounds are alkanes and that all carbon–carbon bonds are single bonds.

TABLE A7.2 Prefixes for Naming Carbon Chains

[illegible] Example
[illegible] $C_{11}H_{24}$ [illegible]ane
[illegible] $C_{12}H_{26}$ [illegible]ane
[illegible] $C_{13}H_{28}$ [illegible]ane
[illegible] $C_{14}H_{30}$ [illegible]cane
[illegible] $C_{15}H_{32}$ [illegible]ecane
[illegible] $C_{16}H_{34}$ [illegible]ecane
[illegible] $C_{17}H_{36}$ [illegible]ecane
[illegible] $C_{18}H_{38}$ [illegible]cane
[illegible] $C_{19}H_{40}$ [illegible]ecane
[illegible] $C_{20}H_{42}$ [illegible]ne

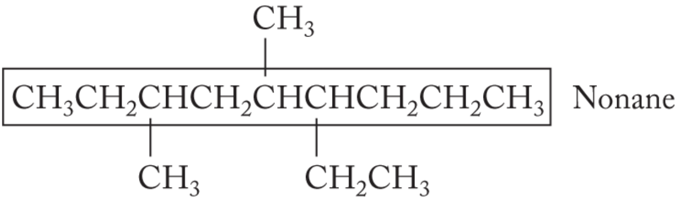
Branched-Chain Alkanes

The alkane drawn here is used to illustrate each step in the naming rules:



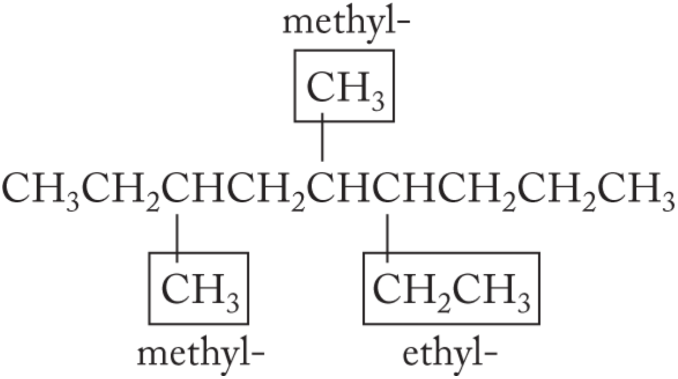
$$\mathrm{CH_3CH_2\underset{\displaystyle CH_3}{\underset{|}{CH}}CH_2\overset{\displaystyle CH_3}{\overset{|}{CH}}\underset{\displaystyle CH_2CH_3}{\underset{|}{CH}}CH_2CH_2CH_3}$$

1. **Identify and name the longest continuous carbon chain.**



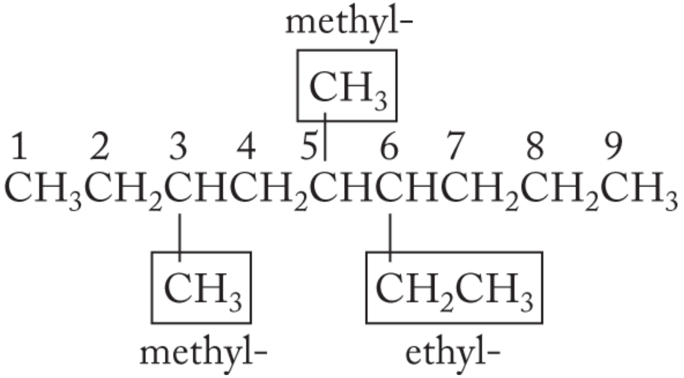
$$\boxed{\mathrm{CH_3CH_2\underset{\displaystyle CH_3}{\underset{|}{CH}}CH_2\overset{\displaystyle CH_3}{\overset{|}{CH}}\underset{\displaystyle CH_2CH_3}{\underset{|}{CH}}CH_2CH_2CH_3}}\ \text{Nonane}$$

2. **Identify the groups attached to this chain and name them.** Names of substituent groups consist of the prefix from Table A7.2 that identifies the length of the group and the suffix *-yl* that identifies it as an alkyl group.



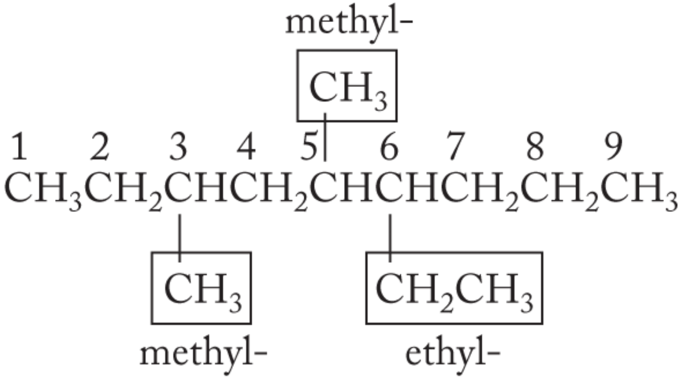
$$\mathrm{CH_3CH_2\underset{\underset{\text{methyl-}}{\boxed{CH_3}}}{\underset{|}{CH}}CH_2\overset{\overset{\text{methyl-}}{\boxed{CH_3}}}{\overset{|}{CH}}\underset{\underset{\text{ethyl-}}{\boxed{CH_2CH_3}}}{\underset{|}{CH}}CH_2CH_2CH_3}$$

3. **Number the carbon atoms in the longest chain,** starting at the end nearest a substituent group. Doing this identifies the points of attachment of the alkyl groups with the lowest possible numbers.



$$\mathrm{CH_3CH_2\underset{\boxed{CH_3}}{CH}CH_2\overset{\boxed{CH_3}}{CH}\underset{\boxed{CH_2CH_3}}{CH}CH_2CH_2CH_3}$$

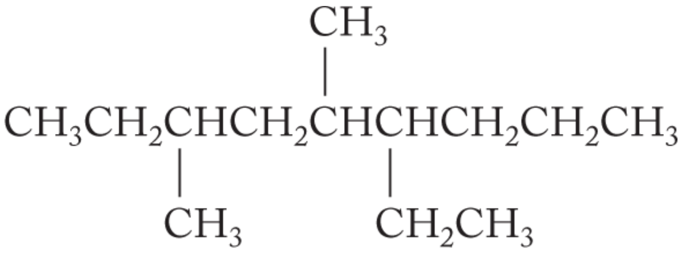
4. **Designate the location and identity of each substituent group with a number,** followed by a hyphen, and its name.



$$\mathrm{CH_3CH_2\underset{\boxed{CH_3}}{CH}CH_2\overset{\boxed{CH_3}}{CH}\underset{\boxed{CH_2CH_3}}{CH}CH_2CH_2CH_3}$$

3-methyl-, 5-methyl-, 6-ethyl-

5. **Put together the complete name by listing the substituent groups in alphabetical order.** If more than one of a given type of substituent group is present, prefixes *di-*, *tri-*, *tetra-*, and so forth, are appended to the names, but these numerical prefixes are not considered when determining the alphabetical order. The name of the last substituent group is written together with the name identifying the longest carbon chain.

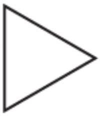


$$\mathrm{CH_3CH_2\underset{\displaystyle CH_3}{\underset{|}{CH}}CH_2\overset{\displaystyle CH_3}{\overset{|}{CH}}\underset{\displaystyle CH_2CH_3}{\underset{|}{CH}}CH_2CH_2CH_3}$$

6-Ethyl-3,5-dimethylnonane

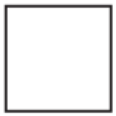
Cycloalkanes

The simplest examples of this class of compounds consist of one unsubstituted ring of carbon atoms. The IUPAC names of these compounds consist of the prefix *cyclo-* followed by the parent name from Table A7.2 to indicate the number of carbon atoms in the ring. As an illustration, the names, formulas, and line structures of the first three cycloalkanes in the homologous series are



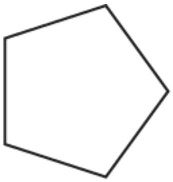
C_3H_6

Cyclopropane



C_4H_8

Cyclobutane



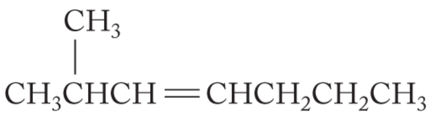
C_5H_{10}

Cyclopentane

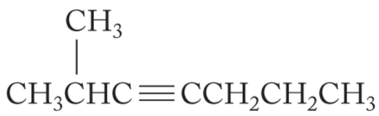
Alkenes and Alkynes

Alkenes have carbon–carbon double bonds and alkynes have carbon–carbon triple bonds as functional groups. The names of these types of compounds consist of (1) a parent name that identifies the longest carbon chain that includes the double or triple bond, (2) a suffix that identifies the class of compound, and (3) names of any substituent groups attached to the longest carbon chain. The suffix *-ene* identifies an alkene; *-yne* identifies an alkyne.

The alkene and alkyne drawn here are used to illustrate each step in the naming rules:

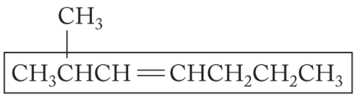


$CH_3\overset{CH_3}{\overset{|}{C}}HCH{=}CHCH_2CH_2CH_3$



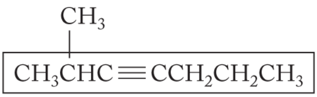
$CH_3\overset{CH_3}{\overset{|}{C}}HC{\equiv}CCH_2CH_2CH_3$

1. **To determine the parent name,** identify the longest chain that contains the unsaturation. Name the parent compound with the prefix that defines the number of carbons in that chain and the suffix that identifies the class of compound.



$CH_3\overset{CH_3}{\overset{|}{C}}HCH{=}CHCH_2CH_2CH_3$

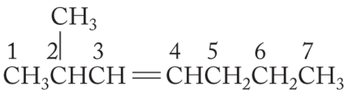
Heptene



$CH_3\overset{CH_3}{\overset{|}{C}}HC{\equiv}CCH_2CH_2CH_3$

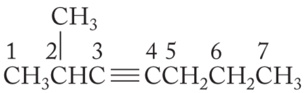
Heptyne

2. **Number the parent chain from the end nearest the unsaturation so that the first carbon in the double or triple bond has the lowest number possible.** (If the unsaturation is in the middle of a chain, the location of any substituent group is used to determine where the numbering starts.) The smaller of the two numbers identifying the carbon atoms involved in the unsaturation is used as the locator of the multiple bond.



$\overset{1}{C}H_3\overset{CH_3}{\overset{2|}{C}}H\overset{3}{C}H{=}\overset{4}{C}H\overset{5}{C}H_2\overset{6}{C}H_2\overset{7}{C}H_3$

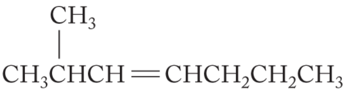
3-Heptene



$\overset{1}{C}H_3\overset{CH_3}{\overset{2|}{C}}H\overset{3}{C}{\equiv}\overset{4}{C}\overset{5}{C}H_2\overset{6}{C}H_2\overset{7}{C}H_3$

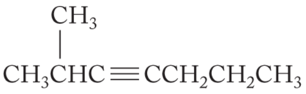
3-Heptyne

3. **Stereoisomers of alkenes are named by writing** *cis*- or *trans*- **before the number identifying the location of the double bond.** Chapter 20 in the text addresses naming stereoisomers.
4. **The rules for naming substituted alkanes are followed to name and locate any other groups on the chain.**



$\mathrm{CH_3\overset{\overset{CH_3}{|}}{C}HCH{=}CHCH_2CH_2CH_3}$

2-Methyl-3-heptene



$\mathrm{CH_3\overset{\overset{CH_3}{|}}{C}HC{\equiv}CCH_2CH_2CH_3}$

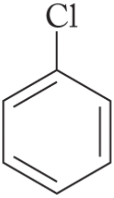
2-Methyl-3-heptyne

Halogens attached to an alkane, alkene, or alkyne are named as fluoro- (F–), chloro- (Cl–), bromo- (Br–), or iodo- (I–) and are located by using the same numbering system described for alkyl groups.

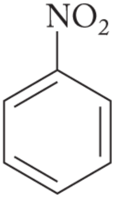
Benzene Derivatives

Naming compounds containing substituted benzene rings is less systematic than naming hydrocarbons. Many compounds have common names that are incorporated into accepted names, but for simple substituted benzene rings, the following rules may be applied.

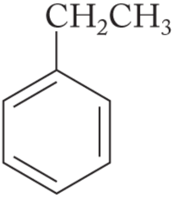
1. **For monosubstituted benzene rings,** a prefix identifying the group is appended to the parent name benzene:



Chlorobenzene

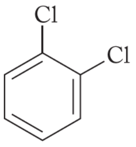


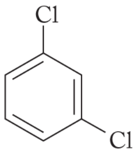
Nitrobenzene

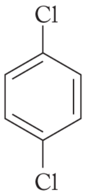


Ethylbenzene

2. **For disubstituted benzene rings,** three isomers are possible. The relative position of the substituent groups is indicated by numbers in IUPAC nomenclature, but the set of prefixes shown are very commonly used as well:

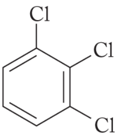




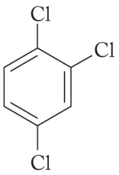


IUPAC:		
1,2-Dichlorobenzene	1,3-Dichlorobenzene	1,4-Dichlorobenzene
Common:		
ortho-Dichlorobenzene	*meta*-Dichlorobenzene	*para*-Dichlorobenzene
o-Dichlorobenzene	*m*-Dichlorobenzene	*p*-Dichlorobenzene

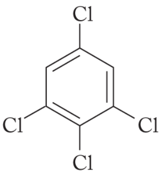
3. **When three or more groups are attached to a benzene ring,** the lowest possible numbers are assigned to locate the groups with respect to each other.



1,2,3-Trichlorobenzene



1,2,4-Trichlorobenzene



1,2,3,5-Tetrachlorobenzene

(*Note*: Not 1,3,4-trichlorobenzene; and not 1,3,4,5-tetrachlorobenzene.)

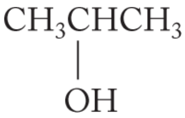
Hydrocarbons Containing Other Functional Groups

The same basic principles developed for naming alkanes apply to naming hydrocarbons with functional groups other than alkyl groups. The name must identify the carbon skeleton, locate the functional group, and contain a suffix that defines the class of compound. The following examples give the suffixes for some common functional groups; when suffixes are used, they replace the final *-e* in the name of the parent alkane. Other functional groups may be identified by including the name of the class of compounds in the name of the molecule.

Alcohols: Suffix -*ol*

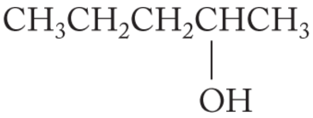
$CH_3CH_2CH_2OH$

1-Propanol



$CH_3\underset{\displaystyle OH}{\underset{|}{C}}HCH_3$

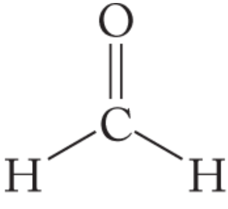
2-Propanol

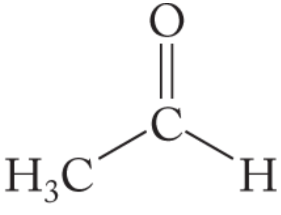


$CH_3CH_2CH_2\underset{\displaystyle OH}{\underset{|}{C}}HCH_3$

2-Pentanol

Aldehydes: Suffix -*al*

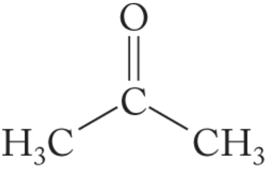


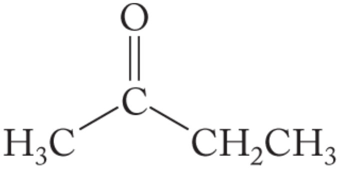


IUPAC:	Methanal	Ethanal
Common:	Formaldehyde	Acetaldehyde

Because the aldehyde group can only be on a terminal carbon, no number is necessary to locate it on the carbon chain.

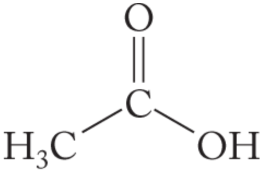
Ketones: Suffix -*one* The location of the carbonyl is given by a number, and the chain is numbered so that the carbonyl carbon has the lowest possible value. Many ketones also have common names generated by identifying the hydrocarbon groups on both sides of the carbonyl group.

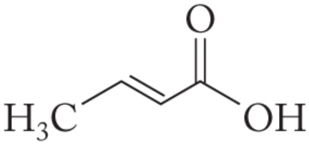




IUPAC:	Propan-2-one	Butan-2-one
Common:	Acetone	Methyl ethyl ketone

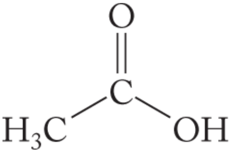
Carboxylic Acids: Suffix -*oic acid* The carboxylic acid group is by definition carbon 1, so no number identifying its location is included in the name.



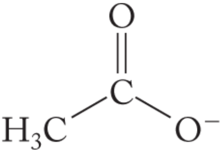


IUPAC:	Ethanoic acid	*trans*-2-Butenoic acid
Common:	Acetic acid	

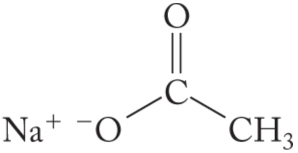
Salts of Carboxylic Acids Salts are named with the cation first, followed by the anion name of the acid from which -*ic acid* is dropped and the suffix -*ate* is added. The sodium salt of acetic acid is sodium acetate.



Acetic acid

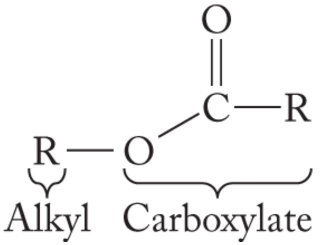


Acetate ion

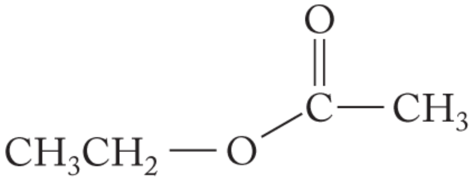


Sodium acetate

Esters Esters are viewed as derivatives of carboxylic acids. They are named in a manner analogous to that of salts. The alkyl group comes first, followed by the name of the carboxylate anion.



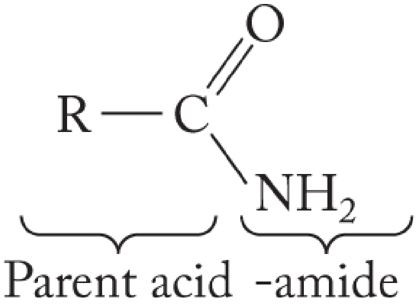
O
C
R
R
O
Alkyl
Carboxylate



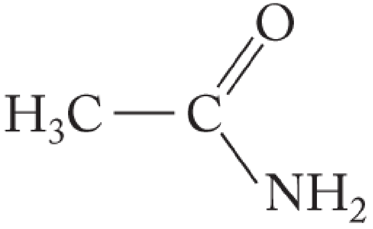
O
C
CH3
CH3CH2
O

Ethyl acetate

Amides Amides are also derivatives of carboxylic acids. They are named by replacing *-ic acid* (of the common names) or *-oic acid* (of the IUPAC names) with *-amide*.



O
R
C
NH2
Parent acid
-amide



Acetamide
(ethanamide)

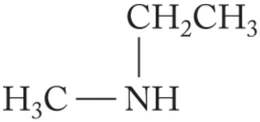
Ethers Ethers are frequently named by naming the two groups attached to the oxygen and following those names by the word *ether*.

CH_3OCH_3	$CH_3CH_2OCH_2CH_3$
Dimethyl ether	Diethyl ether

Amines Aliphatic amines are usually named by listing the group or groups attached to the nitrogen and then appending -*amine* as a suffix. They may also be named by prefixing *amino-* to the name of the parent chain.

$H_3C—NH_2$

Methylamine



$H_3C—NH(CH_2CH_3)$

Ethylmethylamine

$H_2NCH_2CH_2OH$

2-Aminoethanol

This brief summary will enable you to understand the names of organic compounds used in this book. IUPAC rules are much more extensive than this and can be applied to all varieties of carbon compounds, including those with multiple functional groups. It is important to recognize that the rules of systematic nomenclature do not necessarily lead to a unique name for each compound, but they do always lead to an unambiguous one. Furthermore, common names are still used frequently in organic chemistry because the systematic alternatives do not improve communication. Remember that the main purpose of chemical nomenclature is to identify a chemical species by means of written or spoken words. Anyone who reads or hears the name should be able to deduce the structure and thereby the identity of the compound.

Glossary

A

absolute temperature Temperature expressed in kelvins on the absolute (Kelvin) temperature scale, on which 0 K is the lowest possible temperature. (Ch. 5)

absolute zero (0 K) The zero point on the Kelvin temperature scale; theoretically the lowest temperature possible. (Ch. 1)

absorbance (A) A measure of the quantity of light absorbed by a sample. (Ch. 4)

accuracy Agreement between one or more experimental values and the true (or accepted) value. (Ch. 1)

acid (Brønsted–Lowry acid) A proton donor. (Ch. 4)

activated complex A transient species in a chemical reaction in which molecules have both the proper orientation and enough energy to react with each other. (Ch. 13)

activation energy (E_a) The minimum energy molecules need to react when they collide. (Ch. 13)

active site The location on an enzyme where a reactive substance binds. (Ch. 20)

activity series A high-to-low ranking of metals based on their strengths as reducing agents. (Ch. 4)

actual yield The amount of product obtained from a chemical reaction, which may be less than the theoretical yield. (Ch. 3)

addition polymer A polymer formed by an addition reaction. (Ch. 12)

addition reaction A reaction in which two reactants couple to form one product without the loss of any atoms or molecules. (Ch. 12)

alcohol An organic compound containing the OH functional group. (Ch. 2)

aldehyde An organic compound having a carbonyl group with a single bond to a hydrogen atom and a single bond to another atom or group of atoms designated as R– in the general formula RCHO. (Ch. 8)

alkali metals The elements in group 1 of the periodic table. (Ch. 2)

alkaline earth metals The elements in group 2 of the periodic table. (Ch. 2)

alkane A hydrocarbon in which all the bonds are single bonds. (Ch. 2)

alkene A hydrocarbon containing one or more carbon–carbon double bonds. (Ch. 2)

alkyne A hydrocarbon containing one or more carbon–carbon triple bonds. (Ch. 2)

allotropes Different molecular forms of the same element. (Ch. 8)

alloy A blend of a host metal and one or more other elements, which may or may not be metals, that are added to change the properties of the host metal. (Ch. 12)

alpha (α) decay A nuclear reaction in which an unstable nuclide spontaneously emits an alpha particle. (Ch. 19)

α helix A coil in a protein chain's secondary structure held together by hydrogen bonds. (Ch. 20)

alpha (α) particle A radioactive emission with a charge of $2+$ and a mass equivalent to that of a helium nucleus. (Ch. 2)

amide An organic compound in which the same carbon atom is single bonded to a nitrogen atom and double bonded to an oxygen atom. (Ch. 12)

amine An organic compound that functions as a base and has the general formula RNH_2, R_2NH, or R_3N, where R is any organic group. (Ch. 4)

amino acid A molecule that contains at least one amine functional group and one carboxylic acid functional group; in an α-amino acid, the two functional groups are attached to the same (α) carbon atom. (Ch. 20)

Amontons's law The principle that the pressure of a quantity of gas at constant volume is directly proportional to its absolute temperature. (Ch. 5)

amorphous solid A solid that lacks long-range order for the atoms, ions, or molecules in its structure. (Ch. 12)

amphiprotic Describes a substance that can behave as either a proton acceptor or a proton donor. (Ch. 4)

amplitude The height of the crest or depth of the trough of a wave with respect to the center line of the wave. (Ch. 7)

angular The molecular geometry about a central atom with a steric number of 3 (bonds to two atoms + one lone pair) or a steric number of 4 (bonds to two atoms + two one pairs). (Ch. 9)

angular momentum quantum number (ℓ) An integer having any value from 0 to $n - 1$ that defines the shape of an orbital. (Ch. 7)

anion An ion with a negative charge. (Ch. 1)

anode An electrode at which an oxidation half-reaction (loss of electrons) takes place. (Ch. 18)

antibonding orbital A molecular orbital in which electron density is highest outside the region between atom centers. (Ch. 9)

antimatter Particles that are the charge opposites of normal subatomic particles. (Ch. 19)

aromatic compound A cyclic, planar compound with delocalized π (pi) electrons above and below the plane of the molecule. (Ch. 9)

Arrhenius acid A compound that produces H_3O^+ ions in aqueous solution. (Ch. 15)

Arrhenius base A compound that produces OH^- ions in aqueous solution. (Ch. 15)

Arrhenius equation An equation relating the rate constant of a reaction to absolute temperature (T), the activation energy of the reaction (E_a), and the frequency factor (A). (Ch. 13)

atmosphere (atm) A unit of pressure based on Earth's mean atmospheric pressure at sea level. (Ch. 5)

atmospheric pressure (P_{atm}) The force exerted by the gases surrounding Earth on Earth's surface and on all surfaces of all objects. (Ch. 5)

atom The smallest particle of an element that retains the element's properties. (Ch. 1)

atomic absorption spectrum A characteristic series of dark lines produced when free, gaseous atoms are illuminated by a continuous source of radiation. (Ch. 7)

atomic emission spectrum A characteristic series of bright lines produced by high-temperature atoms. (Ch. 7)

atomic number (Z) The number of protons in the nucleus of an atom. (Ch. 2)

atomic solid A solid formed by weak attractions between noble gas atoms. (Ch. 12)

aufbau principle The method of building electron configurations of atoms by adding one electron at a time as atomic number increases across the rows of the periodic table; each electron goes into the lowest-energy orbital available. (Ch. 7)

autoionization The process that produces equal and very small concentrations of H_3O^+ and OH^- ions in pure water. (Ch. 15)

average atomic mass A weighted average of the masses of all the isotopes of an element, calculated by multiplying the natural abundance of each isotope by its mass in atomic mass units and then summing these products. (Ch. 2)

Avogadro constant(N_A) The fundamental constant representing the number of characteristic particles in 1 mole of a substance: $6.02214076 \times 10^{23}$ particles/mol. (Ch. 3)

Avogadro's law The principle that the volume of a gas at a given temperature and pressure is proportional to the quantity of the gas. (Ch. 5)

B

band gap (E_g) The energy gap between the valence and conduction bands. (Ch. 9)

band theory An extension of molecular orbital theory that describes bonding in solids. (Ch. 9)

barometer An instrument that measures atmospheric pressure. (Ch. 5)

base (Brønsted–Lowry base) A proton acceptor. (Ch. 4)

becquerel (Bq) The SI unit of radioactivity equal to the decay of one radioactive atom per second. (Ch. 19)

Beer's Law The relation of the absorbance of a solution (A) to concentration (c), the light's path length (b), and the solute's molar absorptivity (ε) by the equation $A = \varepsilon bc$. (Ch. 4)

belt of stability The region on a graph of number of neutrons versus number of protons that includes all stable nuclei. (Ch. 19)

bent See *angular*.

beta (β) decay A spontaneous process by which a neutron in a radioactive nuclide is transformed into a proton and emits a high-energy electron (β-particle). (Ch. 2, Ch. 19)

beta (β) particle A radioactive emission equivalent to a high-energy electron. (Ch. 2)

β-pleated sheet A puckered two-dimensional array of protein strands held together by hydrogen bonds. (Ch. 20)

bimolecular step A step in a reaction mechanism involving a collision between two molecules. (Ch. 13)

binding energy (BE) The energy that would be released when free nucleons combine to form the nucleus of an atom; it is also the energy needed to split the nucleus into free nucleons. (Ch. 19)

biocatalysis The use of enzymes to catalyze reactions on a large scale; it is becoming especially important in processes that involve chiral materials. (Ch. 13)

biochemistry The study of chemical processes taking place in living organisms. (Ch. 20)

biomass The total mass of organic matter in any given ecological system. (Ch. 20)

biomolecule Any molecule produced by a living organism. (Ch. 20)

body-centered cubic (bcc) unit cell An array of atoms or molecules with one particle at each of the eight corners of a cube and one at the center of the cell. (Ch. 12)

bomb calorimeter A constant-volume device used to measure the energy released during a combustion reaction. (Ch. 6)

bond angle The angle (in degrees) defined by lines joining the centers of two atoms to the center of a third atom to which they are chemically bonded. (Ch. 9)

bond dipole The separation of electrical charge created when atoms with different electronegativities form a covalent bond. (Ch. 9)

bond energy The energy needed to break 1 mole of a covalent bond in a molecule or in a polyatomic ion in the gas phase. (Ch. 8)

bond length The distance between the nuclear centers of two atoms joined in a bond. (Ch. 8)

bond order The number of bonds between atoms: 1 for a single bond, 2 for a double bond, and 3 for a triple bond. (Ch. 8)

bond polarity A measure of the extent to which bonding electrons are unequally shared. (Ch. 8)

bonding capacity The number of covalent bonds an atom forms to have an octet of electrons in its valence shell. (Ch. 8)

bonding orbital A molecular orbital in which electron density is highest in the region between the atom centers. (Ch. 9)

bonding pair A pair of electrons shared between two atoms. (Ch. 8)

Born–Haber cycle A series of steps with corresponding enthalpy changes that describes the formation of an ionic solid from its constituent elements. (Ch. 11)

Boyle’s law The principle that the volume of a given amount of gas at constant temperature is inversely proportional to its pressure. (Ch. 5)

branched-chain hydrocarbon A hydrocarbon in which the chain of carbon atoms is not linear. (Ch. 6)

breeder reactor A nuclear reactor in which fissionable material is produced during normal reactor operation. (Ch. 19)

buffer capacity The quantity of acid or base that a pH buffer can neutralize while keeping its pH within a desired range. (Ch. 16)

C

calibration curve A graph showing how a measurable property, such as absorbance, varies for a set of standard samples of known concentration that can later be used to determine the unknown concentration of a sample from its absorbance. (Ch. 4)

calorie (cal) The amount of energy necessary to raise the temperature of 1 g of water by 1°C; for example, from 14.5°C to 15.5°C. (Ch. 6)

calorimeter A device used to measure the absorption or release of energy by a physical change or chemical process. (Ch. 6)

calorimeter constant ($C_{\text{calorimeter}}$) The heat capacity of a calorimeter. (Ch. 6)

calorimetry The measurement of the quantity of energy transferred during a physical change or chemical process. (Ch. 6)

capillary action The rise of a liquid in a narrow tube because of adhesive forces between the liquid and the tube and cohesive forces within the liquid. (Ch. 10)

carbohydrate An organic molecule with the generic formula $C_x(H_2O)_y$. (Ch. 20)

carbonyl group A carbon atom with a double bond to an oxygen atom. (Ch. 8)

carboxylic acid An organic compound containing the –COOH group. (Ch. 4)

catalyst A substance added to a reaction that increases the rate of the reaction but is not consumed in the process. (Ch. 13)

cathode An electrode at which a reduction half-reaction (gain of electrons) takes place. (Ch. 18)

cathode rays Streams of electrons emitted by the cathode in a partially evacuated tube. (Ch. 2)

cation An ion with a positive charge. (Ch. 1)

cell diagram Symbols that show how the components of an electrochemical cell are connected. (Ch. 18)

cell potential (E_{cell}) The force with which an electrochemical cell can pump electrons through an external circuit. (Ch. 18)

chain reaction A self-sustaining series of fission reactions in which the neutrons released when nuclei split apart initiate additional fission events and sustain the reaction. (Ch. 19)

Charles's law The principle that the volume of a fixed quantity of gas at constant pressure is directly proportional to its absolute temperature. (Ch. 5)

chelate effect The greater affinity of metal ions for polydentate ligands than for monodentate ligands. (Ch. 22)

chelation The interaction of a metal with a polydentate ligand (chelating agent); pairs of electrons on one molecule of the ligand occupy two or more coordination sites on the central metal. (Ch. 22)

chemical bond A force that holds two atoms or ions in a compound together. (Ch. 1)

chemical equation Notation in which chemical formulas express the identities and their coefficients express the quantities of substances involved in a chemical reaction. (Ch. 1)

chemical equilibrium A dynamic process in which the concentrations of reactants and products remain constant over time and the rate of the reaction in the forward direction matches its rate in the reverse direction. (Ch. 14)

chemical formula Notation for representing elements and compounds; consists of the symbols of the constituent elements, each followed by subscripts that identify the number of atoms of each element present. (Ch. 1)

chemical kinetics The study of the rates of change of concentrations of substances involved in chemical reactions. (Ch. 13)

chemical nomenclature The rules that are followed in naming substances. (Ch. 2)

chemical property A property of a substance that can be observed only by reacting it to form another substance. (Ch. 1)

chemical reaction The transformation of one or more substances into different substances. (Ch. 1)

chemistry The study of the composition, structure, and properties of matter, and of the energy consumed or given off during electrochemical reactions. (Ch. 1)

chirality A property of a molecule that is not superimposable on its mirror image. (Ch. 9)

cis isomer (also called *Z isomer*) A molecule with two like groups (such as two R groups or two hydrogen atoms) on the same side of the molecule. (Ch. 20)

Clausius–Clapeyron equation A relationship between the vapor pressure of a substance at two temperatures and its heat of vaporization. (Ch. 10)

closed system A system that exchanges energy but not matter with the surroundings. (Ch. 6)

codon A three-nucleotide sequence that codes for a specific amino acid. (Ch. 20)

coenzyme An organic molecule that, like an enzyme, accelerates the rate of biochemical reactions. (Ch. 22)

colligative properties Characteristics of solutions that depend on the concentration and not the identity of particles dissolved in the solvent. (Ch. 11)

combination reaction A reaction in which two (or more) substances combine to form one product. (Ch. 3)

combined gas law (also called *general gas equation*) The principle relating the pressure, volume, and temperature of a quantity of an ideal gas:

$$\frac{P_1V_1}{T_1} = \frac{P_2V_2}{T_2}$$

(Ch. 5)

combustion analysis A laboratory procedure for determining the composition of a substance by burning it completely in excess oxygen to produce known compounds whose masses are used to determine the composition of the original material. (Ch. 3)

combustion reaction A heat-producing reaction between oxygen and another element or compound. (Ch. 3)

common-ion effect A shift in the position of an equilibrium caused by an ion taking part in the reaction. (Ch. 16)

complex ion An ionic species consisting of a metal ion bonded to one or more Lewis bases. (Ch. 16)

compound A pure substance that is composed of two or more elements combined in fixed proportions and that can be broken down into those elements by a chemical reaction. (Ch. 1)

concentration The amount of a solute in a given mass or volume of solvent or solution. (Ch. 4)

condensation polymer A polymer formed by a condensation reaction. (Ch. 12)

condensation reaction A reaction in which two molecules combine to form a larger molecule and a small molecule, typically water. (Ch. 12)

conduction band In metals, an unoccupied band higher in energy than a valence band, in which electrons are free to migrate. (Ch. 9)

confidence interval A range of values that has a specified probability of containing the true value of a measurement. (Ch. 1)

conjugate acid The acid formed when a Brønsted–Lowry base accepts a H^+ ion. (Ch. 15)

conjugate acid–base pair A Brønsted–Lowry acid and base that differ from each other only by a H^+ ion: acid $\rightleftharpoons$ conjugate base + H^+. (Ch. 15)

conjugate base The base formed when a Brønsted–Lowry acid donates a H^+ ion. (Ch. 15)

constitutional isomers Molecules with the same chemical formula but different connections between the atoms. (Ch. 20)

conversion factor A fraction in which the numerator is equivalent to the denominator, even though they are expressed in different units, making the value of the fraction one. (Ch. 1)

coordinate bond A covalent bond formed when one anion or molecule donates a pair of electrons to another ion or molecule. (Ch. 16)

coordination compound A compound made up of at least one complex ion. (Ch. 22)

coordination number The number of sites occupied by ligands around a metal ion in a complex. (Ch. 22)

copolymer A polymer formed from the chemical reaction of two different monomers. (Ch. 12)

core electrons Electrons in the filled, inner shells of an atom or ion that are not involved in chemical reactions. (Ch. 7)

corrosion A process in which a metal is oxidized by substances in its environment. (Ch. 18)

counterion An ion whose charge balances the charge of a complex ion in a coordination compound. (Ch. 22)

covalent bond A bond between two atoms created by sharing one or more pairs of electrons. (Ch. 2)

covalent network solid A solid formed by covalent bonds among nonmetal atoms in an extended array. (Ch. 12)

critical mass The minimum quantity of fissionable material needed to sustain a chain reaction. (Ch. 19)

critical point The temperature and pressure at and above which the liquid and gas phases of a substance are indistinguishable from each other. (Ch. 10)

crystal field splitting The separation of a set of *d* orbitals into subsets with different energies as a result of interactions between electrons in those orbitals and lone pairs of electrons in ligands. (Ch. 22)

crystal field splitting energy (Δ) The difference in energy between subsets of *d* orbitals split by interactions in a crystal field. (Ch. 22)

crystal lattice A three-dimensional repeating array of particles (atoms, ions, or molecules) in a crystalline solid. (Ch. 12)

crystal structure A particular arrangement in three-dimensional space that specifies the positions of the particles (atoms, ions, or molecules) in relation to one another in a crystalline solid. (Ch. 12)

crystalline solid A solid made of an ordered array of atoms, ions, or molecules. (Ch. 12)

cubic closest-packed (ccp) A crystal lattice in which the layers of atoms or ions in face-centered cubic unit cells have an *abcabc* . . . stacking pattern. (Ch. 12)

curie (Ci) A non-SI unit of radioactivity in which 3.70×10^{10} radioactive atoms decay per second. (Ch. 19)

D

dalton (Da) A unit of mass identical to 1 unified atomic mass unit (u); thus 1 Da = 1 u. (Ch. 2)

Dalton's law of partial pressures The principle that the total pressure of any mixture of gases equals the sum of the partial pressure of each gas in the mixture. (Ch. 5)

degenerate orbitals Describes orbitals of the same energy. (Ch. 7)

degree of ionization The ratio of the quantity of a substance that is ionized to the concentration of the substance before ionization; when expressed as a percentage, called *percent ionization*. (Ch. 15)

delocalized electrons Electrons that are shared among more than two atoms. (Ch. 8)

density (*d*) The ratio of the mass (m) of an object to its volume (V). (Ch. 1)

deposition Transformation of a vapor (gas) directly into a solid. (Ch. 1)

diamagnetic A substance with no unpaired electrons that is weakly repelled by a magnetic field. (Ch. 9)

diffusion The spread of one substance (usually a gas or liquid) through another. (Ch. 5)

dilution The process of lowering the concentration of a solution by adding more solvent. (Ch. 4)

dipole moment (μ) A measure of the degree to which a molecule aligns itself in a strong electric field; a quantitative expression of the polarity of a molecule. (Ch. 9)

dipole–dipole interaction An attractive force between polar molecules. (Ch. 10)

dipole–induced dipole interaction An attraction between a polar molecule and the oppositely charged pole it temporarily induces in another molecule. (Ch. 10)

dispersion force (also called *London force*) An intermolecular force between molecules caused by the presence of temporary dipoles in the molecules. (Ch. 10)

double bond A chemical bond in which two atoms share two pairs of electrons. (Ch. 8)

E

***E*isomer** See *trans isomer*.

effective nuclear charge (Z_{eff}) The attraction toward the nucleus experienced by a valence-shell electron, which is approximately equal to the sum of the positive charge on the nucleus and the total negative charge of all inner-shell electrons. (Ch. 7)

effusion The process by which a gas escapes from its container through a tiny hole into a region of lower pressure. (Ch. 5)

electrochemical cell An apparatus that can either generate electrical energy from a chemical reaction or use electrical energy to produce a chemical reaction. (Ch. 18)

electrochemistry The branch of chemistry that examines the transformations between chemical and electrical energy. (Ch. 18)

electrolysis A process in which electrical energy is used to drive a nonspontaneous chemical reaction. (Ch. 18)

electrolyte A substance that dissociates into ions when it dissolves in water, enhancing the conductivity of the solvent. (Ch. 4)

electrolytic cell A device in which an external source of electrical energy does work on a chemical system, turning reactant(s) into higher-energy product(s). (Ch. 18)

electromagnetic radiation Any form of radiant energy in the electromagnetic spectrum. (Ch. 7)

electromagnetic spectrum A continuous range of radiant energy that includes radio waves, microwaves, infrared radiation, visible light, ultraviolet radiation, X-rays, and gamma rays. (Ch. 7)

electron A subatomic particle that has a negative charge and little mass. (Ch. 2)

electron affinity (EA) The energy change that occurs when 1 mole of electrons combines with 1 mole of atoms or monatomic cations in the gas phase. (Ch. 7)

electron capture A nuclear reaction in which a neutron-poor nucleus draws in one of its surrounding electrons, which transforms a proton in the nucleus into a neutron. (Ch. 19)

electron configuration The distribution of electrons among the orbitals of an atom or ion. (Ch. 7)

electron transition The movement of an electron between energy levels. (Ch. 7)

electronegativity A relative measure of the ability of an atom to attract electrons in a bond to itself. (Ch. 8)

electron-pair geometry The three-dimensional arrangement of bonding pairs and lone pairs of electrons about a central atom. (Ch. 9)

electrostatic potential energy (E_{el}) The energy a particle has because of its electrostatic charge and its position with respect to another particle; it is directly proportional to the product of the charges of the particles and inversely proportional to the distance between them. (Ch. 6)

element A pure substance that cannot be separated into simpler substances. (Ch. 1)

elementary step A molecular view of a collision taking place in a chemical reaction. (Ch. 13)

empirical formula A formula showing the smallest whole-number ratio of the elements in a compound. (Ch. 2)

enantiomer One of a pair of optical isomers of a compound. (Ch. 20)

end point The point in a titration that is reached when just enough standard solution has been added to cause the indicator to change color. (Ch. 4)

endothermic process A thermochemical or physical process in which energy flows from the surroundings into the system. (Ch. 6)

energy The capacity to do work. (Ch. 1)

energy profile A graph showing the changes in energy for a reaction as a function of the progress of the reaction from reactants to products. (Ch. 13)

enthalpy (*H*) The sum of the internal energy and the pressure–volume product of a system; $H = E + PV$. (Ch. 6)

enthalpy change (ΔH) The heat absorbed by an endothermic process or given off by an exothermic process occurring at constant pressure. (Ch. 6)

enthalpy of hydration ($\Delta H_{\text{hydration}}$) The energy change when gas-phase ions dissolve in water. (Ch. 11)

enthalpy of reaction (ΔH_{rxn}) The energy absorbed or given off by a chemical reaction under conditions of constant pressure; also called *heat of reaction*. (Ch. 6)

enthalpy of solution ($\Delta H_{\text{solution}}$) The overall change in enthalpy that occurs when a solute dissolves in a solvent. (Ch. 11)

entropy (*S*) A measure of the dispersion of energy in a system at a specific temperature. (Ch. 17)

enzyme A protein that catalyzes a reaction. (Ch. 13)

equilibrium constant (*K*) The numerical value of the equilibrium constant expression of a reversible chemical reaction at a particular temperature. (Ch. 14)

equilibrium constant expression The ratio of the concentrations or partial pressures of products to reactants at equilibrium, with each term raised to a power equal to the coefficient of that substance in the balanced chemical equation for the reaction. (Ch. 14)

equilibrium (reversal) potential (E_{ion}) An electrochemical potential that results from a concentration gradient of a particular ion on opposite sides of a cell membrane. (Ch. 21)

equivalence point The point in a titration at which just enough titrant has been added to completely react the substance being analyzed. (Ch. 4)

essential amino acid Any of the ten amino acids that make up peptides and proteins but are not synthesized in the human body and must be obtained through the food we eat. (Ch. 20)

essential element An element present in tissue, blood, or other body fluids that has a physiological function. (Ch. 21)

ester An organic compound in which the –OH of a carboxylic acid group is replaced by –OR, where R can be any organic group. (Ch. 12)

ether An organic compound whose moecules have an R—O—R′ structure. (Ch. 10)

excited state Any energy state above the ground state in an atom, ion, or molecule. (Ch. 7)

exothermic process A thermochemical or physical process in which energy flows from a system into its surroundings. (Ch. 6)

extensive property A property that varies with the quantity of the substance present. (Ch. 1)

F

face-centered cubic (fcc) unit cell An array of closest-packed particles that has one particle at each of the eight corners of a cube and one more at the center of each face of the cube. (Ch. 12)

Faraday constant (*F*) The magnitude of electrical charge in 1 mole of electrons; its value to three significant figures is 9.65×10^4 C/mol e^-. (Ch. 18)

fat A solid triglyceride containing primarily saturated fatty acids.

(Ch. 20)

fatty acid A carboxylic acid with a long hydrocarbon chain that may be either saturated or unsaturated. (Ch. 20)

first law of thermodynamics The principle that the energy gained or lost by a system must equal the energy lost or gained by its surroundings. (Ch. 6)

food value The quantity of energy produced when a material consumed by an organism for sustenance is burned completely; it is typically reported in Calories (kilocalories) per gram of food. (Ch. 6)

formal charge (FC) A value calculated for an atom in a molecule or polyatomic ion by determining the difference between the number of valence electrons in the free atom and the sum of lone-pair electrons plus half of the electrons in the atom's bonding pairs. (Ch. 8)

formation constant (K_f) An equilibrium constant describing the formation of a metal complex from a free metal ion and its ligands. (Ch. 16)

formation reaction A reaction in which 1 mole of a substance is formed from its component elements in their standard states. (Ch. 6)

formula mass The mass of one formula unit of an ionic compound. (Ch. 3)

formula unit The smallest electrically neutral unit of an ionic compound. (Ch. 2)

fractional distillation A method of separating a mixture of compounds based on their different boiling points. (Ch. 11)

Fraunhofer lines A set of dark lines in the otherwise continuous solar spectrum. (Ch. 7)

free radical An odd-electron molecule with an unpaired electron in its Lewis structure. (Ch. 8)

frequency (ν) The number of crests of a wave that pass a stationary point of reference per second. (Ch. 7)

frequency factor (A) The product of the frequency of molecular collisions and a factor that expresses the probability that the orientation of the molecules is appropriate for a reaction to occur. (Ch. 13)

fuel cell A voltaic cell based on the oxidation of a continuously supplied fuel; the reaction is the equivalent of combustion, but chemical energy is converted directly into electrical energy. (Ch. 18)

fuel density The quantity of energy released during the complete combustion of 1 L of a liquid fuel. (Ch. 6)

fuel value The quantity of energy released during the complete combustion of 1 g of a substance. (Ch. 6)

functional group A group of atoms in the molecular structure of an organic compound that imparts characteristic chemical and physical properties. (Ch. 2)

G

gas A form of matter that has neither definite volume nor shape and that expands to fill its container; also called *vapor*. (Ch. 1)

gauge pressure The pressure of a gas that is above atmospheric pressure. (Ch. 5)

Geiger counter A portable device for determining nuclear radiation levels by measuring how much the radiation ionizes the gas in a sealed detector. (Ch. 19)

general gas equation See *combined gas law*.

Gibbs free energy (G) The maximum energy released by a process occurring at constant temperature and pressure that is available to do useful work. (Ch. 17)

glyceride A lipid consisting of esters formed between fatty acids and the alcohol glycerol. (Ch. 20)

glycolysis A series of reactions that converts glucose into pyruvate; a major anaerobic (no oxygen required) pathway for the metabolism of glucose in the cells of almost all living organisms. (Ch. 17)

glycosidic bond A C—O—C bond between sugar molecules. (Ch. 20)

Graham's law of effusion The principle that the rate of effusion of a gas is inversely proportional to the square root of its molar mass. (Ch. 5)

gray (Gy) The SI unit of absorbed radiation; 1 Gy = 1 J/kg of tissue. (Ch. 19)

ground state The most stable, lowest-energy state available to an atom, ion, or molecule. (Ch. 7)

group All the elements in the same column of the periodic table; also called *family*. (Ch. 2)

Grubbs' test A statistical test used to detect an outlier in a set of data. (Ch. 1)

H

half-life ($t_{1/2}$) The time in the course of a chemical reaction during which the concentration of a reactant decreases by half. (Ch. 13)

half-reaction One of the two halves of an oxidation–reduction reaction; one half-reaction is the oxidation component, and the other is the reduction component. (Ch. 4)

halogens The elements in group 17 of the periodic table. (Ch. 2)

heat The energy transferred between objects because of a difference in their temperatures. (Ch. 5)

heat capacity (C_P) The quantity of energy needed to raise the temperature of an object by 1°C at constant pressure. (Ch. 6)

Heisenberg uncertainty principle The principle that we cannot determine both the position and the momentum of a particle in an atom at the same time. (Ch. 7)

Henderson–Hasselbalch equation An equation used to calculate the pH of solutions containing comparable concentrations of acid and conjugate base. (Ch. 16)

Henry's law The principle that the concentration of a sparingly soluble, chemically unreactive gas in a liquid is proportional to the partial pressure of the gas. (Ch. 10)

hertz (Hz) The SI unit of frequency, equivalent to 1 cycle per second, or simply 1/s. (Ch. 7)

Hess's law The principle that the enthalpy of reaction ΔH_{rxn} for a reaction that is the sum of two or more reactions is equal to the sum of the ΔH_{rxn} values of the constituent reactions; also called *Hess's law of constant heat of summation*. (Ch. 6)

heteroatom An atom of an element other than carbon and hydrogen within a molecule of an organic compound. (Ch. 2)

heterogeneous catalyst A catalyst in a different phase from the reactants. (Ch. 13)

heterogeneous equilibria Equilibria that involve reactants and products in more than one phase. (Ch. 14)

heterogeneous mixture A mixture in which the components are not distributed uniformly, so that the mixture contains distinct regions of different compositions. (Ch. 1)

heteropolymer A polymer made of three or more different monomer units. (Ch. 12)

hexagonal closest-packed (hcp) A crystal lattice in which the layers of atoms or ions in hexagonal unit cells have an *ababab* . . . stacking pattern. (Ch. 12)

hexagonal unit cell An array of closest-packed particles that includes parts of four particles on the top and four on the bottom faces of a hexagonal prism and one particle in a middle layer. (Ch. 12)

homogeneous catalyst A catalyst in the same phase as the reactants. (Ch. 13)

homogeneous equilibria Equilibria that involve reactants and products in the same phase. (Ch. 14)

homogeneous mixture A mixture in which the components are distributed uniformly throughout and have no visible boundaries or regions. (Ch. 1)

homopolymer A polymer composed of only one kind of monomer. (Ch. 12)

Hund's rule The lowest-energy electron configuration of an atom has the maximum number of unpaired electrons, all of which have the same spin, in degenerate orbitals. (Ch. 7)

hybrid atomic orbital In valence bond theory, one of a set of equivalent orbitals about an atom created when specific atomic orbitals are mixed. (Ch. 9)

hybridization In valence bond theory, the mixing of atomic orbitals to generate new sets of orbitals that are then available to form covalent bonds with other atoms. (Ch. 9)

hydrocarbon An organic compound whose molecules are composed only of carbon and hydrogen atoms. (Ch. 2)

hydrogen bond The strongest dipole–dipole interaction. It occurs between a hydrogen atom bonded to a small, highly electronegative element (O, N, F) and an atom of oxygen or nitrogen in another polar molecule. Molecules of HF also form hydrogen bonds. (Ch. 10)

hydrolysis The reaction of water with another material. The hydrolysis of nonmetal oxides produces acids. (Ch. 4)

hydronium ion (H_3O^+) A H^+ ion bonded to a molecule of water, H_2O; the chemical form of a hydrogen ion in an aqueous solution. (Ch. 4)

hydrophilic A “water-loving,” or attractive, interaction between a solute and water that promotes water solubility. (Ch. 10)

hydrophobic A “water-fearing,” or repulsive, interaction between a solute and water that diminishes water solubility. (Ch. 10)

hypothesis A tentative and testable explanation for an observation or a series of observations. (Ch. 1)

I

***i*factor** See *van ’t Hoff factor*.

ideal gas A gas whose behavior is predicted by the linear relationships defined by Boyle’s, Charles’s, Avogadro’s, and Amontons’s laws. (Ch. 5)

ideal gas equation (also called *ideal gas law*) The principle relating the pressure, volume, number of moles, and temperature of an ideal gas; expressed as $PV = nRT$, where R is the universal gas constant. (Ch. 5)

ideal gas law See *ideal gas equation*.

ideal solution A solution that obeys Raoult’s law. (Ch. 11)

induced dipole The separation of charge produced in an atom or molecule by a momentary uneven distribution of electrons. (Ch. 10)

inhibitor A compound that diminishes or destroys the ability of an enzyme to catalyze a reaction. (Ch. 20)

initial rate The rate of a reaction at $t = 0$, immediately after the reactants are mixed. (Ch. 13)

inner coordination sphere The ligands that are bound directly to a metal via coordinate bonds. (Ch. 22)

integrated rate law A mathematical expression that describes the change in concentration of a reactant in a chemical reaction with time. (Ch. 13)

intensive property A property that is independent of the amount of substance present. (Ch. 1)

intermediate A species produced in one step of a reaction and consumed in a subsequent step. (Ch. 13)

internal energy (*E*) The sum of all the kinetic and potential energies of all the components of a system. (Ch. 6)

interstitial alloy An alloy in which atoms of the added element occupy the spaces between atoms of the host. (Ch. 12)

ion A particle consisting of one or more atoms that has a net positive or negative electrical charge. (Ch. 1)

ion channel A group of helical proteins that penetrate cell membranes and allow selective transport of ions. (Ch. 21)

ion exchange A process by which one ion is displaced by another. (Ch. 11)

ion pair A cluster formed when a cation and an anion associate with each other in solution. (Ch. 11)

ion pump A system of membrane proteins that exchange ions inside the cell with those in the intercellular fluid. (Ch. 21)

ion–dipole interaction An attractive force between an ion and a molecule that has a permanent dipole moment. (Ch. 10)

ionic bond A chemical bond that results from the electrostatic attraction between a cation and an anion. (Ch. 8)

ionic character An estimate of the magnitude of charge separation in a covalent bond. (Ch. 8)

ionic compound A compound composed of positively and negatively charged ions held together by electrostatic attraction.

(Ch. 2)

ionic solid A solid formed by ionic bonds among monatomic or polyatomic ions. (Ch. 12)

ionization energy (IE) The quantity of energy needed to remove 1 mole of electrons from 1 mole of ground-state atoms or ions in the gas phase. (Ch. 7)

ionizing radiation High-energy products of radioactive decay that can ionize molecules. (Ch. 19)

isoelectric point See *pI*.

isoelectronic Atoms or ions having identical electron configurations. (Ch. 7)

isolated system A system that exchanges neither energy nor matter with the surroundings. (Ch. 6)

isomers Compounds with the same molecular formula but different arrangements of the atoms in their molecules. (Ch. 3)

isotopes Atoms of the same element that contain different numbers of neutrons. (Ch. 2)

J

joule (J) The SI unit of energy; 4.184 J = 1 cal. (Ch. 6)

K

kelvin (K) The SI unit of temperature. (Ch. 1)

ketone Organic molecule containing a carbonyl group in which the carbonyl carbon is bonded to two other carbon atoms. (Ch. 9)

kinetic energy The energy of an object in motion due to its mass (m) and its speed (u): $\frac{1}{2}mu^2$. (Ch. 5)

kinetic molecular theory A model that describes the behavior of ideal gases; all equations defining relationships between pressure, volume, temperature, and number of moles of gases can be derived from the theory. (Ch. 5)

L

lattice energy (*U*) The enthalpy change that occurs when 1 mole of an ionic compound forms from its free ions in the gas phase. (Ch. 11)

law of conservation of energy The principle that energy cannot be created or destroyed but can be converted from one form into another. (Ch. 6)

law of conservation of mass The principle that the sum of the masses of the reactants in a chemical reaction is equal to the sum of the masses of the products. (Ch. 3)

law of constant composition The principle that all samples of a compound contain the same elements combined in the same proportions. (Ch. 1)

law of mass action The principle relating the balanced chemical equation of a reversible reaction to its mass action expression (or equilibrium constant expression). (Ch. 14)

law of multiple proportions The principle that, when two masses of one element react with a given mass of another element to form two different compounds, the two masses of the first element have a ratio of two small whole numbers. (Ch. 2)

Le Châtelier's principle The principle that a system at equilibrium responds to a stress in such a way that it relieves that stress. (Ch. 14)

leveling effect The observation that all strong acids have the same strength in water and are completely converted into solutions of H_3O^+ ions; strong bases are likewise leveled in water and are completely converted into solutions of OH^- ions. (Ch. 15)

Lewis acid A substance that *accepts* a lone pair of electrons in a chemical reaction. (Ch. 16)

Lewis base A substance that *donates* a lone pair of electrons in a chemical reaction. (Ch. 16)

Lewis dot symbol See *Lewis symbol*.

Lewis structure A two-dimensional representation of the bonds and lone pairs of valence electrons in a molecule or polyatomic ion. (Ch. 8)

Lewis symbol (also called *Lewis dot symbol*) A system in which the chemical symbol for an element is surrounded by one or more dots representing each of its atom's valence electrons. (Ch. 8)

ligand A Lewis base bonded to the central metal ion of a complex ion. (Ch. 16)

limiting reactant A reactant that is consumed completely in a chemical reaction. The amount of product formed depends on the amount of the limiting reactant available. (Ch. 3)

linear The molecular geometry about a central atom with a steric number of 2 and no lone pairs of electrons; the bond angle is 180°. (Ch. 9)

lipid A class of water-insoluble, oily organic compounds that are common structural materials in cells. (Ch. 20)

lipid bilayer A double layer of molecules whose polar head groups interact with water molecules and whose nonpolar tails interact with each other. (Ch. 20)

liquid A form of matter that occupies a definite volume but flows to assume the shape of its container. (Ch. 1)

London force See *dispersion force*.

lone pair A pair of electrons that is not shared. (Ch. 8)

M

macrocyclic ligand A ring containing multiple electron-pair donors that bind to a metal ion. (Ch. 22)

macromolecule See *polymer*.

magnetic quantum number (m_O) An integer that may have any value from $-\ell$ to $+\ell$, where ℓ is the angular momentum quantum number; it defines the orientation of an orbital in space. (Ch. 7)

main group elements (also called *representative elements*) The elements in groups 1, 2, and 13 through 18 of the periodic table. (Ch. 2)

major essential element An essential element present in the body in average concentrations greater than 1 mg of element per gram of body mass, resulting in gram quantities in the human body. (Ch. 21)

manometer An instrument for measuring the pressure exerted by a gas. (Ch. 5)

mass The property that defines the quantity of matter in an object. (Ch. 1)

mass action expression An expression equivalent in form to the equilibrium constant expression but applied to reaction mixtures that may or may not be at equilibrium. (Ch. 14)

mass defect (Δm) The difference between the mass of a nucleus and the masses of the individual nucleons that make it up. (Ch. 19)

mass number (A) The number of nucleons in an atom. (Ch. 2)

mass spectrometer An instrument that separates and counts ions according to their mass-to-charge ratios. (Ch. 3)

mass spectrum A graph of the data from a mass spectrometer. (Ch. 3)

matter Anything that has mass and occupies space. (Ch. 1)

matter wave The wave associated with any particle. (Ch. 7)

mean (arithmetic mean, $\bar{x}$) An average calculated by summing a set of related values and dividing the sum by the number of values in the set. (Ch. 1)

membrane potential (E_{membrane}) A weighted average of the equilibrium (reversal) potentials of the major ions based on concentration and permeability of the individual ions. (Ch. 21)

meniscus The concave or convex surface of a liquid in a small-diameter tube. (Ch. 10)

messenger RNA (mRNA) The form of RNA that carries the code for synthesizing proteins from DNA to the site of protein synthesis in a cell. (Ch. 20)

metallic bond A chemical bond consisting of metal atoms sharing a “sea” of electrons. (Ch. 8)

metallic solid A solid formed by metallic bonds among atoms of metallic elements. (Ch. 12)

metalloids (also called *semimetals*) The elements along the border between the metals and nonmetals in the periodic table; they have some metallic and some nonmetallic properties. (Ch. 2)

metals The elements on the left side of the periodic table that are typically shiny solids that conduct heat and electricity well and are malleable and ductile. (Ch. 2)

meter The standard unit of length, equivalent to 39.37 inches. (Ch. 1)

methyl group ($—CH_3$) A structural unit that can make only one bond. (Ch. 6)

methylene group ($—CH_2—$) A structural unit that can make two bonds. (Ch. 6)

microstate A unique distribution of particles among energy levels. (Ch. 17)

miscible Capable of being mixed in any proportion. (Ch. 5)

mixture A combination of pure substances in variable proportions in which the individual substances retain their chemical identities and can be separated from one another by a physical process. (Ch. 1)

molality (m) Concentration expressed as the number of moles of solute per kilogram of solvent. (Ch. 11)

molar absorptivity (e) A measure of how well a compound or ion absorbs light. (Ch. 4)

molar enthalpy of fusion (ΔH_{fus}) The energy required to convert 1 mole of a solid substance at its melting point into the liquid state. (Ch. 6)

molar enthalpy of vaporization (ΔH_{vap}) The energy required to convert 1 mole of a liquid substance at its boiling point to the vapor state. (Ch. 6)

molar heat capacity (c_P) The quantity of energy required to raise the temperature of 1 mole of a substance by 1°C at constant pressure. (Ch. 6)

molar mass ($\mathcal{M}$) The mass of 1 mole of a substance; the molar mass of an element in grams per mole is numerically equal to that element’s average atomic mass in unified atomic mass units. (Ch. 3)

molar volume The volume occupied by 1 mole of an ideal gas at STP; 22.4 L. (Ch. 5)

molarity (M) The concentration of a solution expressed in moles of solute per liter of solution ($M = n/V$). (Ch. 4)

mole (mol) The SI base unit for expressing quantities of substances. One mole contains $6.02214076 \times 10^{23}$ particles: atoms, molecules, or formula units. (Ch. 3)

mole fraction (*X*x) The ratio of the number of moles of a component in a mixture to the total number of moles in the mixture. (Ch. 5)

molecular compound A compound composed of molecules that contain the atoms of two or more elements covalently bonded together. (Ch. 2)

molecular equation An equation describing a reaction in solution in which the reactants and products are written as neutral compounds. (Ch. 4)

molecular formula A notation showing the number and type of atoms present in one molecule of a molecular compound. (Ch. 2)

molecular geometry The three-dimensional arrangement of the atoms in a molecule. (Ch. 9)

molecular ion (M^+) The peak of highest mass in a mass spectrum; it has the same mass as the molecule from which it came. (Ch. 3)

molecular mass The mass of one molecule of a molecular compound. (Ch. 3)

molecular orbital A region of characteristic shape and energy where electrons in a molecule are delocalized over two or more atoms in a molecule. (Ch. 9)

molecular orbital diagram An energy-level diagram showing the relative energies and electron occupancy of the molecular orbitals for a molecule. (Ch. 9)

molecular orbital (MO) theory A bonding theory based on the mixing of atomic orbitals of similar shapes and energies to form molecular orbitals that extend across two or more atoms. (Ch. 9)

molecular recognition The process by which molecules interact with other molecules in living tissues to produce a biological effect. (Ch. 9)

molecular solid A solid formed by intermolecular attractive forces among neutral, covalently bonded molecules. (Ch. 12)

molecularity The number of ions, atoms, or molecules involved in an elementary step in a reaction. (Ch. 13)

molecule A collection of atoms chemically bonded together in characteristic proportions. (Ch. 1)

monodentate ligand A species that forms only a single coordinate bond to a metal ion in a complex. (Ch. 22)

monomer A small molecule that bonds with others like it to form polymers. (Ch. 12)

monoprotic acid An acid that has one ionizable hydrogen atom per molecule. (Ch. 15)

monosaccharide A single-sugar unit and the simplest carbohydrate. (Ch. 20)

N

nanoparticle An approximately spherical sample of matter with dimensions smaller than 100 nm (1×10^{-7} m). (Ch. 12)

natural abundance The proportion of an isotope, usually expressed in percent, relative to all the isotopes of that element in a natural sample. (Ch. 2)

Nernst equation An equation relating the potential of a cell (or half-cell) reaction to its standard potential ($E°$) and to the concentrations of its reactants and products. (Ch. 18)

net ionic equation An equation describing a reaction in solution that contains only the species changed by the reaction; it is obtained by eliminating the spectator ions from the overall ionic equation. (Ch. 4)

neutralization reaction A reaction that takes place when an acid reacts with a base and produces a solution of a salt in water. (Ch. 4)

neutron An electrically neutral (uncharged) subatomic particle found in the nucleus of an atom. (Ch. 2)

neutron capture The absorption of a neutron by a nucleus. (Ch. 2)

noble gases The elements in group 18 of the periodic table. (Ch. 2)

node A location in a standing wave that experiences no displacement; in the context of orbitals, nodes are locations at which electron density goes to zero. (Ch. 7)

nonelectrolyte A substance that does *not* dissociate into ions and therefore does *not* result in conductivity when dissolved in water. (Ch. 4)

nonessential element An element present in humans that has no known function. (Ch. 21)

nonmetals The elements with properties opposite those of metals, including poor conductivity of heat and electricity. (Ch. 2)

nonspontaneous process A process that occurs only as long as energy is continually added to the system. (Ch. 17)

normal boiling point The temperature at which the vapor pressure of a liquid equals 1 atm (760 torr). (Ch. 10)

n-type semiconductor A semiconductor containing electron-rich dopant atoms that contribute excess electrons. (Ch. 9)

nuclear chemistry A subdiscipline of chemistry that explores the properties and reactivity of atomic nuclei. (Ch. 19)

nuclear fission A nuclear reaction in which the nucleus of an element splits into two lighter nuclei; the process is usually accompanied by the release of one or more neutrons and energy. (Ch. 19)

nuclear fusion A nuclear reaction in which subatomic particles or atomic nuclei collide with each other at very high speeds and fuse, forming more massive nuclei and releasing energy. (Ch. 19)

nuclear reaction A process that changes the number of neutrons or protons in the nucleus of an atom. (Ch. 19)

nucleic acid One of a family of large molecules; nucleic acids include deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), molecules that store the genetic blueprint of an organism and control the production of proteins. (Ch. 20)

nucleon Either a proton or a neutron in a nucleus. (Ch. 2)

nucleosynthesis The natural formation of nuclei because of fusion and other nuclear processes. (Ch. 2)

nucleotide A monomer unit from which nucleic acids are made. (Ch. 20)

nucleus The positively charged center of an atom that contains nearly all the atom's mass. (Ch. 2)

nuclide An atom with particular numbers of neutrons and protons in its nucleus. (Ch. 2)

O

octahedral The molecular geometry about a central atom with a steric number of 6 and no lone pairs of electrons, in which all six sites are equivalent. (Ch. 9)

octet rule The tendency of atoms of main group elements to make bonds by gaining, losing, or sharing electrons to achieve a valence shell containing eight electrons (i.e., four electron pairs). (Ch. 8)

oil A liquid triglyceride containing primarily unsaturated fatty acids. (Ch. 20)

open system A system that exchanges both energy and matter with the surroundings. (Ch. 6)

optical activity A property of a compound that refers to the rotation of a beam of plane-polarized light when it passes through a solution of the compound. (Ch. 20)

optical isomers Molecules that are not superimposable on their mirror images. (Ch. 20)

orbital A region around the nucleus of an atom where the probability of finding an electron is high; each orbital is defined by the square of the wave function (ψ^2) and is identified by a unique combination of three quantum numbers. (Ch. 7)

orbital diagram Depiction of the arrangement of electrons in an atom or ion, using boxes to represent orbitals. (Ch. 7)

organic chemistry The study of organic compounds. (Ch. 2)

organic compound A compound composed of molecules containing carbon combined with hydrogen and other elements, such as nitrogen, oxygen, phosphorous, and sulfur. (Ch. 2)

organometallic compound A molecule containing direct carbon–metal covalent bonds. (Ch. 22)

osmosis The flow of a fluid through a semipermeable membrane to balance the concentration of solutes in solutions on the two sides of the membrane. The solvent particles' flow proceeds from the more dilute solution into the more concentrated one. (Ch. 11)

osmotic pressure (π) The pressure applied across a semipermeable membrane to stop the flow of solvent from the compartment containing pure solvent or a less concentrated solution to the compartment containing a more concentrated solution. The osmotic pressure of a solution increases with solute concentration, M, and with solution temperature, T. (Ch. 11)

outlier A data point that is distant from the other observations. (Ch. 1)

overall ionic equation An equation describing a reaction in solution that shows all the species, both ionic and molecular, present in the reaction mixture. (Ch. 4)

overall reaction order The sum of the exponents of the concentration terms in the rate law. (Ch. 13)

overlap The degree to which atomic orbitals on adjoining atoms occupy the same region of space. (Ch. 9)

oxidation A chemical change in which a species loses electrons; the oxidation number of the species increases. (Ch. 4)

oxidation number (O.N.) (also called *oxidation state*) A positive or negative number based on the number of electrons an atom gains or loses when it forms an ion, or that it shares when it forms a covalent bond with another element; pure elements have an oxidation number of zero. (Ch. 4)

oxidation state See *oxidation number (O.N.)*.

oxidizing agent A substance in a redox reaction that contains the element being reduced. (Ch. 4)

oxoanion A polyatomic ion that contains oxygen in combination with one or more other elements. (Ch. 2)

P

packing efficiency The percentage of the total volume of a unit cell occupied by the atoms, ions, or molecules. (Ch. 12)

paramagnetic A substance with one or more unpaired electrons that is attracted to a magnetic field. (Ch. 9)

partial pressure The contribution to the total pressure made by one gas in a mixture of gases. (Ch. 5)

Pauli exclusion principle The principle that no two electrons in an atom can have the same set of four quantum numbers. (Ch. 7)

peptide A compound of two or more amino acids joined by peptide bonds; small peptides containing up to 20 amino acids are oligopeptides, whereas polypeptides are chains longer than 20 amino acids but shorter than proteins. (Ch. 20)

peptide bond The result of a condensation reaction between the carboxylic acid group of one amino acid and the amine group of another. (Ch. 20)

percent composition The composition of a compound expressed in terms of the percentage by mass of each element in the compound. (Ch. 3)

percent ionization See *degree of ionization*.

percent yield The ratio, expressed as a percentage, of the actual yield of a chemical reaction to the theoretical yield. (Ch. 3)

period A horizontal row in the periodic table. (Ch. 2)

periodic table of the elements A chart of the elements arranged in order of their atomic numbers and in a pattern based on their physical and chemical properties. (Ch. 2)

pH The negative logarithm of the hydronium ion concentration in an aqueous solution. (Ch. 15)

pH buffer A solution that resists changes in pH when acids or bases are added to it; typically a solution of a weak acid and its conjugate base or a weak base and its conjugate acid. (Ch. 16)

pH indicator A water-soluble weak organic acid that changes color as it ionizes. (Ch. 16)

phase diagram A graphical representation of how the stabilities of the physical states of a substance depend on temperature and pressure. (Ch. 10)

phospholipid A molecule of glycerol with two fatty acid chains and one polar group containing a phosphate; phospholipids are major constituents of cell membranes. (Ch. 20)

phosphorylation A reaction resulting in the addition of a phosphate group to an organic molecule. (Ch. 17)

photochemical smog A mixture of gases formed in the lower atmosphere when sunlight interacts with compounds produced in internal combustion engines and other pollution sources. (Ch. 13)

photoelectric effect The phenomenon of light striking a metal surface and producing an electric current (a flow of electrons). (Ch. 7)

photon A quantum of electromagnetic radiation. (Ch. 7)

physical process A transformation of a sample of matter, such as a change in its physical state, that does not alter the chemical identity of any substance in the sample. (Ch. 1)

physical property A property of a substance that can be observed without changing it into another substance. (Ch. 1)

p*I* (also called *isoelectric point*) The pH at which molecules of the amino acid have, on average, zero charge. (Ch. 20)

pi (π) bond A covalent bond in which electron density is greatest around—not along—the bonding axis; it forms from side-on overlap of two parallel *p* orbitals. (Ch. 9)

pi (π) molecular orbitals Molecular orbitals formed by the mixing of atomic orbitals oriented above and below, or in front of and behind, the bonding axis. (Ch. 9)

Planck constant (*h*) The proportionality constant between the energy and frequency of electromagnetic radiation: $E = h\nu$; $h = 6.626 \times 10^{-34}\ \text{J} \cdot \text{s}$. (Ch. 7)

pOH The negative logarithm of the hydroxide ion concentration in an aqueous solution. (Ch. 15)

polar covalent bond A bond characterized by unequal sharing of bonding pairs of electrons between atoms. (Ch. 8)

polarizability The relative ease with which the electron clouds surrounding the nuclei of individual atoms or molecules can be distorted, thereby inducing a temporary dipole. (Ch. 10)

polyatomic ion A charged group of two or more atoms joined by covalent bonds. (Ch. 2)

polydentate ligand A species that can form more than one coordinate bond per molecule. (Ch. 22)

polymer (or *macromolecule*) A very large molecule with high molar mass formed by bonding many small molecules of low molecular mass. (Ch. 12)

polyprotic acid An acid that has two or more ionizable hydrogen atoms per molecule. (Ch. 15)

polysaccharide A polymer of monosaccharides. (Ch. 20)

porphyrin A type of tetradentate macrocyclic ligand. (Ch. 22)

positron ($\left({}^{0}_{1}\beta\right)$**)** A particle with the mass of an electron but with a positive charge. (Ch. 19)

positron emission The spontaneous emission of a positron from a neutron-poor nucleus. (Ch. 19)

potential energy (PE) The energy stored in an object because of its position or composition. (Ch. 6)

precipitate A solid product formed from a reaction in solution. (Ch. 4)

precipitation reaction A reaction that produces a slightly soluble product upon mixing two solutions. (Ch. 4)

precision Agreement between the results of multiple measurements that were carried out in the same way. (Ch. 1)

pressure (*P*) The ratio of a force to the surface area over which the force is applied. (Ch. 5)

pressure–volume (*P*–*V*) work The work associated with the expansion or compression of a gas. (Ch. 6)

primary (1°) structure The sequence in which amino acid monomers occur in a protein chain. (Ch. 20)

principal quantum number (*n*) A positive integer describing the relative size and energy of an atomic orbital or group of orbitals in an atom. (Ch. 7)

product A substance formed during a chemical reaction. (Ch. 3)

protein A biological polymer made of amino acids. (Ch. 20)

proton A positively charged subatomic particle present in the nucleus of an atom. (Ch. 2)

p-type semiconductor A semiconductor containing electron-poor dopant atoms that cause a reduction in the number of electrons, which is equivalent to the presence of positively charged holes. (Ch. 9)

pure substance Matter that has a constant composition and cannot be broken down into simpler matter by any physical process. (Ch. 1)

Q

quantized Having values restricted to whole-number multiples of a specific base value. (Ch. 7)

quantum (plural *quanta*) The smallest discrete quantity of a form of energy. (Ch. 7)

quantum mechanics See *wave mechanics*.

quantum number A number that specifies the energy, the probable location or orientation of an orbital, or the spin of an electron within an orbital. (Ch. 7)

quantum theory A model based on the idea that energy is absorbed and emitted in discrete quantities of energy called quanta. (Ch. 7)

quarks Elementary particles that combine to form neutrons and protons. (Ch. 2)

quaternary (4°) structure The larger structure functioning as a single unit that results when two or more proteins associate. (Ch. 20)

R

racemic mixture A sample containing equal amounts of both enantiomers of a compound. (Ch. 20)

radioactive decay The spontaneous disintegration of unstable particles accompanied by the release of radiation. (Ch. 19)

radioactivity The spontaneous emission of high-energy radiation and particles by materials. (Ch. 2)

radiocarbon dating A method for establishing the age of a carbon-containing object by measuring the amount of radioactive carbon-14 remaining in the object. (Ch. 19)

radiometric dating A method for determining the age of an object on the basis of the quantity of a radioactive nuclide, the products of its decay that the object contains, or both. (Ch. 19)

radionuclide An unstable nuclide that undergoes radioactive decay. (Ch. 19)

Raoult's law The principle that the vapor pressure of the solvent in a solution is equal to the vapor pressure of the pure solvent multiplied by the mole fraction of the solvent in the solution. (Ch. 11)

rate constant The proportionality constant that relates the rate of a reaction to the concentrations of reactants at a particular temperature. (Ch. 13)

rate law An equation that defines the experimentally determined relation between the concentrations of reactants in a chemical reaction and the rate of that reaction. (Ch. 13)

rate-determining step The slowest step in a multistep reaction mechanism. (Ch. 13)

reactant A substance consumed during a chemical reaction. (Ch. 3)

reaction mechanism A set of steps describing how a reaction occurs at the molecular level; the mechanism must be consistent with the experimentally determined rate law for the reaction. (Ch. 13)

reaction order An experimentally determined number defining the dependence of the reaction rate on the concentration of a reactant. (Ch. 13)

reaction quotient (*Q*) The numerical value of the mass action expression based on the concentrations or partial pressures of the reactants and products present at any time during a reaction; at equilibrium, $Q = K$. (Ch. 14)

redox flow battery An electrochemical cell consisting of two solutions separated by an ion-exchange membrane. (Ch. 18)

reducing agent A substance in a redox reaction that contains the element being oxidized. (Ch. 4)

reduction A chemical change in which a species gains electrons; the oxidation number of the species decreases. (Ch. 4)

relative biological effectiveness (RBE) A factor that accounts for the differences in physical damage caused by different types of radiation. (Ch. 19)

replication The process by which one double-stranded DNA forms two new DNA molecules, each one containing one strand from the original molecule and one new strand. (Ch. 20)

representative elements See *main group elements*.

resonance A characteristic of electron distributions when two or more equivalent Lewis structures can be drawn for one compound. (Ch. 8)

resonance stabilization The stability of a molecular structure due to delocalization of its electrons. (Ch. 9)

resonance structure One of two or more Lewis structures with the same arrangement of atoms but different arrangements of bonding pairs of electrons. (Ch. 8)

reverse osmosis A process in which solvent is forced through semipermeable membranes, leaving a more concentrated solution behind. (Ch. 11)

reversible process A process that can be run in the reverse direction in such a way that, once the system has been restored to its original state, no net energy has flowed either to the system or to its surroundings. (Ch. 17)

root-mean-square speed (u_{rms}) The square root of the average of the squared speeds of all the molecules in a population of gas molecules; a molecule possessing the average kinetic energy moves at this speed. (Ch. 5)

S

salt The product of a neutralization reaction; it is made up of the cation of the base in the reaction plus the anion of the acid. (Ch. 4)

saturated hydrocarbon An alkane; compounds containing the maximum ratio of hydrogen atoms to carbon atoms. (Ch. 6)

saturated solution A solution that contains the maximum concentration of a solute possible at a given temperature. (Ch. 4)

Schrödinger wave equation A description of how the electron matter wave varies with location and time around the nucleus of a hydrogen atom. (Ch. 7)

scientific method An approach to acquiring knowledge based on observation of phenomena, development of a testable hypothesis, and additional experiments that test the validity of the hypothesis. (Ch. 1)

scientific theory (model) A general explanation of a widely observed phenomenon that has been extensively tested and validated. (Ch. 1)

scintillation counter An instrument that determines the level of radioactivity in samples by measuring the intensity of light emitted by phosphors in contact with the samples. (Ch. 19)

second law of thermodynamics The principle that the total entropy of the universe increases in any spontaneous process. (Ch. 17)

secondary (2°) structure The pattern of arrangement of segments of a protein chain. (Ch. 20)

seesaw The molecular geometry about a central atom with a steric number of 5 and one lone pair of electrons in an equatorial position. (Ch. 9)

semiconductor A metalloid with electrical conductivity between that of metals and insulators that can be chemically altered to increase its electrical conductivity. (Ch. 9)

semimetals See *metalloids*.

sievert (Sv) The SI unit used to express the amount of biological damage caused by ionizing radiation. (Ch. 19)

sigma (σ) bond A covalent bond in which the highest electron density lies between the two atoms along the bond axis. (Ch. 9)

sigma (σ) molecular orbital A molecular orbital in which the greatest electron density is concentrated along an imaginary line drawn through the bonded atom centers. (Ch. 9)

significant figures All the certain digits in a measured value plus one estimated digit; the greater the number of significant figures, the greater the certainty with which the value is known. (Ch. 1)

simple cubic (sc) unit cell An array of atoms or molecules with one particle at the eight corners of a cube. (Ch. 12)

single bond A chemical bond that results when two atoms share one pair of electrons. (Ch. 8)

solid A form of matter that has a definite volume and shape. (Ch. 1)

solubility The maximum amount of a substance that dissolves in a given volume of solution at a given temperature. (Ch. 4)

solubility product (K_{sp}) (also called *solubility-product constant*) An equilibrium constant that describes the formation of a saturated solution of a slightly soluble salt. (Ch. 16)

solubility-product constant See *solubility product* (K_{sp}).

solute Any component in a solution other than the solvent. A solution may contain one or more solutes. (Ch. 4)

solution Another name for homogeneous mixture; solutions are often liquids, but they may also be solids or gases. (Ch. 1)

solvent The component of a solution that is present in the largest number of moles. (Ch. 4)

***sp* hybrid orbitals** Two hybrid orbitals oriented 180° from one another, formed by mixing one *s* and one *p* orbital. (Ch. 9)

sp^2 hybrid orbitals Three hybrid orbitals in a trigonal planar orientation, formed by mixing one *s* and two *p* atomic orbitals. (Ch. 9)

sp^3 hybrid orbitals A set of four hybrid orbitals with a tetrahedral orientation, formed by mixing one *s* and three *p* atomic orbitals. (Ch. 9)

specific heat (c_s) The quantity of energy required to raise the temperature of 1 g of a substance by 1°C at constant pressure. (Ch. 6)

spectator ion An ion present in a reaction mixture in solution that is unchanged by the reaction; spectator ions appear in overall ionic equations but not in net ionic equations. (Ch. 4)

spectrochemical series A list of ligands rank-ordered by their ability to split the energies of the *d* orbitals of transition metal ions. (Ch. 22)

sphere of hydration The cluster of water molecules surrounding an ion in aqueous solution; the general term applied to such a cluster forming in any solvent is *sphere of solvation*. (Ch. 10)

spin magnetic quantum number (m_s) Either $+\frac{1}{2}$ or $-\frac{1}{2}$, indicating that the spin orientation of an electron is either up or down, respectively. (Ch. 7)

spontaneous process A process that occurs without outside intervention. (Ch. 17)

square planar The molecular geometry about a central atom with a steric number of 6 and two lone pairs of electrons that occupy axial sites; the atoms occupy four equatorial positions. (Ch. 9)

square pyramidal The molecular geometry about a central atom with a steric number of 6 and one lone pair of electrons; as typically drawn, the atoms occupy four equatorial and one axial site. (Ch. 9)

standard cell potential (E°_{cell}) A measure of how forcefully an electrochemical cell in which all reactants and products in their standard states can pump electrons through an external circuit. (Ch. 18)

standard conditions In thermodynamics: a pressure of 1 bar (~1 atm) and some specified temperature, assumed to be 25°C unless otherwise stated; for solutions, a concentration of 1 *M* is specified. (Ch. 6)

standard deviation (*s*) A measure of the amount of variation, or dispersion, in a set of related values. The lowercase Greek letter sigma (σ) is also used as the symbol for standard deviation. (Ch. 1)

standard enthalpy of formation $(\Delta H^\circ_{\text{f}})$ The enthalpy change of a formation reaction; also called *standard heat of formation* or *heat of formation*. (Ch. 6)

standard enthalpy of reaction $(\Delta H^\circ_{\text{f}})$ The energy associated with a reaction that takes place under standard conditions; also called *standard heat of reaction*. (Ch. 6)

standard free energy of formation ($(\Delta G^\circ_{\text{f}})$**)** The change in free energy associated with the formation of 1 mole of a compound in its standard state from its component elements. (Ch. 17)

standard hydrogen electrode (SHE) A reference electrode based on the half-reaction $2\ H^+(aq) + 2\ e^- \rightarrow H_2(g)$ that produces a standard electrode potential of 0.000 V. (Ch. 18)

standard molar entropy (S°) The absolute entropy of 1 mole of a substance in its standard state. (Ch. 17)

standard reduction potential (E°) The potential of a reduction half-reaction in which all reactants and products are in their standard states at 25°C. (Ch. 18)

standard solution A solution of known concentration used in titrations. (Ch. 4)

standard state The most stable form of a substance under 1 bar pressure and some specified temperature (25°C unless otherwise stated). (Ch. 6)

standard temperature and pressure (STP) 0°C and 1 bar as defined by IUPAC; 0°C and 1 atm are commonly used in the United States and in this textbook. (Ch. 5)

standing wave A wave confined to a given space, with a wavelength (λ) related to the length L of the space by $L = n(\lambda/2)$, where n is a whole number. (Ch. 7)

state function A property of an entity based solely on its chemical or physical state or both, but not on how it achieved that state. (Ch. 6)

stereoisomers Isomers created by differences in the orientations of the bonds in molecules. (Ch. 20)

steric number (SN) The sum of both the number of atoms bonded to a central atom and the number of lone pairs of electrons on the central atom. (Ch. 9)

stimulatory effect Increased activity, growth, or other biological response to the presence of a nonessential element. (Ch. 21)

stock solution A concentrated solution of a substance used to prepare solutions of lower concentration. (Ch. 4)

stoichiometry The quantitative relationship between reactants and products in a chemical reaction. (Ch. 3)

straight-chain hydrocarbon A hydrocarbon in which the carbon atoms are bonded together in one continuous carbon chain. (Ch. 6)

strong acid An acid that completely dissociates into ions in aqueous solution. (Ch. 4)

strong base A base that completely dissociates into ions in aqueous solution. (Ch. 4)

strong electrolyte A substance that dissociates completely into ions when it dissolves in water. (Ch. 4)

strong nuclear force The fundamental force of nature that keeps nucleons together in atomic nuclei. (Ch. 19)

sublimation Transformation of a solid directly into a vapor (gas). (Ch. 1)

substitutional alloy An alloy in which atoms of the nonhost metal replace host atoms in the crystal lattice. (Ch. 12)

substrate The reactant that binds to the active site in an enzyme-catalyzed reaction. (Ch. 20)

supercritical fluid A substance at conditions above its critical temperature and pressure, where the liquid and vapor phases are indistinguishable and have some characteristics of both a liquid and a gas. (Ch. 10)

supersaturated solution A solution that contains more than the maximum quantity of solute predicted to be soluble in a given volume of solution at a given temperature. (Ch. 4)

surface tension The energy needed to separate the molecules at the surface of a liquid. (Ch. 10)

surroundings Everything that is not part of the system. (Ch. 6)

system The part of the universe that is the focus of a thermochemical study. (Ch. 6)

T

termolecular step A step in a reaction mechanism involving a collision among three molecules. (Ch. 13)

tertiary (3°) structure The three-dimensional, biologically active structure of a protein that arises because of interactions between the R groups on its amino acids. (Ch. 20)

tetrahedral The molecular geometry about a central atom with a steric number of 4 and no lone pairs of electrons; the bond angles are all 109.5°. (Ch. 9)

theoretical yield The maximum amount of product possible in a chemical reaction for given quantities of reactants; also called *stoichiometric yield*. (Ch. 3)

thermal energy The kinetic energy of atoms, ions, and molecules. (Ch. 6)

thermal equilibrium A condition in which temperature is uniform throughout a material and no energy flows from one point to another. (Ch. 6)

thermochemical equation The chemical equation of a reaction that includes the change in enthalpy that accompanies that reaction. (Ch. 6)

thermochemistry The study of energy changes that occur during chemical reactions. (Ch. 6)

thermodynamics The study of energy and its transformations. (Ch. 6)

third law of thermodynamics The entropy of a perfect crystal is zero at absolute zero. (Ch. 17)

threshold frequency (ν_0) The minimum frequency of light required to produce the photoelectric effect. (Ch. 7)

titrant The standard solution added to the sample in a titration. (Ch. 4)

titration An analytical method for determining the concentration of a solute in a sample by reacting the solute with a standard solution of known concentration. (Ch. 4)

torr A unit of pressure. There are exactly 760 torr in one atm of pressure. (Ch. 5)

trace essential element An essential element present in the body in average concentrations between 1 and 1000 μg of element per gram of body mass. (Ch. 21)

trans isomer (also called *E isomer*) A molecule with two like groups (such as two R groups or two hydrogen atoms) on opposite sides of the molecule. (Ch. 20)

transcription The process of copying the information in DNA to RNA. (Ch. 20)

transfer RNA (tRNA) The form of the nucleic acid RNA that delivers amino acids, one at a time, to polypeptide chains being assembled by the ribosome–mRNA complex. (Ch. 20)

transition metals The elements in groups 3 through 12 of the periodic table. (Ch. 2)

transition state A high-energy state between reactants and products in a chemical reaction. (Ch. 13)

translation The process of assembling proteins from the information encoded in RNA. (Ch. 20)

tricarboxylic acid (TCA) cycle A series of reactions that continue the oxidation of pyruvate formed in glycolysis. (Ch. 20)

trigonal bipyramidal The molecular geometry about a central atom with a steric number of 5 and no lone pairs of electrons; three atoms occupy equatorial sites (bond angle 120°) and two other atoms occupy axial sites (bond angle 180°) above and below the equatorial plane; the bond angle between the axial and equatorial bonds is 90°. (Ch. 9)

trigonal planar The molecular geometry about a central atom with a steric number of 3 and no lone pairs of electrons; the bond angles are all 120°. (Ch. 9)

trigonal pyramidal The molecular geometry about a central atom with a steric number of 4 and one lone pair of electrons. (Ch. 9)

triple bond A chemical bond in which two atoms share three pairs of electrons. (Ch. 8)

triple point The temperature and pressure at which all three phases of a substance coexist. (Ch. 10)

T-shaped The molecular geometry about a central atom with a steric number of 5 and two lone pairs of electrons that occupy equatorial positions; the outer atoms occupy two axial sites and one equatorial site. (Ch. 9)

U

ultratrace essential element An essential element present in the body in average concentrations less than 1 μg of element per gram of body mass. (Ch. 21)

unified atomic mass unit (u) The unit used to express the relative masses of atoms and subatomic particles; it is exactly 1/12 the mass of one atom of carbon with six protons and six neutrons in its nucleus. (Ch. 2)

unimolecular step A step in a reaction mechanism involving only one molecule on the reactant side. (Ch. 13)

unit cell The repeating unit of the arrangement of atoms, ions, or molecules in a crystal lattice. (Ch. 12)

universal gas constant The constant R in the ideal gas equation; its value and units depend on the units used for the variables in the equation. (Ch. 5)

V

valence band A band of orbitals that are filled or partially filled by valence electrons. (Ch. 9)

valence bond theory A quantum mechanics–based theory of bonding incorporates the assumption that covalent bonds form when half-filled orbitals on different atoms overlap or occupy the same region in space. (Ch. 9)

valence electrons Electrons in the outermost occupied shell of an atom; the electrons that are transferred or shared in chemical reactions. (Ch. 7)

valence shell The outermost occupied shell of an atom. (Ch. 7)

valence-shell electron-pair repulsion (VSEPR) theory A model predicting that the arrangement of valence electron pairs around a central atom minimizes their mutual repulsion to produce the lowest-energy orientations. (Ch. 9)

van der Waals equation An equation that includes experimentally determined factors a and b that quantify the contributions of non-negligible molecular volume and non-negligible intermolecular interactions to the behavior of real gases with respect to changes in P, V, and T. (Ch. 5)

van 't Hoff factor (also called *i factor*) The ratio of the experimentally measured value of a colligative property to the theoretical value expected for that property if the solute were a nonelectrolyte. (Ch. 11)

vapor pressure The pressure exerted by a gas at a given temperature in equilibrium with its liquid phase. (Ch. 10)

vinyl group The subgroup $\mathrm{CH_2{=}CH}$—. (Ch. 12)

viscosity The resistance to flow of a liquid. (Ch. 10)

voltaic cell An electrochemical cell in which chemical energy is transformed into electrical work by a spontaneous cell reaction.

(Ch. 18)

W

wave function (ψ) A solution to the Schrödinger wave equation. (Ch. 7)

wave mechanics (also called *quantum mechanics*) A mathematical description of the wavelike behavior of particles on the atomic level. (Ch. 7)

wavelength (λ) The distance from crest to crest or trough to trough on a wave. (Ch. 7)

wave–particle duality The behavior of an object that exhibits the properties of both a wave and a particle. (Ch. 7)

weak acid An acid that is a weak electrolyte and so has a limited capacity to donate protons to the medium. (Ch. 4)

weak base A base that is a weak electrolyte and so has a limited capacity to accept protons. (Ch. 4)

weak electrolyte A substance that dissolves in water with most molecules staying intact, but with a small fraction dissociating into ions. (Ch. 4)

work A form of energy—specifically, the energy required to move an object through a given distance. (Ch. 6)

work function (ϕ) The amount of energy needed to remove an electron from the surface of a metal. (Ch. 7)

Z

***Z*isomer** See *cis isomer*.

zeolites Natural crystalline minerals or synthetic materials consisting of three-dimensional networks of channels that contain sodium or other 1+ cations. (Ch. 11)

zwitterion A molecule that has both negatively and positively charged groups in its structure. (Ch. 20)

Answers to Particulate Review, Concept Tests, and Practice Exercises

Chapter 1

Particulate Review

8 hydrogen atoms

4 hydrogen molecules

5 helium atoms

Molecules are composed of atoms.

Concept Tests

p. 6	(b) and (c) show a physical process (a solid substance that melts does not change its identity), whereas (a) and (d) show a chemical reaction (burning fuel produces different substances).
p. 8	1:1
p. 12	(b)
p. 15	Energy is absorbed.
p. 18	(b) Decreasing
p. 23	(1) 3 significant figures; (2) 3 significant figures; (4) 4 significant figures
p. 26	The volume value (it has 4 significant figures) is the weak link because the mass value has 6.
p. 31	2.805 g. No penny would have a mass equal to the average mass.
p. 36	Hypothesis, because his explanation had not been thoroughly tested yet.

Practice Exercises

1.1.	Properties (a) and (c) are physical properties; property (d) is a chemical property; property (b) is both physical and chemical.
1.2.	1. The diatomic gas on the left undergoes deposition as it becomes a solid on the right. 2. Sublimation
1.3.	0.324 km; 3.24×10^4 cm
1.4.	9.45×10^{12} km (using 365 days/yr)
1.5.	1.14

1.6 Statistics (a) and (e) are exact numbers; statistics (b)–(d) have inherent uncertainty.

1.7 Mean $= 36.38$ mg/dL
STDEV $= 0.38$ mg/dL
95% CL $= 36.38 \pm 0.47$ mg/dL or 36.4 ± 0.5 mg/dL

1.8 The mean and standard deviation are 194 ± 18.6 mg/dL. Testing 215 mg/dL as an outlier gives us a calculated *Z* value of 1.1 mg/dL, which is less than the reference *Z* values for *n* = 3 from Table 1.8 at both the 95% and 99% confidence levels. The high value of 215 should *not* be considered an outlier.

1.9 $233^\circ\mathrm{C} = -387^\circ\mathrm{F} = 40$ K
$123^\circ\mathrm{C} = 253^\circ\mathrm{F} = 396$ K

Chapter 2

Particulate Review

Helium, He, element

Nitrogen, N_2, element

Gold, Au, element

Ethanol, CH_3CH_2OH, compound

Sodium chloride, NaCl, compound

Concept Tests

p. 51 Matter is neutral, so some positive particle must be present to provide electrical neutrality.

${}^{87}_{38}\mathrm{X}$ is an isotope of strontium because its atomic number is 38 (each of its nuclei contains 38 protons). ${}^{90}_{40}\mathrm{X}$ is an isotope of zirconium with a mass number of 90 (40 protons, 50 neutrons), and ${}^{234}_{90}\mathrm{X}$ is an isotope of thorium because it has an atomic number of 90.

p. 58 Because sometimes the next heaviest element that was known in the early 1870s did not have chemical properties similar to the other elements in the next column to be filled. For example, the next heaviest element after calcium (a group II element in Mendeleev's table) was titanium, whose properties fit those of the elements in group IV, not group III. So, Mendeleev skipped the cell in group III and placed titanium in group IV. The missing group III element, scandium, was discovered (by a Scandinavian chemist) in 1879.

p. 64 (c) CsN

p. 78 (a) aldehyde; (b) ether; (c) amine

Practice Exercises

2.1.
1. a. ^{56}Fe
2. ^{15}N
3. ^{37}Cl
4. ^{39}K

2.2. (a) 27 p, 33 n; (b) 53 p, 78 n; (c) 77 p, 115 n

2.3. ^{107}Ag – 51.85%; ^{109}Ag – 48.15%

2.4.
1. As, arsenic
2. K, potassium
3. Cd, cadmium
4. Se, selenium

2.5. 40.0 g

2.6. (a)–(d) are molecular; (e) is ionic.

2.7.
1. Tetraphosphorus decoxide
2. Nitrogen monoxide
3. Nitrogen trichloride
4. SF_6
5. ICl
6. Br_2O

2.8.
1. $SrCl_2$
2. MgO
3. NaF
4. $CaBr_2$

2.9. $MnCl_2$ and MnO_2

2.10.
1. $Sr(NO_3)_2$
2. K_2SO_4

3. Sodium hypochlorite
4. Potassium permanganate

2.11
1. Hypobromous acid
2. Iodous acid
3. Selenous acid

Chapter 3

Particulate Review

CO_2, carbon dioxide

H_2O, water

N_2, nitrogen

CO, carbon monoxide

H_2S, hydrogen sulfide

Concept Tests

p. 93

Both the mole and a gross represent a specific number of particles independent of the size, mass, or identity of an individual particle.

p. 95

One gram of Ag has more atoms because Ag has a smaller molar mass: fewer grams per mole mean more moles (or atoms) per gram.

p. 104

Changing the formula of a reactant or product changes its identity. In this reaction oxygen gas consists of molecules of O_2, not individual atoms of O.

p. 122

(a) C_2H_4 and (c) $C_{20}H_{40}$ have the same empirical formula (CH_2) and, therefore, the same percent composition (85.6% C, 14.4% H); (b) C_2H_2 and (d) C_6H_6 have the same empirical formula (CH) and are 92.3% C and 7.7% H.

p. 125

The empirical formula of (b) C_3H_8O is identical to its molecular formula; (a) $C_2H_6O_2$ and (c) $C_6H_{12}O_6$ have empirical formulas that differ from the given molecular formulas. The empirical formula of $C_2H_6O_2$ is CH_3O, and the empirical formula of $C_6H_{12}O_6$ is CH_2O.

p. 127	No, because they have different molecular formulas.
p. 128	Molecular formula

Practice Exercises

3.1.	1.5 × 10^{10} atoms
3.2.	6.80 × 10^{24} electrons
3.3.	5.41 × 10^{-2} mol C
3.4.	49.2 g Au
3.5.	CO_2 = 44.01 g/mol; O_2 = 32.00 g/mol; $C_6H_{12}O_6$ = 180.16 g/mol
3.6.	5.00 × 10^{-3} mol; 3.01 3 10^{21} formula units
3.7.	72.2 g Cr, 89.3 g Cr
3.8.	3.9.	(a) $P_4(s) + 5\ O_2(g) \rightarrow P_4O_{10}(s)$; (b) $P_4O_{10}(s) + 6\ H_2O(\ell) \rightarrow 4\ H_3PO_4(aq)$
3.10.	$2\ CO(g) + O_2(g) \rightarrow 2\ CO_2(g)$
3.11.	$C_3H_8(g) + 5\ O_2(g) \rightarrow 3\ CO_2(g) + 4\ H_2O(g)$
3.12.	$2\ C_4H_{10}(g) + 13\ O_2(g) \rightarrow 8\ CO_2(g) + 10\ H_2O(g)$; 3.03 g CO_2 produced
3.13.	321 g Cu_2S; 129 g SO_2
3.14.	This combustion mixture is fuel lean.
3.15.	3.74 g $C_2H_4N_2$
3.16.	70.4%
3.17.	1.10 × 10^3 g Al_2O_3; 194 g C
3.18.	21.32% C; 78.68% F
3.19.	NO
3.20.	Li_2CO_3
3.21.	$C_{20}H_{40}$
3.22.	C_5H_8 and $C_{20}H_{32}$
3.23.	$C_8H_8O_3$

Chapter 4

Particulate Review

Ethylene glycol is a covalent compound with covalent bonds, whereas sodium sulfate is an ionic compound with ionic bonds. The space-filling representations of the molecules of ethylene glycol remain “intact” and do not separate into smaller particles, whereas the particles shown for sodium sulfate are separate sodium cations and sulfate anions. (Note that the space-filling sulfate anions contain covalent bonds between the sulfur and oxygen atoms.)

Concept Tests

p. 151	(c) Clear cough syrup; (d) Filtered dry air
p. 154	(d) 56,000 n*M* NaCl is the least concentrated solution.
p. 162	Solvent is added to dilute the stock solution, which decreases the concentration.
p. 165	Equivalent molar concentrations mean that the same number of moles of solute are dissolved in a given solution volume. Differences in conductivity result from the different numbers of ions the solutes make when they dissolve.
p. 165	Drawing (a) represents a weak electrolyte and (b) represents a strong electrolyte.
p. 169	(a) H_2E^{2-}; (b) H_4E
p. 170	(a) weak acid; (b) neither; (c) weak base; (d) strong acid
p. 180	Mix solutions containing equal numbers of moles of $Pb(NO_3)_2(aq)$ and $Na_2CrO_4(aq)$. Let the mixture stand for 10 min; filter off the yellow $PbCrO_4$ precipitate; wash the precipitate with water; let dry overnight and remove from the filter.
p. 184	In the reaction between Fe_3O_4 between O_2 that forms Fe_2O_3, iron is oxidized because Fe_2O_3 contains more O atoms per Fe atom (1.50) than Fe_3O_4 does (1.33). As Fe is oxidized, O is reduced.
p. 187	Reactions (a) and (b) are redox reactions. In reaction (a), the O.N. of Br goes from 0 to -1 as the O.N. of Sn goes from $+2$ to $+4$. In reaction (b), the O.N. of F goes from 0 to -1 as the O.N. of O goes from -2 to 0.

Practice Exercises

4.1	The arsenic concentration in the well water is 120 times the WHO standard.

4.1. 1.88 M $MgCl_2$

4.2. 0.109 M KCl

4.3. 4.48 g $NaC_3H_5O_3$

4.4.

4.5. $V_{\text{initial}} = 12.5$ mL

4.6. $1.16 \times 10^{-4} M$

4.7.
1. $CH_3COOH(aq) + NaOH(aq) \rightarrow CH_3COONa(aq) + H_2O(\ell)$
2. $CH_3COOH(aq) + Na^+(aq) + OH^-(aq) \rightarrow Na^+(aq) + CH_3COO^-(aq) + H_2O(\ell)$
3. $CH_3COOH\ (aq) + OH^-(aq) \rightarrow CH_3COO^-(aq) + H_2O(\ell)$

4.8. (a) strong electrolyte, neither acidic nor basic; (b) strong electrolyte, strong acid; (c) weak electrolyte; weak base, (d) nonelectrolyte, neither acidic nor basic

4.9. The lemon juice is 0.238 M $C_6H_8O_7$; 100.0 mL of juice contains 4.57 g $C_6H_8O_7$.

4.10. 0.0987 M

4.11. (a) no; (b) yes, Hg_2Cl_2 precipitates (c) $Hg_2{}^{2+}(aq) + 2\ Cl^-(aq) \rightarrow Hg_2Cl_2(s)$

4.12. $3\ Ba^{2+}(aq) + 6\ OH^-(aq) + 2\ H_3PO_4(aq) \rightarrow Ba_3(PO_4)_2(s) + 6\ H_2O(\ell)$

4.13. 0.174 g HgS

4.14. $1.31 \times 10^{-4} M\ SO_4{}^{2-}$

4.15. Yes

4.16.
1. +3
2. +6
3. +6

4.17. Oxygen is reduced and is the oxidizing agent; S is oxidized and SO_2 is the reducing agent.

4.18.
1. Yes, because the oxidation numbers for iron and palladium change from reactants to products.
2. $2\ Fe(s) + 3\ Pd^{2+}(aq) \rightarrow 2\ Fe^{3+}(aq) + 3\ Pd(s)$

4.19. $Au^{3+}(aq)$ is most easily reduced. $Li(s)$ is most easily oxidized.

4.20. The products are $Al(NO_3)_3(aq)$ and $Ag(s)$. $Al(s) + 3\ Ag^+(aq) \rightarrow Al^{3+}(aq) + 3\ Ag(s)$

4.21. $3\ HO_2{}^-(aq) + 2\ MnO_4{}^-(aq) + H_2O(\ell) \rightarrow 3\ O_2(g) + 2\ MnO_2(s) + 5\ OH^-(aq)$

Chapter 5

Particulate Review

The balanced chemical equation is 2 $H_2O(\ell) \rightarrow 2\ H_2(g) + O_2(g)$. The product is a mixture of two elements.

Concept Tests

p. 222	(c)
p. 224	The two graphs have different slopes because volume is inversely proportional to pressure. The slope of graph 1 is twice the slope of graph 2.
p. 226	(c)
p. 230	a and c
p. 235	Kr
p. 236	(a) i; (b) ii
p. 239	Any quantity of a gas has only one pressure that can be measured directly. For a mixture, this is P_{total}.
p. 241	Yes
p. 245	Lower
p. 247	$UF_6 < SF_6 < Kr < CO_2 < Ar < H_2$
p. 248	The change in temperature produces the same proportionate change in the u_{rms} values of the two gases.
p. 252	CO_2, CH_4

Practice Exercises

5.1.	$P = 410\ \text{Pa} = 0.41\ \text{kPa}$
5.2.	$\Delta h = 72$ mm. The mercury level in the right-hand (atmosphere) side of the manometer would still be higher.
5.3.	$V_2 = 10.5$ L
5.4.	$V_1/V_2 = 0.622$
5.5.	$P = 2.5$ atm
5.6.	$V_2 = 2.10 \times 10^3$ L
5.7.	$V = 1.8 \times 10^3$ L

5.8. 1.10×10^2 g

5.9. 259 mL of N_2O

5.10. The balloon will sink to the floor.

5.11. $\mathcal{M} = 44.0$ g/mol;
$HCl(aq) + NaHCO_3(aq) \rightarrow NaCl(aq) + CO_2(g) + H_2O(\ell)$

5.12. $O_2 = 0.1201$, He $= 0.8799$

5.13. $X_{O_2} = 0.042$

5.14. 2.2 mg of H_2

5.15. $u_{rms,He} = 1.367 \times 10^3$ m/s, or 2.645 times faster than N_2

5.16. Ar

5.17. $P_{He} = 25.2$ atm, which is slightly higher than that of an ideal gas, whereas P_{N2} was slightly lower. The lower value for N_2 results from the stronger interactions between its molecules, compared to the much smaller atoms of He, which offset the increase in *PV/RT* that both gases experience because of the incompressibility of their atoms and molecules.

Chapter 6

Particulate Review

The molecule is H_2O (water). The ions are H_3O^+ (hydronium), Cl^- (chloride), Na^+ (sodium), and OH^- (hydroxide). The buret contains H_2O molecules, OH^- ions, and Na^+ ions. The solution in the flask initially contains H_2O molecules, Cl^- ions, and H_3O^+ ions. After the acid in the flask has been neutralized, the flask contains H_2O molecules, Cl^- ions, and Na^+ ions. The net ionic equation is $H_3O^+(aq) + OH^-(aq) \rightarrow 2\ H_2O(\ell)$.

Concept Tests

p. 275 No; rider 1 has more potential energy:
$m_1\,gh = (PE)_{rider\ 1} > (PE)_{rider\ 2} = m_2\,gh$

p. 275 The potential energy of rider 1 is greater than the potential energy of rider 2; rider 1 has greater kinetic energy:

$$\tfrac{1}{2}m_1u^2 = (KE)_{rider\ 1} > (KE)_{rider\ 2} = \tfrac{1}{2}m_2u^2$$

---

p. 277 There is far more water in the pool than in the cup. The thermal energy in the cup is “less than,” even if the pool temperature is, say, 20°C.

(a) open; (b, c) closed, because the bottle and the sandwich wrap can conduct heat; (d) open

p. 280

p. 295

The mass of the aluminum is much less than the mass of the water, and the molar heat capacity of aluminum is much less than that of water.

p. 314

Each alkane has two terminal $–CH_3$ groups, which have a mass of 15 g/mol each. Therefore, the mass of the $–CH_2–$ groups is 114 g/mol − 2(15 g/mol) = 84 g/mol. Each $–CH_2–$ group has a mass of 14 g/mol. So, 84 g/mol would be the mass of the $–CH_2–$ units, so there are (84 g/mol)/(14 g/mol) = 6 $–CH_2–$ units. Therefore, $n = 2 + 6 = 8$.

p. 316

(a) 1 mole CH_4; (b) 1 g H_2

Practice Exercises

6.1. About 13% slower

6.2.
1. The match is the system, $q < 0$, and the process is exothermic.
2. The wax is the system, $q < 0$, and the process is exothermic.
3. The liquid is the system, $q > 0$, and the process is endothermic.

6.3. $\Delta E = -32$ J

6.4. $w = -1.58 \times 10^6$ kJ

6.5. 1.13×10^3 g or 1.13 kg

6.6. ΔH_{sys} is negative; q_{surr} is positive.

6.7. −321 kJ

6.8. 16.2°C

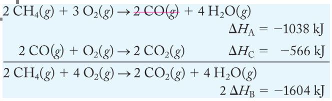
6.9. 118 J

6.10. $C_{calorimeter} = 4.390$ kJ/°C. Energy released = 16.4 kJ.

6.11. −14.6 kJ/mol

6.12. Reverse B and then add the three equations.

6.13.



$$2\,CH_4(g) + 3\,O_2(g) \rightarrow \cancel{2\,CO(g)} + 4\,H_2O(g) \qquad \Delta H_A = -1038\text{ kJ}$$
$$\cancel{2\,CO(g)} + O_2(g) \rightarrow 2\,CO_2(g) \qquad \Delta H_C = -566\text{ kJ}$$
$$2\,CH_4(g) + 4\,O_2(g) \rightarrow 2\,CO_2(g) + 4\,H_2O(g) \qquad 2\,\Delta H_B = -1604\text{ kJ}$$

For 1 mole CH_4, $\Delta H_{comb} = -802$ kJ

6.14.

a. $Ca(s) + C(s, \text{graphite}) + \frac{3}{2} O_2(g) \rightarrow CaCO_3(s)$

b. $2\ C(s, \text{graphite}) + 2\ H_2(g) + O_2(g) \rightarrow CH_3COOH(\ell)$

c. $K(s) + Mn(s) + 2\ O_2(g) \rightarrow KMnO_4(s)$

6.15. $\Delta H^\circ_{rxn} = -41.2$ kJ

6.16. Fuel value of kerosene = 43.0 kJ/g; fuel density of kerosene = 35.3 kJ/mL

6.17. $C_{calorimeter} = 11.2$ kJ/°C

Chapter 7

Particulate Review

The ions from left to right are K^+, S^{2-}, Al^{3+}, and F^-. Potassium has 19 electrons in a neutral atom and 18 electrons in its cation, K^+. Sulfur has 16 electrons in a neutral atom and 18 electrons in its anion, S^{2-}. Aluminum has 13 electrons in a neutral atom and 10 electrons in its cation, Al^{3+}. Fluorine has 9 electrons in a neutral atom and 10 electrons in its anion, F^-.

Concept Tests

p. 338 (c)

p. 340 Higher frequency

p. 342 (a) continuous; (b) quantized; (c) continuous; (d) quantized

p. 345 Yes; the excess energy increases the kinetic energy of the electron.

p. 349 (c) > (a) > (b) > (d)

p. 350 No, because He atoms have two electrons.

p. 361 Five

p. 372 Ground-state potassium atom: $[Ar]4s^1$; excited-state potassium atom: $[Ar]3p^1$ (others would be possible as well); potassium ion, K^+: [Ar]. The potassium atom has one more electron than the potassium ion.

p. 373 A half-filled set of *f* orbitals is more stable because adding another *f* electron requires pairing energy.

p. 376 $1s > 2s > 2p > 3s > 3p > 4s > 4p$

p. 379 Because the valence electrons are farther from the nucleus and shielded from it by more inner-shell electrons

p. 380 The magnitude of IE and EA both increase with increasing *Z* across a row (except for group 18). EA values do not display clear trends within groups, whereas IE values decrease with increasing Z.

Practice Exercises

7.1. $\lambda = 3.30$ m

7.2. $E_{453} = 4.39 \times 10^{-19}$ J; $E_{482} = 4.12 \times 10^{-19}$ J

7.3. $\lambda = 2.62 \times 10^{-7}$ m, or 262 nm

7.4. 486 nm

7.5. Prediction: Less energy is required to remove an electron from the hydrogen atom in the $n = 3$ state than for a hydrogen atom in the $n = 1$ state. Calculated value: 2.420×10^{-19} J

7.6. $\lambda = 3.3 \times 10^{-10}$ m

7.7. $\Delta x \geq 7 \times 10^{-11}$ m

7.8. 25

7.9.

(n) (ℓ) (m_ℓ) (m_s)
$+\frac{1}{2}$
$+\frac{1}{2}$
$+\frac{1}{2}$

7.10. Ga: $[Ar]3d^{10}4s^24p^1$ As: $[Ar]3d^{10}4s^24p^3$

7.11. Co = $[Ar]3d^74s^2$

7.12. $K^+ = [Ar]$; $I^- = [Kr]4d^{10}5s^25p^6 = [Xe]$; $Ba^{2+} = [Xe]$; $Rb^+ = [Kr]$; $O^{2-} = [He]2s^22p^6 = [Ne]$; $Al^{3+} = [Ne]$; $Cl^- = [Ne]3s^23p^6 = [Ar]$. K^+ and Cl^- are isoelectronic with Ar.

7.13. $Mn = [Ar]3d^54s^2$; $Mn^{3+} = [Ar]3d^4$; $Mn^{4+} = [Ar]3d^3$

7.14.
1. $Li^+ < F^- < Cl^-$
2. $Al^{3+} < Mg^{2+} < P^{3-}$

7.15. Ne > Ca > Cs

Chapter 8

Particulate Review

$CH_4(g) + 2\,O_2(g) \rightarrow CO_2(g) + 2\,H_2O(g)$

For each mole of CH_4 that is combusted:

4 moles of C—H bonds and 2 moles of O=O bonds are broken;

2 moles of C=O bonds and 4 moles of O—H bonds are formed.

Concept Tests

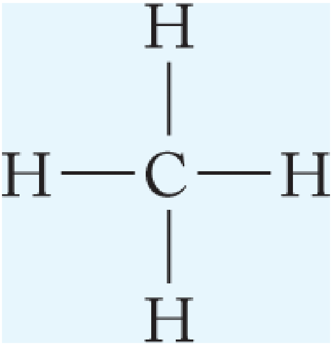
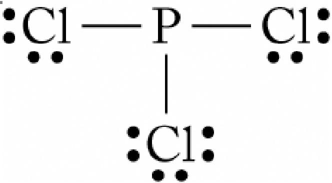
p. 407	p. 409	No, stretching in N≡N or O=O does *not* result in infrared absorptions because the bonds are nonpolar, so no change in polarity occurs when they stretch.
p. 417	1
p. 426	$N_2O > NO_2 > NO$
p. 430	The O=O bond is not as strong as the N≡N bond, so the O=O bond is more easily broken.

Practice Exercises

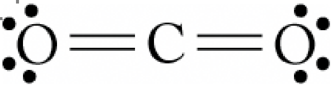
8.1	(i) gold, metallic bonds attract each gold atom to the gold atoms directly surrounding it. (ii) calcium carbonate, ionic bonds attract calcium cations (Ca^{2+}) and carbonate anions (CO_3^{2-}) to each other. The C and O atoms in each carbonate ion are covalently bonded together. (iii) phosphorus, covalent bonds attract each of the four P atoms to the other three in a P_4 molecule.
8.2.	



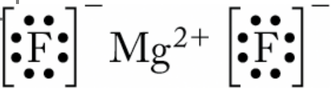
8.3.



8.4.



8.5.



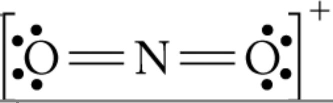
8.6. Be—Cl; the bond is a polar covalent bond. There would be no ionic bonds formed among any of these pairs.

8.7.

8.8. Resonance forms for N_3^-:

Resonance forms for NO_2^+:

8.9.



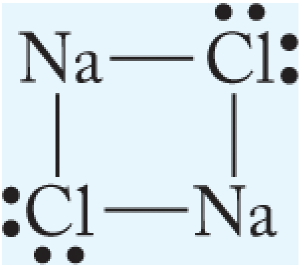
8.10.

(with 6 resonance structures)
is preferred because it has lower formal charges than
(with 3 resonance structures)

8.11.

8.12.

Sodium atoms do not have an octet.



8.13.

$\Delta H_{\mathrm{rxn}} = -79\ \mathrm{kJ}$

Chapter 9

Particulate Review

Malic acid is $C_4H_6O_5$ and contains two carboxylic acid functional groups (one at each end of the molecule) and one alcohol functional group in the middle. Putrescine is $C_4H_{12}N_2$ and contains two amine functional groups.

Concept Tests

p. 447

Molecular geometry is derived from electron-pair geometry. They are the same if there are no lone pairs around the central atom but different if there are lone pairs around the central atom.

p. 451

(a) > (c) > (b)

p. 456

The bond angles will be slightly smaller because of greater repulsion between the lone pair of electrons and the bonding pairs in the seesaw shape.

p. 460

The lone pair on the N atom in NCl_3 gives it a steric number of 4, which means it has a trigonal pyramidal molecular shape. The asymmetry of this shape means the NiCl bond dipoles do not completely offset each other so that NCl_3 has a permanent dipole. The Al atom in $AlCl_3$ has no lone pairs of valence electrons, so its SN = 3 giving $AlCl_3$ a symmetrical trigonal planar molecular shape. All its bond dipoles offset one another, and it has no permanent dipole.

p. 461

The electronegativity difference between H and S is less than the difference between H and O.

p. 469

It needs unhybridized *p* orbitals to form π bonds.

p. 473

(a) and (c), because there are alternating double and single bonds at sp^2 hybridized carbons

p. 476

(b) and (c) are chiral

p. 478

They are similar in that they are the products of mixing atomic orbitals, but different in that MOs are delocalized over the entire molecule.

p. 483

Yes, because O_2 is paramagnetic and N_2 is not.

p. 486

No, the bond orders in the ground states are higher because each has one more electron in a bonding orbital and one fewer in an antibonding orbital.

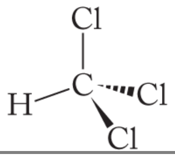
p. 491

Overlapping conduction and valence bands, because the filled valence band formed by magnesium atoms' filled 3*s* orbitals overlaps the conduction band formed by their empty *p* orbitals.

Practice Exercises

9.1.

Tetrahedral:



9.2.

The bond angles in SO_3 are 120°; the bond angle in SO_2 should be slightly less than 120°.

9.3.

(a) Tetrahedral; bond angles ~109.5° (b) T-shaped; bond angles slightly less than 90° and 180° (c) Square planar; bond angles = 90° and 180°

9.4.

No, because the molecular geometry of CS_2 is linear. Yes, because the CiOiC bond angle is about 109.5°, which means the two CiO bond dipoles do not completely offset one another, giving the molecule a permanent dipole.

9.5. 5*p* on I and 4*p* on Br

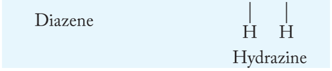
9.6. (a) CCl_4 and (d) PH_3

9.7.

Hexane: ;

heptane: $CH_3(CH_2)_5CH_3$

9.8.



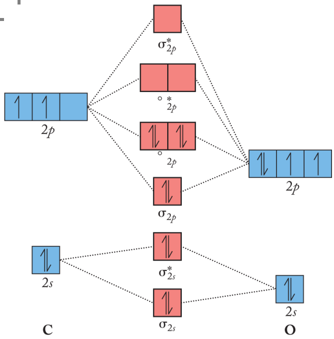
;

Each N in diazene is trigonal planar. With one lone pair on each N atom, the molecular geometry around the N atoms is bent with HiNiN bond angles of less than 120°. The N atoms are sp^2 hybridized and the molecule is flat. Each N in hydrazine is tetrahedral. With one lone pair on each N atom, the molecular geometry around the N atoms is trigonal pyramidal with HiNiN bond angles of less than 109.5°. The N atoms are sp^3 hybridized and the molecule is nonplanar.

9.9. H_2^+ can exist; its bond order is 0.5.

9.10. The bond order increases with the addition of an electron to B_2 and C_2.

9.11.



The C—O bond order is 3.

9.12. Selenium

Chapter 10

Particulate Review

Carbon dioxide is not polar despite containing polar bonds. Water is polar and contains polar bonds. Ozone is polar even though it contains nonpolar bonds.

Concept Tests

p. 510	He < Ne < Ar < Kr
p. 510	Molecules of CCl_4 are larger and experience larger dispersion forces.
p. 513	Acetone has the higher boiling point. Its larger dipole moment results in stronger dipole–dipole interactions, meaning that a higher temperature (more energy) is required to overcome them to convert liquid acetone to acetone vapor.
p. 515	(a) CH_3Br; (b) CH_3CH_2OH; (c) $(CH_3)_2NH$
p. 516	Yes. Ion–induced dipole forces should be slightly stronger than dipole–induced dipole forces, but weaker than dipole–dipole interactions.
p. 521	Gasoline
p. 524	Yes, it's possible that increased pressure will cause the ice to melt, according to the slope of the blue line in Figure 10.23 and the footprint of the tires.
p. 526	No, the slope of the line separating solid and liquid CO_2 indicates that the solid expands when it melts, which means it is denser than liquid CO_2.
p. 528	No, the adhesive forces are weak.

Practice Exercises

10.1	As pure substances, all five compounds experience dispersion forces. Compounds (b)–(e) are polar and experience dipole–dipole forces. Only (e) can participate in hydrogen bonding.
10.2	To vaporize, molecules of liquid ethylene glycol each need to break as many as six hydrogen bonds compared to a maximum of three hydrogen bonds per molecule of 2-

propanol. Therefore, ethylene glycol has a higher boiling point.

10.3. 28.4 kJ/mol

10.4. As its temperature is raised from $-100^\circ C$ to $50^\circ C$ at $P = 10$ atm, solid CO_2 melts at about $-55^\circ C$ and liquid CO_2 vaporizes at about $-35^\circ C$.

10.5. Helium, being smaller and with fewer electrons than nitrogen, is less soluble in blood because it is less polarizable and experiences weaker dipole–induced dipole interactions.

10.6. Methanol. Both methanol and hexanol have an –OH group that can form hydrogen bonds with the oxygen on acetone. Hexanol has a much longer hydrocarbon chain than methanol, and its molecules would interact via dispersion forces, which might cause hexanol to interact more strongly with itself than with acetone and hence cause it to be less soluble in acetone.

10.7. 9.57×10^{-5} mol/L

Chapter 11

Particulate Review

Potassium and sodium are both metals; sulfur and fluorine are nonmetals. We learned in Chapter 7 that atomic radii increase down a group (so potassium is larger than sodium) and across a period (so metals are larger than nonmetals). We also know that cations are smaller than their neutral parent atoms, and anions are larger than their neutral parent atoms. The image is drawn with neutral atoms above their ions, so the atoms and ions are

---

Concept Tests

p.553 (a) $LiF < NaF < KF$; (b) $CaF_2 < CaCl_2 < CaBr_2$

p.562 The vapor pressure of a pure solvent is an intensive property. The vapor pressure of a solution is an extensive property.

p.566 Dimethyl ether will distill first because its smaller dipole moment means its intermolecular attractions are weaker than those of acetone.

p.569 (c)

p.571 The solution is mostly water, which has a density of 1 kg/L, so

$$\text{volume}_{H_2O} \approx \text{mass}_{H_2O}.$$

p.576 (b)

p.578 (c)

p.581 Toward the KCl

p.581 Doubling the concentration

p.585 Although more opposing pressure is needed at 50°C than at 20°C, the greater molecular motion would cause osmosis to occur faster.

Practice Exercises

11.1. BaO > $CaCl_2$ > KCl

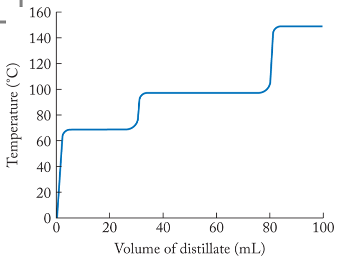
11.2. TiO_2

11.3. $U = -3792$ kJ/mol

11.4. $U = -670$ kJ/mol

11.5. $P_{solution} = 0.848$ atm or 644 torr

11.6.



11.7. 1.4

11.8. 0.84 *m*

11.9. 4.4 *m*

11.10. −15.2°C

11.11. $i = 3$; 102.7°C

11.12. −0.12°C

11.13. 28.1 atm

11.14. 3.7 atm

11.15. 27.5 atm

11.16. 6.40×10^4 g/mol

Chapter 12

Particulate Review

Platinum is a metal with delocalized electrons. Reacting elemental potassium with elemental iodine results in the transfer of electrons from potassium atoms to iodine atoms. The K^+ cations and I^- anions that form potassium iodide are held together by ion–ion electrostatic attractions. Platinum atoms are attracted to one another through London forces resulting from electrostatic attractions between nuclei in neighboring platinum atoms and the valence electrons in those same atoms.

Concept Tests

p. 607 A crystal lattice is a three-dimensional repeating array of particles in a crystalline solid; a unit cell is the smallest repeating pattern within a crystal lattice.

p. 613 Yes, because it is homogeneous; the tin atoms are uniformly distributed among the copper atoms.

p. 614 Both alloys could be either.

p. 621 A group 15 element such as N or P

p. 623 Different molecular structures and properties mean LDPE and HDPE must be recycled separately.

p. 628 The longer the hydrocarbon portion of the chain, the lower the water solubility.

Practice Exercises

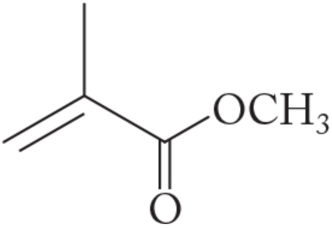
12.1 The atomic radii of both silver and gold are 144 pm (see Appendix 3). For silver, $d = 10.57$ g/mL, close to the 10.50 g/mL value for the density of silver from Appendix 3; for gold, $d = 19.41$ g/mL, close to the 19.3 g/mL value for the density of gold from Appendix 3.

12.2 The sizes of the titanium and molybdenum atoms relative to niobium both fall within the 15% radii guideline. However, niobium and molybdenum both form body-centered cubic structures, whereas titanium is hexagonal closest-packed. Therefore, molybdenum will form an alloy, but titanium will not.

12.3. $TlBr_3$ will crystallize in the CsCl structure rather than the rock salt structure because the anion and cation have nearly the same ionic radii. The ratio of Tl^{3+} to Br^{+} in $TlBr_3$ does not match the stoichiometry of the unit cell in the CsCl structure.

12.4. 191 pm; 2.16 g/cm^3

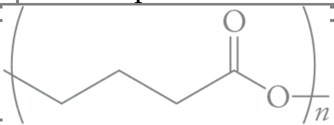
12.5. The carbon skeleton of the monomer is



The condensed structure of the monomer is H_2C□$C(CH_3)C(O)OCH_3$

12.6. London dispersion and dipole–induced dipole interactions

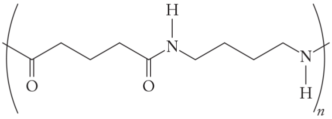
12.7.



12.8. The polar fibers of cotton and polyester repel very nonpolar greases and oils but attract water molecules, so perspiration wicks out of the gloves to cool the skin.

12.9. The carbon-skeleton structures of the monomers are

The repeating unit in the polymer is



Chapter 13

Particulate Review

Cylinder 1 contains the more concentrated solution (0.01 *M*). The concentration of cylinder 2 is 0.005 *M*. The two cylinders contain equivalent amounts of dissolved solid.

Concept Tests

p. 658	(d)
p. 662	(a) 1; (b) 0
p. 663	Four: rate $= k[A][B]^2$; rate $= k[A]^2[B]$; rate $= k[A]^3$; rate $= k[B]^3$
p. 669	Fast
p. 674	Molecules are moving faster, so the likelihood of collisions is greater.
p. 680	(c)
p. 682	*n*
p. 684	No
p. 687	Similar rate laws indicate similar reaction mechanisms.
p. 689	(a)
p. 689	Intermediate

Practice Exercises

13.1.	The rate of formation of CO_2 (a product) is twice the rate of consumption of O_2.
13.2.	$\frac{\Delta[N_2]}{\Delta t} = 10.8\ M/s$ and $\frac{\Delta[H_2O]}{\Delta t} = 21.5\ M/s$
13.3.	$1.2 \times 10^{-6} M/s$
13.4.	Rate $= k[NO][NO_3]$; $k = 1.57 \times 10^{10}/(M \cdot s)$
13.5.	The decomposition of H_2O_2 is first order; $k = 8.30 \times 10^{-4}\ s^{-1}$
13.6.	0.430 *M*
13.7.	$k = 2.5 \times 10^{-2}/day$
13.8.	This reaction is second order in $[NO_2]$; $k = 0.751/(M \cdot h)$
13.9.	6.9 kJ/mol
13.10.	306 K
13.11.	Rate $= k_{overall}[A]^2[B]^2$
13.12.	Because none of the rate laws possible with this mechanism match the experimental rate law, this proposed mechanism cannot be valid.

13.13	Yes, NO_2 acts as a catalyst in this reaction.

Chapter 14

Particulate Review

NO and O_2 combine to produce NO_2; NO and O_2 are produced when NO_2 molecules collide. The chemical equation for the two simultaneous reactions is

$$2\ NO(g) + O_2(g) \rightleftharpoons 2\ NO_2(g)$$

The rate would be increased by any change that increases the number of collisions between NO molecules and O_2 molecules, such as increasing temperature or decreasing the volume of the container in which the reaction takes place. These changes would also increase collisions between NO_2 molecules, that is, increase the rate of the reverse reaction.

Concept Tests

p. 710	Increased temperature or pressure for a gas-phase reaction increases the number of collisions.
p. 714	(b) $[CO_2] = [H_2] > [CO] = [H_2O]$
p. 726	Zone (a)
p. 733	The number of moles of gaseous reactants and products is the same.

Practice Exercises

14.1.	$K_c = \frac{[CO][H_2]^3}{[CH_4][H_2O]} \qquad K_p = \frac{(P_{CO})(P_{H_2})^3}{(P_{CH_4})(P_{H_2O})}$
14.2.	$K_c = \frac{[CH_3OH]}{[CO][H_2]^2} = 2.9 \times 10^2$
14.3.	$K_p = 2.7 \times 10^4$
14.4.	$K_c = 3.6 \times 10^8$
14.5.	$K_{p,reverse} = 2.3 \times 10^2$

14.6. $K_c = 0.13$

14.7. $K_{c,\text{overall}} = 1.7 \times 10^2$

14.8. $Q < K$, so this reaction is not at equilibrium and it proceeds to the right.

14.9.

a. $K_p = \dfrac{(P_{CO})^2}{(P_{CO_2})}$

b. $K_p = \dfrac{(P_{CO})}{(P_{CO_2})(P_{H_2})}$

14.10.

1. When the reaction is cooled and water vapor condenses, one product is removed from the reaction mixture and the equilibrium shifts to the right, forming more SO_2.
2. When SO_2 gas dissolves in liquid water as it condenses, products are removed, and the equilibrium shifts to the right, forming more products.
3. When O_2 is added, the concentration of one reactant increases and the equilibrium shifts to the right, forming more products.

14.11. Increasing the pressure shifts the equilibrium in the reaction to the products, the side of the reaction that has the fewest moles of gas.

14.12. The value of K for the endothermic reaction increases with increasing reaction temperature.

14.13. $P_{Cl_2} = 0.0902$ atm; $P_{Br_2} = 0.0902$ atm; $P_{BrCl} = 0.0196$ atm

14.14. $P_{PCl_5} = 3.5$ atm; $P_{PCl_3} = 0.216$ atm; $P_{Cl_2} = 0.216$ atm

14.15. $P_{CO} = 3.5 \times 10^{-5}$ atm; $P_{Cl_2} = 3.5 \times 10^{-5}$ atm

Chapter 15

Particulate Review

Only HCl and CH_3COOH produce H^+ (H_3O^+) ions when dissolved in water. HCl molecules dissociate completely, whereas only a small fraction of the CH_3COOH molecules dissociate. The acidic hydrogen in CH_3COOH is the hydrogen atom bonded to oxygen; the hydrogen atoms in the –CH_3 group are not acidic.

Concept Tests

p. 757 As CO_2 is removed more rapidly than it can be produced, both equilibria shift to the left.

p. 769 pH 0.22 = strongly acidic; 4.37 = weakly acidic; 7.00 = neutral; 10.03 = weakly basic; 13.77 = strongly basic

p. 771 Higher

p. 772 The larger its K_a, the greater the percent ionization for a given concentration of HA.

p. 775 Most: C; least: A

p. 783 C and D

p. 784 $H_3PO_4 > H_2PO_4^- > HPO_4^{2-} > PO_4^{3-}$

p. 787 Phosphoric acid: no. Citric acid: yes, the second ionization step.

Practice Exercises

15.1. $HClO_2 > CH_2BrCOOH >$ Lactic $> C_6H_5COOH > HN_3$

15.2. Strongest: H_2SO_4; weakest: H_2SeO_3

15.3.

$$\underset{\text{acid}}{CH_3COOH(aq)} + \underset{\text{base}}{H_2O(\ell)} \rightleftharpoons \underset{\text{conjugate base}}{CH_3COO^-(aq)} + \underset{\text{conjugate acid}}{H_3O^+(aq)}$$

15.4. $S^{2-} > ClO^- > CH_3COO^- > HSO_3^- > Br^-$

15.5. Greatest increase: b; greatest decrease: d

15.6. The acidity ($[H_3O^+]$) of the ocean now is $10^{-8.07} = 8.5 \times 10^{-9} M$. It was $6.6 \times 10^{-9} M$, which means it has increased by

$$\frac{(8.5 - 6.6) \times 10^{-9}\, M}{6.6 \times 10^{-9}\, M} = \frac{1.9}{6.6} = 27\%$$

15.7. $[H_3O^+] = 2.0 \times 10^{-12} M$; $[OH^-] = 5.0 \times 10^{-3} M$

15.8. pH = 2.23; percent ionization = 12%; $K_a = 7.9 \times 10^{-4}$

15.9. 7.2% ionized, $K_b = 5.7 \times 10^{-4}$

15.10. 12.65

15.11. pH = 3.10

15.12. pH = 11.97

15.13. pH = 7.52

15.14. pH = 0.68. Note that doubling the concentration decreased the pH by only 0.28 units. Had $[H_3O^+]$ doubled, pH would have decreased by $-\log 2 = 0.30$ units.

15.15. pH = 5.60

15.16.	$SO_4^{2-}(aq) + H_2O(\ell) \rightleftharpoons HSO_4^-(aq) + OH^-(aq)$
15.17.	pH = 11.66
15.18.	pH = 5.62

Chapter 16

Particulate Review

The compounds are (a) PbS, (b) Li_2S, (c) CaF_2, and (d) KF; PbS and CaF_2 are much less soluble than Li_2S and KF.

Concept Tests

p. 816	(b) because there is a 1:1 ratio of base to acid.
p. 820	(c) is the equivalence point. The titration starts at (b) and proceeds through (d), (c), and then (a).
p. 821	(b) depicts HClO(*aq*) before the titration, (a) depicts the midpoint, and (c) depicts the equivalence point.
p. 822	Titrating with a weak base would produce too small a change in pH at the equivalence point to be detected precisely.
p. 823	10.64
p. 824	(c) depicts $NH_3(aq)$ before the titration, (b) the buffer region, and (a) the equivalence point.
p. 827	Because neutralization of the CO_3^{2-} produces more HCO_3^-, which adds to the HCO_3^- present initially in the sample, which makes the second pH plateau wider than the first
p. 833	$Fe^{2+}(aq)$ should be a weaker Lewis acid than $Fe^{3+}(aq)$ because of its smaller charge and larger size. Therefore the K_a for $Fe^{2+}(aq)$ would be below that of (smaller than) $Fe^{3+}(aq)$.
p. 835	$K_{sp} = 1.7 \times 10^{-6}$
p. 838	Decrease: NaF; increase: HNO_3; no effect: neither
p. 840	The value $[OH^-]$ is defined by the initial $[Ca^{2+}]$ and the K_{sp} of $Ca(OH)_2$.

Practice Exercises

16.1.	pH = 3.25
16.2.	pH = 10.46
16.3.	H_2SO_3 ($pK_a = 1.77$)

16.4. $(CH_3CH_2)_2NH$ ($pK_b = 3.07$)

16.5. 980 g of sodium ascorbate + 51 g of ascorbic acid

16.6. pH = 4.97; pH = 4.98

16.7. (a) change in pH of +0.11; (b) change in pH of +0.22

16.8. Both buffer A and buffer B decrease in pH by 0.15.

16.9. pH = 11.39

16.10. (a) pH = 3.45; (b) pH = 3.75; (c) pH = 4.05

16.11. No, not always, because HCO_3^- ions initially present in the sample cause the midpoint pH to be lower than pK_{a2}.

16.12. 10.3 mL followed by an additional 13.7 mL.

16.13. CaO acts as a Lewis base, whereas CO_2 acts as a Lewis acid.

16.14. $[Ag^+(aq)] = 1.6 \times 10^{-8} M$

16.15. $3.1 \times 10^{-6} M$

16.16. $8.2 \times 10^{-4} M$

16.17. $1.1 \times 10^{-5} M$

16.18. Yes

16.19. Yes, Ba^{2+} and Ca^{2+} ions in solution can be completely separated by selective precipitation with F^-.

Chapter 17

Particulate Review

Combustion is an exothermic process resulting from the endothermic breaking of bonds in propane (C—H single bonds and C—C single bonds) and oxygen (O═O double bonds) along with the exothermic formation of bonds in carbon dioxide (C═O double bonds) and water (H—O single bonds).

Concept Tests

p. 855 (a), (c), and (d)

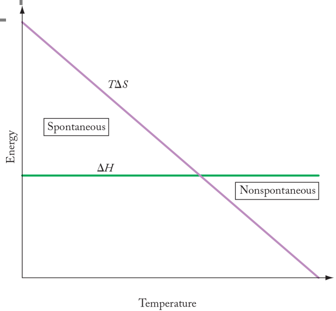
p. 858 $\Delta S_{univ} > 0$

p. 865 (a) Yes, it is spontaneous because $\Delta G < 0$; (b) thermodynamics says nothing about the rate of reaction.

p. 867 The reaction is very slow, and the activation energy is large.

p. 868 No. The sum of $\Delta G°_{f,prod}$ are all the same, but the reactants have different $\Delta G°_f$ values, so each reaction will have a different $\Delta G°$ value.

p. 870



p. 876 (e)

p. 886 (e)

Practice Exercises

17.1. (a) increase in entropy; (b) decrease in entropy

17.2. (a) > (b) > (d) > (c)

17.3. Prediction: S_{sys} decreases; $\Delta S^\circ_{\text{rxn}} = -243$ J/K

17.4.
1. ΔS_{rxn} is expected to be negative.
2. $\Delta S^\circ_{\text{rxn}} = -326$ J/K
3. $\Delta H^\circ_{\text{rxn}} = -571.6$ kJ/mol
4. $\Delta G^\circ_{\text{rxn}} = -474.3$ kJ, so the reaction is spontaneous under standard conditions.

17.5. 142.2 kJ/mol

17.6. $T < 5939$ K

17.7. The reaction is spontaneous only at high temperatures.

17.8. 6.09×10^5

17.9. 2.95×10^{-37} at 298 K; 9.20×10^{-13} at 2000 K

17.10. $\Delta G^\circ = -196$ kJ

Chapter 18

Particulate Review

In the reaction $4\ \text{Fe}(s) + 3\ \text{O}_2(g) \rightarrow 2\ \text{Fe}_2\text{O}_3(s)$, iron is oxidized and oxygen is reduced as electrons transfer from iron to oxygen.

Concept Tests

p. 902	No, because the atomic masses of Cu and Zn are different.
p. 904	The cell consists of a zinc anode, which is oxidized to Zn^{2+} ions as Cu^{2+} ions are reduced to Cu metal at the cathode.
p. 908	The most reactive metals listed at the top of the activity series form ions that are the least likely to be reduced, which is reflected in their very negative standard reduction potentials that are listed at the bottom of Table A6.1.
p. 908	(a)
p. 912	$E^\circ_{cell} < 0$, negative; $\Delta G^\circ_{cell} > 0$, positive
p. 916	SHE: 0.257 V; Ag/AgCl: 0.479 V
p. 917	Less than 0.800 V
p. 924	C is oxidized; Co is reduced.
p. 930	H_2
p. 934	Redox flow batteries are designed to meet very large electrical energy needs, so they need very large volumes of dissolved electrolytes to produce that energy.

Practice Exercises

18.1.	$O_2(g) + 2\ NO_2^-(aq) \rightarrow 2\ NO_3^-(aq)$
18.2.	The balanced redox reaction is $3\ Cu^{2+}(aq) + 2\ Al(s) \rightarrow 3\ Cu(s) + 2\ Al^{3+}(aq)$ The cell diagram is $Al(s) \mid Al^{3+}(aq) \parallel Cu^{2+}(aq) \mid Cu(s)$
18.3.	The net ionic equation is $Cd(s) + 2\ NiO(OH)(s) + 2\ H_2O(\ell) \rightarrow Cd(OH)_2(s) + 2\ Ni(OH)_2(s) \qquad E^\circ_{cell} = 1.33\ V$
18.4.	$\Delta G_{cell} = -2.90 \times 10^2\ kJ$
18.5.	$E_{cell} = 1.63\ V$
18.6.	$K = 6.2 \times 10^{62}$
18.7.	1.30×10^2 g
18.8.	1.5 g

Chapter 19

Particulate Review

From left to right: Nuclide 1 has a mass number of 11 (5 protons + 6 neutrons; 5 electrons), as does nuclide 2 (6 protons + 5 neutrons;

6 electrons). Nuclide 3 has a mass number of 13 (6 protons + 7 neutrons; 6 electrons). Nuclides 2 and 3 are isotopes.

Concept Tests

p. 950	The loss in mass becomes an energy that must be added to separate the nucleons that are bound together.
p. 955	The neutron-to-proton ratio for stable isotopes increases with atomic number. For heavy isotopes it is about 1.5 to 1. Losing α particles increases this ratio, creating neutron-rich nuclides that undergo β decay.
p. 961	Increased CO_2 (^{14}C depleted) in the air from burned fossil fuels will reduce the $^{14}C/^{12}C$ ratio in the air and in plant tissues.
p. 966	More. 200 Bq/m^3 − 5.4 pCi/L.
p. 974	To fuse nuclei, their coulombic repulsion must be overcome, which requires they collide at very high velocities, requiring very high temperatures. Human-made fusion has not been carried out except in a hydrogen bomb. We cannot make a fusion reactor until the process itself can be safely carried out.

Practice Exercises

19.1.	β decay; $^{28}_{14}\text{Si}$
19.2.	$A - 6.91 \times 10^9$ Bq; $A - 187$ mCi
19.3.	98.6%
19.4.	4900 years old
19.5.	1×10^{11} X-rays
19.6.	1.70×10^9 kJ/mol

Chapter 20

Particulate Review

The functional groups from left to right in the top row are carboxylic acid, alcohol, and amine. In the second row from left to right, the functional groups are an ether, amide, and aldehyde. In the bottom row from left to right they are a ketone and ester. The carboxylic acid and the amine function as a Brønsted–Lowry acid and base, respectively. When they react, they form the amide.

Concept Tests

p. 995	(e)
p. 1003	(a) alkane; (b) aromatic; (c) alcohol; (d) amide; (e) carboxylic acid; (f) amine
p. 1003	Glycine is not chiral because the α-carbon is not bonded to four different groups (there are two hydrogen atoms). Isoleucine and threonine each have two chiral centers.
p. 1010	Those with nonpolar R groups, such as alanine, leucine, and isoleucine.
p. 1012	No, a change in the 2° structure is involved.
p. 1019	 OH HO O HO OH O HO OH OH O OH (a)
p. 1023	At low temperatures the unsaturated fatty acids remain liquid.
p. 1028	Olestra is a much larger molecule with many more C—C and C—H bonds, so on a per-mole basis it would give off much more energy.
p. 1029	No, the direction in which the code is read matters; UUG codes for leucine.

Practice Exercises

20.1	(a) Constitutional isomers; (b) two different compounds; (c) constitutional isomers
20.2.

20.5. Six

20.6. Val-Ala-Leu-Leu-Thr-Gly

20.7 The fatty acids could be bonded as ABC, ACB, BAC, BCA, CAB, or CBA. However, ABC and CBA would be equivalent, as would ACB and BCA, and BAC and CAB. Therefore there are three unique triglycerides.

20.8 (a) GCCATAGGCTA; (b) AATTCGGCGATC

Chapter 21

Particulate Review

Sulfur atoms are in keratin: disulfide bonds are located between the α helices.

Phosphorus atoms are in the phospholipid bilayer in the phosphate units in the hydrophilic head-groups. Phosphorus atoms are also in DNA in the phosphate units connecting the ribose units in the backbone.

Keratin has nitrogen atoms in the amide groups of amino acids; phospholipids contain nitrogen atoms in the quaternary amine groups in the hydrophilic head group; DNA contains nitrogen atoms in the nucleotide bases.

Concept Tests

p. 1054 Nonspontaneous—they require energy to pump ions.

p. 1057 $K > 1$ for the drug to be effective.

p. 1060 Solubility rules and K_{sp} values indicate that all nitrates are soluble but many phosphates are not. This is borne out by the presence of phosphate in biominerals such as bone and teeth.

p. 1068 Essential elements tend to be the first or second elements in a group. Nonessential elements are generally located toward the bottom of the periodic table. They have larger atomic numbers and are less abundant than the essential elements in the same group.

p. 1069 To avoid tissue damage, the nuclide should not emit high-energy α or β particles, which have greater RBE.

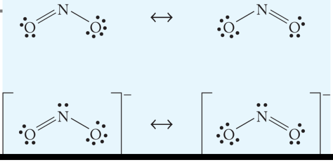
Practice Exercises

21.1. $E_K = -179$ mV; $\Delta G_{\text{transport}} = +17$ kJ/mol; because $\Delta G > 0$, the transport is nonspontaneous.

21.2. pH = 1.194; the volume of $Mg(OH)_2$ solution required to neutralize the acid solution is 0.584 mL.

21.3. $N_2(g) + 10\ H^+(aq) + 8\ e^- \rightarrow 2\ NH_4^+(aq) + H_2(g)$

21.4.



Both species have bent molecular geometry about the nitrogen atoms; the nitrogen atoms are sp^2 hybridized, and lone pairs are in sp^2 hybrid orbitals.

21.5 Bismuth-212: 2.0×10^{-6} mg; bismuth-213: 9.5×10^{-9} mg

Chapter 22

Particulate Review

The Lewis structures for ammonia (NH_3), borane (BH_3), and water (H_2O) are

Ammonia has one lone pair on its central atom, and water has two lone pairs on its central atom; therefore both can function as Lewis bases. Borane has no lone pairs on the central boron atom and an incomplete octet; it can function as a Lewis acid.

Concept Tests

p. 1086 Solutions of the orange compound will have greater electrical conductivity and a lower freezing point than solutions of the reddish purple compound because they form four and three ions, respectively, in aqueous solution.

p. 1087 CN^- ions occupy the inner coordination of Fe^{3+}; Na^+ is the counterion. $Na_3[Fe(CN)_6]$ would have the same conductivity as $[Co(NH_3)_6]Cl_3$.

p. 1092 Tetrachloroplatinate(II)

p. 1102 Green

p. 1104 (a) CN^- is a stronger field ligand than pyridine. (b) Ru^{2+} ions are larger than Fe^{2+} and have a larger Δ_o; their 4*d* electrons interact more with ligand lone pairs than do the 3*d* electrons of Fe^{2+}.

p. 1106 No for square planar; yes for tetrahedral

p. 1109 Yes. Manganese(IV) has three unpaired *d* electrons with only one possible distribution; there is no other option. Manganese(III) has four *d* electrons; depending on the strength of the ligands, it can be either high spin (4 unpaired electrons) or low spin (2 unpaired electrons).

p. 1111 H_2

p. 1116 A longer half-life means slower decay; collecting a sufficient signal to get an image will take longer.

Practice Exercises

22.1. $[Ru(NH_3)_4Cl_2]^+$ is the complex ion; Ru is present as Ru^{3+}; chloride is the counterion.

22.2.

LIGAND

[illegible]

[illegible] $[Zn(NH_3)_4]Cl_2$

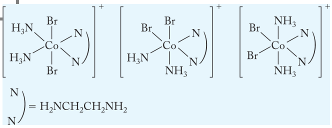
[illegible] $[Co(NH_3)_4(H_2O)_2](NO_2)_2$

1. $[Zn(NH_3)_4]Cl_2$ = tetraamminezinc(II) chloride
2. $[Co(NH_3)_4(H_2O)_2](NO_2)_2$ = tetraamminediaquacobalt(II) nitrite

22.3. Six, if we count the six oxygens in the $–CO_2^-$ groups or three if we consider each $–CO_2^-$ as one group.

22.4. Ni^{3+} can have either a high-spin or a low-spin configuration; none of the ions is diamagnetic.

22.5.



---

cis-Diammine-*trans*-dibromo(ethylenediamine)cobalt(III)
cis-Diammine-*cis*-dibromo(ethylenediamine)cobalt(III)
trans-Diammine-*cis*-dibromo(ethylenediamine)cobalt(III)

22.6. 2.5×10^6

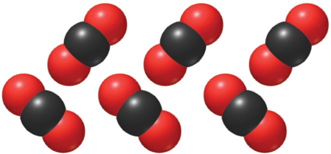
Answers to Selected End-of-Chapter Questions and Problems

Chapter 1

1.1. (a) A pure compound in the gas phase; (b) a heterogeneous mixture of blue-element atoms and red-element atoms: blue atoms are in the gas phase and red atoms are in the liquid phase.

1.3. (b)

1.5. CO_2 would be a solid at 180 K, and a solid is characterized by having a rigid three-dimensional array in which the molecules are in close proximity to one another.



1.7. (a) $C_4H_{10}O$; (b) $C_2H_6O_2$; (c) CCl_4

1.9. Sample A is both accurate and precise. Sample B is precise but not accurate.

1.11. (a); (b); (e)

1.13. (a)

1.15. (a)

1.17. Nitrogen is N_2 and oxygen is O_2.

1.19. (a) N_2O; (b) NO_2; (c) NO

1.21. $H_2O(g) + SO_3(g) \rightarrow H_2SO_4(\ell)$

1.23. Density, melting point, thermal and electrical conductivity, and softness (a–d) are all physical properties, whereas both tarnishing and reaction with water (e and f) are chemical properties.

1.25. Parts (a), (b), (c), (e), and (f) are physical properties; part (d) is a chemical property.

1.27. (c) and (f)

1.29. (b)

1.31. Particles are most free to move about in the gas phase and least free in the solid phase.

1.33. The snow sublimed to form water vapor.

1.35. Extensive properties will change with the size of the sample and therefore cannot be used to identify a substance.

1.37. To form a hypothesis we need at least one observation, experiment, or idea (from examining nature).

1.39. yes

1.41. *Theory* in normal conversation refers to someone's idea or opinion or speculation that can be changed. Scientifically, *theory* refers to an idea that has been validated by experimentation.

1.43. SI units can be easily converted into a larger or smaller unit by multiplying or dividing by multiples of 10. USC units are based on other number multiples and thus are more cumbersome to manipulate.

1.45. 23 g

1.47. (a) $\frac{1\ \text{ps}}{1 \times 10^{3}\ \text{fs}}$; (b) $\frac{1\ \text{kg}}{1 \times 10^{6}\ \text{mg}}$; (c) $\frac{1\ \text{kg Ti}}{2.20 \times 10^{-4}\ \text{m}^{3}}$ or $\frac{4540\ \text{kg Ti}}{1\ \text{m}^{3}}$

1.49. 1.99 m

1.51. 3.27 m/s

1.53. 9.1 Calories

1.55. 58.0 cm^3

1.57. 73.8 mL

1.59. (a) 5.8×10^3 g; (b) 2.1×10^2 oz.

1.61. Only one data point may be eliminated.

1.63. The standard deviation (*s*) is larger than the range described by the 95% confidence interval. The formula for calculating confidence interval in part relies on the standard deviation multiplied by the ratio of the *t* value divided by the square root of *n* (the number of data points). In this case the *t* value is less than the square root of the number of data points so the 95% confidence interval will be less than the standard deviation.

1.65. (b) and (c), depending on the significance of the zero in (c).

1.67. (b) and (c), depending on the significance of the zero in (c).

1.69. (b), (c), and (d), depending on the significance of the zero in (d).

1.71. (a) 17.4; (b) 7×10^{-14}; (c) 5.70×10^{-23}; (d) 3.58×10^{-3}

1.73. (a) 7.0×10^5 g/mL; (b) 7.88 g; (c) 4.29×10^{-21} J; (d) 461 m/s

1.75. (a) Manufacturer 1 has $\bar{x} = 0.511$ and $s = 0.005$; manufacturer 2 has $\bar{x} = 0.513$ and $s = 0.001$; manufacturer 3 has $\bar{x} = 0.501$ and $s = 0.001$; (b) manufacturer 3; (c) manufacturer 3 is precise and accurate; manufacturer 2 is precise but not accurate.

1.77. Yes, it is an outlier.

1.79. A scale where all possible values of temperature are above zero. The coldest possible temperature would correspond to a value of 0.

1.81. 12.5 K and 1337 K

1.83. Converting all temperatures to Kelvin for comparison: The first is already in Kelvin, 93.0 K; 250.0°C converts to 23.2 K; and − 231.1°F converts to 127.0 K. The highest critical temperature is 127.0 K for the sample originally measured in °F.

1.85. −269.0°C

1.87. 39.2°C

1.89. −89.2°C; 183.9 K

1.91. Both mixtures (a) and (b) react so that there is neither sodium nor chlorine left over.

1. Peanuts $\bar{x} = 63\%, s = 3.9$; raisins $\bar{x} = 37\%, s = 3.9$.
2. Yes, peanuts $\mu = 63 \pm 4.6\%$; raisins $\mu = 37 \pm 4.6\%$.

1.93.

1.95. The procedure that scientists use to measure values such as the age of a dinosaur bone doesn't provide a precision that allows the measurement to be reliable to within a single year. A range of values that includes the uncertainty of the measurement in question (this bone is between 67 million and 69 million years old) might be more relatable.

1.97. 5.2×10^2 mg of NaF

1.99. 10 tablets

Chapter 2

2.1. The positively charged alpha particle will be attracted to the negative (left) plate, whereas the negatively charged beta particle will be attracted to the positive (right) plate.

2.3. (a) $^{11}_{5}B$; (b) $^{11}_{6}C$; (c) $^{13}_{6}C$

2.5. (c)

2.7. (a) chlorine (Cl_2) (yellow); (b) neon (Ne) (red); (c) sodium (Na) (dark blue)

2.9. (a) Mg (green) will form MgO; (b) K (red) will form K_2O; (c) Ti (yellow) will form TiO_2; (d) Al (dark blue) will form Al_2O_3.

2.11. The element shaded in red (Zn) is too heavy to have been produced by stellar fusion.

2.13. Because some of the alpha particles were bounced back toward their source and some were scattered at large angles of deflection, Rutherford concluded that the positive charge in the atom could not be spread out (as described in the plum-pudding model) in the atom, but must be concentrated in the center of the atom (the nucleus). Because most of the particles passed directly through the gold foil, he reasoned that the nucleus must be small compared to the entire atom. The negatively charged electrons do not deflect the particles, and Rutherford reasoned that the electrons took up the remainder of the space of the atom outside of the nucleus.

2.15. The fact that cathode rays were deflected by a magnetic field indicated that the rays were streams of charged particles.

2.17. A *weighted average* takes into account the proportion of each value in the group of values to be averaged.

2.19. The element symbol (X) and the atomic number (*Z*) provide the same information. Any change to the number of protons would change the identity of the element.

2.21. (a) ^{11}B; (b) ^{7}Li; (c) ^{14}N; (d) ^{20}Ne

2.23.

[illegible]	Atomic Number
(a) ^{14}C [illegible]	
(b) ^{56}Fe [illegible]	
(c) ^{90}Sr [illegible]	
(d) ^{210}Pb [illegible]	

2.25.

Symbol	[illegible]
Number of Protons	[illegible]
Number of Neutrons	[illegible]
Number of Electrons	[illegible]
Mass Number	[illegible]

2.27. Average atomic mass for the Australian volcanic crater lake sample is 10.82 u. This is slightly higher than the textbook value of 10.811 u.

2.29. The average atomic mass of magnesium is slightly higher on Mars, 24.32 u.

2.31. 47.95 u

2.33. Mendeleev knew only the masses of the elements at the time he arranged the elements in his periodic table.

2.35. group 2, RO; group 3, R_2O_3; group 4, RO_2

2.37. (d)

2.39. (a), (b), (d)

2.41. (a) metal; (b) metal; (c) metal; (d) metalloid; (e) nonmetal

2.43. (a) Bromine is a halogen; (b) calcium is an alkaline earth metal; (c) potassium is an alkali metal; (d) krypton is a noble gas; (e) vanadium is a transition metal.

2.45. carbon (C), nitrogen (N), and oxygen (O), respectively

2.47. (a) palladium (Pd); (b) rhodium (Rh); (c) gold (Au)

2.49. Dalton's atomic theory states that because atoms are indivisible, the ratio of the atoms in a compound must be a ratio of whole numbers. When water decomposes the ratio of the volume of hydrogen to oxygen is 2:1, a whole-number ratio, because the atoms in water are present in that same 2:1 ratio.

2.51. Molecular compounds are composed of nonmetals; ionic compounds are formed between a metal (or metals) and a nonmetal (or nonmetals).

2.53. 1:1.5 (or 2:3) for CoS:Co_2S_3

2.55. 7.5 g O

2.57.

Symbol	[illegible]
Number of Protons	[illegible]
Number of Neutrons	[illegible]
Number of Electrons	[illegible]
Mass Number	[illegible]

2.59. Compounds (a) and (d) consist of molecules; compounds (b) and (c) consist of ions.

2.61. (a) ionic bonds; (b) covalent bonds; (c) covalent bonds; (d) ionic bonds

2.63. (a) 9 atoms; (b) 5 atoms; (c) 14 atoms; (d) 13 atoms

2.65. XO_2^{2-}

2.67. Roman numerals indicate the charge on the transition metal cation in the compound.

2.69. (a) phosphorus monoxide; (b) diphosphorus trioxide; (c) diphosphorus tetroxide; (d) diphosphorus pentoxide

2.71. (a) Na_2S, sodium sulfide; (b) $SrCl_2$, strontium chloride; (c) Al_2O_3, aluminum oxide; (d) LiH, lithium hydride

2.73. magnesium hydroxide

2.75. (a) sodium oxide; (b) sodium sulfide; (c) sodium sulfate; (d) sodium nitrate; (e) sodium nitrite

2.77. (a) K_2S; (b) K_2Se; (c) Rb_2SO_4; (d) $RbNO_2$; (e) $MgSO_4$

(a) NaBrO; (b) K_2SO_4; (c) $LiIO_3$; (d) $Mg(NO_2)_2$

2.79.

2.81. (b)

2.83. (b), lithium sulfate should be Li_2SO_4

2.85.

[illegible]				
[illegible]				
[illegible]				

2.87. (a) chromium(III) telluride; (b) vanadium(III) sulfate; (c) iron(I) chromate; (d) manganese(II) oxide

2.89. (a) $ZnCr_2O_7$; (b) $Fe(CH_3CO_2)_3$; (c) Hg_2O_2; (d) $Sc(SCN)_3$

2.91. (a) HI; (b) HBrO; (c) HIO_3; (d) HBr

2.93. (a) hydrofluoric acid; (b) bromic acid; (c) hydrobromic acid; (d) periodic acid

2.95. alkanes, alkenes, and alkynes

2.97. Amines and amides contain nitrogen atoms. Amides contain both nitrogen and oxygen atoms.

2.99. (a) alkanes; (b) alkynes

2.101. RCO_2R9, the ester functional group

2.103. Electrons (d) formed first; deuterons (a) formed last.

2.105. The density of the universe is decreasing with time.

2.107. $HClO_3$, chloric acid

2.109.

$$^{21}_{10}Ne + ^{4}_{2}\alpha \rightarrow ^{1}_{0}n + ^{24}_{12}Mg$$

2.111\.

1. two
2. The beta particle would be deflected toward the top—away from the negative plate (toward the positive plate). The alpha particle would be deflected down—away from the positive plate (toward the negative plate).

2.113\. (a) 12 H atoms for every 1 He atom; (b) the ratio is smaller so there is more helium present now; (c) stars consume hydrogen and produce helium; (d) evaluate the elemental composition of older galaxies and compare to our galaxy.

2.115\. 14 Cu:1 Sn

2.117\. (a) Scandium (Sc) with an average mass of 44.956 u, gallium (Ga) with an average mass of 69.723 u, and germanium (Ge) with an average mass of 72.61 u; (b) ekaaluminum is gallium, ekaboron is scandium, and ekasilicon is germanium; (c) scandium was discovered in 1879 by Lars Fredrik Nilson in Sweden, gallium was discovered in 1875 by Paul-Émile Lecoq de Boisbaudran in France, and germanium was discovered in 1886 by Clemens Winkler in Germany.

2.119\. 60.11%

2.121\. (a) $^{79}Br–^{79}Br$ = 157.8366 u, $^{79}Br–^{81}Br$ = 159.8346 u, $^{81}Br–^{81}Br$ = 161.8326 u; (b) $^{79}Br–^{79}Br$, 25.41% abundant, $^{79}Br–^{81}Br$, 50.00% abundant, $^{81}Br–^{81}Br$, 24.59% abundant

2.123\. (a) CO_2, carbon dioxide; (b) Li_3N, lithium nitride

2.125\. Radium will adopt a 2+ charge to form Ra^{2+} ions. It will likely be malleable, be relatively dense, conduct heat and electric current, and melt at a fairly high temperature in its metallic state.

	Melting Point (ºC)	
$CaCl_2$	772	[illegible]
$SrCl_2$	874	[illegible]
$BaCl_2$	962	[illegible]
$RaCl_2$	(900 to 1000)	(1500 to 2000)

2.127\. Despite being heavier (on average), argon contains 18 protons, whereas potassium contains 19 protons. Because the modern periodic table is organized by increasing atomic number, argon is placed before potassium.

Chapter 3

3.1. (a) X(g) + Y(g) → XY(g); (b) X(g) + Y(g) → XY(s); (c) 2 X(g) + 2 Y(g) → XY_2(g); (d) X_2(g) + Y_2(g) → 2 XY(g)

3.3. (b)

3.5. (a) and (c) have the same empirical formula (NO_2), and (b) and (d) have the same empirical formula (N_2O).

3.7. (a) water; (b) carbon dioxide

3.9. 75%

3.11. All would be combination reactions (any two or more substances combine to form one product).

3.13. (c) Fe(ℓ)

3.15. Dozen is too small of a unit to conveniently express the very large number of atoms, ions, or molecules present in laboratory quantities.

3.17. No, the molar mass of a substance does not directly correlate to the number of atoms in a molecular compound. The statement would be true only if the two compounds were composed of the same element.

3.19. (a) 7.3×10^{-10} mol Ne; (b) 7.0×10^{-11} mol CH_4; (c) 4.2×10^{-12} mol O_3; (d) 8.1×10^{-15} mol NO_2

3.21. (a) 7.53×10^{22} Ti atoms; (b) 7.53×10^{22} Ti atoms; (c) 1.51×10^{23} Ti atoms; (d) 2.26×10^{23} Ti atoms

3.23. (a) 4 moles of Fe_2S_3; (b) 4 moles of CaS; (c) each quantity contains the same number of moles of S

3.25. (a) 3.00 mol; (b) 3.00 mol; (c) 4.50 mol

3.27. 41.63 mol

3.39. H_2O

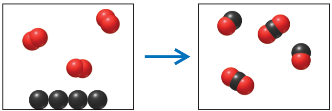
3.41. 10.3 g

3.43. diamond

3.45. no

3.47. no

3.49.



3.51. 2

3.53.
1. 3 a. $FeSiO_3(s) + 4\ H_2O(\ell) \rightarrow Fe_3Si_2O_5(OH)_4(s) + H_4SiO_4(aq)$
2. $Fe_2SiO_4(s) + 2\ CO_2(g) + 2\ H_2O(\ell) \rightarrow 2\ FeCO_3(s) + H_4SiO_4(aq)$
3. $Fe_3Si_2O_5(OH)_4(s) + 3\ CO_2(g) + 2\ H_2O(\ell) \rightarrow 3\ FeCO_3(s) + 2\ H_4SiO_4(aq)$

3.55.
1. $N_2(g) + O_2(g) \rightarrow 2\ NO(g)$
2. $2\ NO(g) + O_2(g) \rightarrow 2\ NO_2(g)$
3. $NO(g) + NO_3(g) \rightarrow 2\ NO_2(g)$
4. $2\ N_2(g) + O_2(g) \rightarrow 2\ N_2O(g)$

3.57.
1. $N_2O_5(g) + Na(s) \rightarrow NaNO_3(s) + NO_2(g)$
2. $H_2O(\ell) + N_2O_4(g) \rightarrow HNO_3(aq) + HNO_2(aq)$
3. $3\ NO(g) \rightarrow N_2O(g) + NO_2(g)$
4. $2\ C_2H_2(g) + 5\ O_2(g) \rightarrow 4\ CO_2(g) + 2\ H_2O(g)$

3.59. Yes; if the masses were unequal, then the equation would be missing either some reactants or products.

3.61. 1.17 kg

3.63. 31.5 g

3.65. 60. g of SO_2

3.67. $2\ C_8H_{18} + 25\ O_2 \rightarrow 16\ CO_2 + 18\ H_2O$; $C_2H_6O + 3\ O_2 \rightarrow 2\ CO_2 + 3\ H_2O$; octane produces more CO_2 per gram

3.69. 3.6 g

3.71. (c) less than the sum of the masses of Fe and S at the start

3.73. Reactions do not always go to completion because the reaction may be slow or may have, for a portion of the reaction, yielded different products than expected.

3.75. The lowered mass of reactant will lead to a lowered mass of decomposition products and therefore a lower actual yield. Because percent yield compares actual yield to theoretical yield (which would be based on the mass of $NaHCO_3$ before the spill) it will also be lower.

3.77. 3 cups

3.79. (a) 5.0 g Li_3N; (b) 34.5 g H_3PO_4; (c) 8.0 g SO_3

3.81. $NH_3(g) + HCl(g) \rightarrow NH_4Cl(aq)$; 0.7 g NH_3

3.83. (a) $2\ PbO(s) + 2\ NaCl(aq) + H_2O(\ell) + CO_2(g) \rightarrow$

$Pb_2Cl_2CO_3(s) + 2\ NaOH(aq)$; (b) 12.2 g; (c) 22.3%

3.85. 56%

3.87. (a) $C_6H_{12}O_6(aq) \rightarrow 2\ C_2H_5OH(l) + 2\ CO_2(g)$; (b) 77.1%

3.89. An empirical formula shows the lowest whole-number ratio of atoms in a substance. A molecular formula shows the actual numbers of each kind of atom that compose one molecule of the substance.

3.91. Yes, an empirical formula gives the simplest whole-number ratio of the elements. The molecular formula has the same ratio of elements but may be a whole-number multiple of the empirical formula.

3.93. Yes. All of these have the same empirical and molecular formulas. These three molecules are isomers (molecules with the same molecular formula but different connections between atoms).

3.95.

Molecular Formula	[illegible]
Empirical Formula	[illegible]

3.97. (a) 74.19% Na, 25.81% O; (b) 57.48% Na, 40.00% O, 2.52% H; (c) 27.37% Na, 1.20% H, 14.30% C, 57.14% O; (d) 43.38% Na, 11.33% C, 45.28% O

3.99. Pyrene, $C_{16}H_{10}$, has the greatest percent carbon by mass. All four compounds have different empirical formulas.

3.101. CH_4

3.103. Ti_6Al_4V

3.105. citric acid

3.107. $Mg_3Si_2H_4O_9$

3.109. The empirical formula is CHN; the molecular formula is $C_5H_5N_5$.

3.111. The excess of oxygen is required in combustion analysis to ensure the complete reaction of the hydrogen and carbon to form water and carbon dioxide.

3.113. the molar mass of the compound

3.115. NO_2

3.117. The empirical formula is C_2H_3; the molecular formula is $C_{20}H_{30}$.

3.119. $C_{10}H_{18}O$ (empirical and molecular)

3.121. $C_9H_8O_4$ (empirical and molecular)

4.1. yellow

4.3. (a) Cl (purple); (b) S (orange); (c) N (green); (d) P (blue)

4.5. strong electrolyte: (a) and (c); weak electrolyte: (b); strong acid: (c); weak acid: (b); nonelectrolyte: (d)

4.7. Hydronium and nitrate ions will remain in solution.

4.9. The solvent is usually the liquid component of the solution. If both the solvent and solute are liquids or solids, the solvent is the component present in the greatest amount.

4.11. 1.00 *M*

4.13. (a) 5.6 *M* $BaCl_2$; (b) 1.00 *M* Na_2CO_3; (c) 1.30 *M* $C_6H_{12}O_6$; (d) 5.92 *M* KNO_3

4.15. (a) 0.14 *M* Na^+; (b) 0.11 *M* Cl^-; (c) 0.096 *M* SO_4^{2-}; (d) 0.20 *M* Ca^{2+}

4.17. (a) 11.7 g NaCl; (b) 4.99 g $CuSO_4$; (c) 6.41 g CH_3OH

4.19. 0.590 g of dissolved ions in 2.75 L

4.21. (a) 0.0096 mol; (b) 7.80×10^{-4} mol; (c) 8.8×10^{-2} mol; (d) 4.22 mol

4.23. orchard sample: 3.4×10^{-4} mmol/L, 0.12 ppm; residential area sample: 5.6×10^{-6} mmol/L, 0.020 ppm; after storm sample: 0.032 mmol/L, 11 ppm

4.25. 4.54×10^{-7} mg NF_3/kg air

4.27. $4 \times 10^{-5} M$

4.29. (a) 0.0210 M K^+; (b) 1.06 mM LiCl; (c) 0.0434 mM Zn^{2+}

4.31. 58.6 mL

4.33. 0.40 M

4.35. 12.3 mL

4.37. $A = 0.75$

4.39. Table salt produces Na^+ and Cl^- ions in solution when it dissolves. Sugar does not dissociate into ions because it is a molecular compound with only covalent bonds. Ions are required to conduct electricity.

4.41. The lack of ions in methanol means that the liquid is nonconductive. Molten NaOH, however, has freely moving Na^+ and OH^- ions, which can conduct electricity.

The conductivity of the more concentrated solution will be higher than that of the dilute solution.

4.43.

4.45. In order of decreasing conductivity: 1.0 M $Na_2SO_4 >$ 1.2 M KCl $>$ 1.0 M NaCl $>$ 0.75 M LiCl

4.47. (a) 0.025 M; (b) 0.050 M; (c) 0.075 M

4.49. (b)

4.51. (a) < (c) < (b)

4.53. acid

4.55. (a) strong acid; (b) weak acid; (c) weak acid; (d) strong acid

4.57. base

4.59. (a) strong base; (b) weak base; (c) weak base; (d) strong base

4.61. (a) Ionic and net ionic equations are the same: $H^+(aq) + SO_4{}^-(aq) + Ca^{2+}(aq) + OH^-(aq) \rightarrow CaSO_4(s) + H_2O(\ell)$, the acid is H_2SO_4 and the base is $Ca(OH)_2$; (b) ionic and net ionic equations are the same: $PbCO_3(s) + H^+(aq) + HSO_4{}^-(aq) \rightarrow PbSO_4(s) + CO_2(g) + H_2O(\ell)$, the acid is H_2SO_4 and the base is $PbCO_3$; (c) ionic equation: $Ca^{2+}(aq) + 2\ OH^-(aq) + 2\ CH_3COOH(aq) \rightarrow Ca^{2+}(aq) + 2\ CH_3COO^-(aq) + 2\ H_2O(\ell)$, net ionic equation ($Ca^{2+}$ is a spectator ion): $OH^-(aq) + CH_3COOH(aq) \rightarrow CH_3COO^-(aq) + H_2O(\ell)$, CH_3COOH is the acid and $Ca(OH)_2$ is the base

4.63. (a) molecular equation: $Mg(OH)_2(s) + H_2SO_4(aq) \rightarrow$

$MgSO_4(aq) + 2\ H_2O(\ell)$, net ionic equation: $Mg(OH)_2(s) + HSO_4^-(aq) + H^+(aq) \rightarrow Mg^{2+}(aq) + SO_4^{2-}(aq) + 2\ H_2O(\ell)$; (b) molecular equation: $MgCO_3(s) + 2\ HCl(aq) \rightarrow MgCl_2(aq) + H_2O(\ell) + CO_2(g)$, net ionic equation: $MgCO_3(s) + 2\ H^+(aq) \rightarrow Mg^{2+}(aq) + H_2O(\ell) + CO_2(g)$; (c) molecular equation and net ionic equation are the same: $NH_3(g) + HCl(g) \rightarrow NH_4Cl(s)$; (d) molecular equation: $SO_3(g) + 2\ NaOH(aq) \rightarrow Na_2SO_4(aq) + H_2O(\ell)$, net ionic equation: $SO_3(g) + 2\ OH^-(aq) \rightarrow SO_4^{2-}(aq) + H_2O(\ell)$

4.65. $PbCO_3(s) + 2\ H^+(aq) \rightarrow Pb^{2+}(s) + CO_2(g) + H_2O(\ell)$; $Pb(OH)_2(s) + 2\ H^+(aq) \rightarrow Pb^{2+}(s) + 2\ H_2O(\ell)$

4.67. (a) 18.0 mL, (b) 31.6 mL, (c) 114 mL

4.69. 0.72 g HI

4.71. 0.499 L

4.73. 2.0 mL

4.75. A saturated solution contains the maximum concentration of a solute. A supersaturated solution *temporarily* contains *more* than the maximum concentration of a solute at a given temperature.

4.77. $CaCO_3$

4.79. A saturated solution may not be a concentrated solution if the solute is only sparingly or slightly soluble in the solvent. In that case, the solution is saturated but dilute.

4.81. (a) Barium sulfate is insoluble, (e) lead(II) hydroxide is insoluble, and (f) calcium phosphate is insoluble

4.83. (a) Balanced equation: $Pb(NO_3)_2(aq) + Na_2SO_4(aq) \rightarrow PbSO_4(s) + 2\ NaNO_3(aq)$, overall ionic equation: $Pb^{2+}(aq) + 2\ NO_3^-(aq) + 2\ Na^+(aq) + SO_4^{2-}(aq) \rightarrow PbSO_4(s) + 2\ Na^+(aq) + 2\ NO_3^-(aq)$, net ionic equation: $Pb^{2+}(aq) + SO_4^{2-}(aq) \rightarrow PbSO_4(s)$; (b) no precipitation reaction occurs; (c) balanced equation: $FeCl_2(aq) + Na_2S(aq) \rightarrow FeS(s) + 2\ NaCl(aq)$, overall ionic equation: $Fe^{2+}(aq) + 2\ Cl^-(aq) + 2\ Na^+(aq) + S^{2-}(aq) \rightarrow FeS(s) + 2\ Na^+(aq) + 2\ Cl^-(aq)$, net ionic equation: $Fe^{2+}(aq) + S^{2-}(aq) \rightarrow FeS(s)$; (d) balanced equation: $MgSO_4(aq) + BaCl_2(aq) \rightarrow MgCl_2(aq) + BaSO_4(s)$, overall ionic equation: $Mg^{2+}(aq) + SO_4^{2-}(aq) + Ba^{2+}(aq) + 2\ Cl^-(aq) \rightarrow Mg^{2+}(aq) + 2\ Cl^-(aq) + BaSO_4(s)$, net ionic equation: $SO_4^{2-}(aq) + Ba^{2+}(aq) \rightarrow BaSO_4(s)$

4.85. 0.0211 g

4.87. 0.054 g

4.89. 1.8×10^5 g

4.91. (a) $[Na^+]$ and $[NO_3{}^-]$ remain the same, and $[Ag^+]$ and $[Cl^-]$ decrease; (b) $[Na^+]$ and $[Cl^-]$ remain the same, and $[H^+]$ and $[OH^-]$ decrease; (c) all ionic concentrations remain the same.

4.93. The number of electrons gained or lost is directly related to the change in oxidation number of a species.

4.95. (a) − 1, (b) + 1, (c) − 2, (d) − 3

4.97. Silver

4.99. $Na^+(l) + e^- \rightarrow Na(s)$, $2\ Cl^-(l) \rightarrow Cl_2(g) + 2\ e^-$

4.101. (a) +3, (b) +3, (c) +3

4.103. (a) $2\ e^- + Br_2(l) \rightarrow 2\ Br^-(aq)$, reduction; (b) $Pb(s) + 2\ Cl^-(aq) \rightarrow PbCl_2(s) + 2\ e^-$, oxidation; (c) $2\ e^- + O_3(g) + 2\ H^+(aq) \rightarrow O_2(g) + H_2O(l)$, reduction; (d) $2\ H_2SO_3(aq) + H^+(aq) + 2\ e^- \rightarrow HS_2O_4{}^-(aq) + 2\ H_2O\ (l)$, reduction

4.105. (a) $2\ H^+(aq) + MnO_2(s) + 2\ HCl(aq) \rightarrow Mn^{2+}(aq) + Cl_2(g) + 2\ H_2O(l)$, HCl is the reducing agent and MnO_2 is the oxidizing agent, manganese is reduced and chlorine is oxidized. (b) $I_2(s) + 2\ S_2O_3{}^{2-}(aq) \rightarrow S_4O_6{}^{2-}(aq) + 2\ I^-(aq)$, $S_2O_3{}^{2-}$ is the reducing agent and I_2 is the oxidizing agent, sulfur is oxidized and iodine is reduced; (c) $8\ H^+(aq) + MnO_4{}^-(aq) + Fe^{2+}(aq) \rightarrow Mn^{2+}(aq) + Fe^{3+}(aq) + 4\ H_2O(l)$, Fe^{2+} is the reducing agent and $MnO_4{}^-$ is the oxidizing agent, iron is oxidized and manganese is reduced

4.107.

4.149. 87.3 g CaF_2

Chapter 5

5.1. The height of mercury in a barometer depends on the atmospheric pressure: the higher the pressure the higher the column of mercury. Because Denver, CO, has lower atmospheric pressure (as a result of being at a higher elevation), the barometer labeled (a) represents the pressure in Denver, CO.

5.3. Situation 1 (atmospheric pressure is increased at constant temperature) could be represented by either (a) or (c). Situation 2 (temperature is increased at constant pressure) would be represented by (b).

5.5. (c)

5.7. line 1; no

5.9. line 2

5.11. The right-hand tube contains N_2.

5.13. (b)

5.15. Curve 1 represents SO_2. Curve 2 could represent CO_2, or C_3H_8.

5.17. Br_2 (orange)

5.19. (c)

5.21. (a)

5.23. Force is the product of the mass of an object and the acceleration due to gravity. Pressure uses force in its definition: it is the force exerted over a given area.

5.25. The weight of the column of mercury lowers the overall height of the mercury in the column, creating a space at the closed end of the column that is under vacuum (no gas molecules). As the pressure of the atmosphere increases over the open pool of mercury, the column of mercury rises in the tube to indicate rising pressure.

5.27. 10 atm

5.29. 1 millibar = 100 pascals

5.31. A sharpened skate blade has a smaller area over which the force is distributed than that of a dull skate blade.

5.33. As we go up in altitude, the overlying mass of the atmosphere above us decreases, which causes the pressure to decrease.

5.35. The column of air exerts a pressure of 3780 Pa or 0.0385 kg/cm^2, which is far less than the pressure exerted by the tower itself.

5.37. (a) 0.020 atm; (b) 0.739 atm

5.39. (a) 814.6 mmHg; (b) 1.072 atm; (c) 1086 mbar

5.41. (a) 91 atm; (b) CO_2 is a heavier molecule than N_2 so the atmosphere of Venus has a greater mass than the atmosphere of Earth.

5.43. The volume increases by a factor of 5.

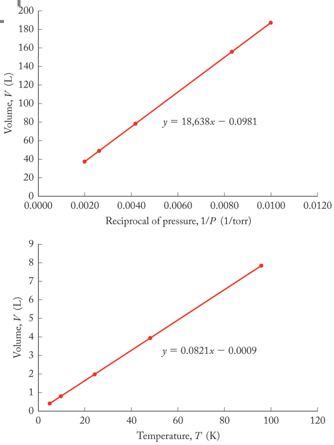
5.45. decrease

5.47. increase

5.49. (a) 2.00 atm; (b) 0.664 atm; (c) 1.67 atm

5.51. 2.30 atm; 13.0 m

5.53.



---

1. There would be no difference in the graphs if 1 mole of argon gas was used.
2. The general relationship remains the same (volume is inversely related to pressure) but the slope of the line would be smaller (slope would equal *nRT*).

3. The general relationship remains the same (volume is directly proportional to temperature) but the slope of the line will decrease (slope would equal nR/P).

5.55. 5.6 K, or 323°C

5.57. (a) 4.27 L; (b) 2.02 L; (c) 2.41 L

5.59. (b)

5.61. (a) no change; (b) decrease to 1/4 the original volume; (c) increase of 17%

5.63. 1.39×10^5 L

5.65. 6.6 atm

5.67. Standard temperature and pressure (STP) is defined as 1 atm and 0°C (273 K); $V = 22.4$ L

5.69. the product of the number of moles of gas in the sample, the temperature, and the gas constant

5.71. 0.67 mol

5.73. 1.50 atm

5.75. (a) 1.8×10^3 L; (b) 800% change; (c) 1.8×10^5 L; (d) the balloon will break under both sets of conditions

5.77. (a) 0.0419 mol/h; (b) 10.7 g

5.79. 1.5×10^3 g $(NH_4)_2Cr_2O_7$ and 1.2×10^2 g $KClO_3$

5.81. 7.5 g

5.83. The densities of different gases are not necessarily the same for a particular temperature and pressure. Gases with different molar masses will exhibit different densities.

5.85. Density (a) increases with increasing pressure and (b) increases with decreasing temperature.

5.87. (a) 9.08 g/L; (b) in the basement

5.89. SO_2

5.91. 78.1 g/mol

5.93. the pressure that a particular gas individually contributes to the total pressure of a mixture

5.95. (c)

5.97. oxygen

5.99. $P_{total} = 5.56$ atm and $P_{N2} = 1.12$ atm

5.101. (a) $4\,NH_3(g) + 7\,O_2(g) \rightarrow 4\,NO_2(g) + 6\,H_2O(g)$; (b) Partial pressures are directly proportional to the number of moles of gas present so the ratio of partial pressures needed would match the stoichiometry of the reaction: $4\,NH_3{:}7\,O_2$.

5.103. (a) 0.0190 mol; (b) no, there will be fewer moles of O_2 if collected over ethanol

5.105. (a) greater than; (b) less than; (c) greater than; (d) greater than

5.107. 1.7 times more

5.109. 6.0 torr

5.111. 25%

5.113. The speed of a molecule in a gas that has the average kinetic energy of all the molecules in the sample.

5.115. (a) As the molar mass increases the u_{rms} decreases; (b) as temperature increases the u_{rms} increases.

5.117. To determine the molar mass of an unknown gas, measure the rate of its effusion (r_x) relative to the rate of effusion of a known gas (r_y). Because we know the molar mass of the known gas, $\mathcal{M}_y$, we can use the equation for Graham's law to solve for the unknown $\mathcal{M}_x$.

5.119. Group 18 elements are all gases, but this is not true for the elements of group 15—only nitrogen, N_2, is a gas in its elemental form.

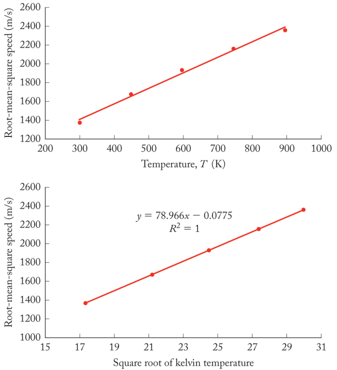
5.121. The rank order in terms of increasing root-mean-square speed is $SO_2 < NO_2 < CO_2$.

5.123. (a) Gas C is O_2; (b) the other gases are heavier than O_2; (c) gas A matches the molar mass of F_2.

5.125. No, the graphed points curve away from the line (the points are below the line at low and high temperatures and above the line at intermediate temperatures) as would be expected due to the right side of the root-mean-square speed equation being proportional to the square root of

$$T\left(u_{rms} = \sqrt{3RT/\mathcal{M}}\right)$$

. A second plot below of u_{rms} versus $\sqrt{T}$ using the same data is shown to be a perfectly straight line.



5.127. 0.707

5.129. No, the molar masses are nearly identical.

5.131. 128.0 g/mol

5.133. (a) $r(^{12}CO_2)/r(^{13}CO_2) - 1.01$; (b) $^{12}CO_2$

5.135. the smaller balloon

5.137.

$$P = \frac{nRT}{(V - nb)} - \frac{n^2 a}{V^2}$$

Real gases exhibit lower pressures than we would expect for an ideal gas because of the slight attractive forces between particles. Other particles exert a force that cancels out a small amount of the force exerted by the gas particle on the container wall, resulting in a lower pressure.

5.139. krypton (Kr)

5.141. H_2

5.143. (a) $P = 910$ atm; (b) $P = 476$ atm; (c) at higher pressures the gas molecules are closer together and attractive forces (variable a in the van der Waals equation) can play a larger role.

5.145. 1.6 L

5.147. 28.5 psi

5.149. 3.31 L

5.151. 1.0 mmHg = (a) 120 torr = (b) 0.158 atm = (c) 0.160 bar = (d) 16.0 kPa; 80 mmHg = (a) 80 torr = (b) 0.11 atm = (c) 0.11 bar − (d) 11 kPa

5.153. 21 L

5.155. $V - 2.59$ L; $d - 7.33$ g/L

5.157. (a) CH_3CO_2H and $(CH_3)_3N$; (b) HCl and $(CH_3)_3N$; (c) no

5.159. 3.5 atm, or 4490 psi (well below the unsafe pressure range)

5.161. 79.3 g/mol

5.163. 1.7 g/mol

5.165.

$$u_{\text{rms}} = \sqrt{\frac{3P}{d}}$$

5.167. 2.7 atm

5.169. 38.4 L of N_2; 192 L of CO_2; 1.74 g/L

5.171. 3.2 L

5.173. 54.9 L

5.175. 0.00781 mol

Chapter 6

6.1. At 35 ft above street level, KE = 150 J; just before hitting the street, KE = 500 J.

6.3. (a) The piston is higher in the cylinder; (b) yes; (c) the system did work on the surroundings.

6.5. (a) No; (b) the internal energy of the system increases.

6.7. (a) $2\ SO_2(g) + O_2(g) \rightarrow 2\ SO_3(g)$; (b) positive; (c) − 98.9 kJ/mol

6.9. Energy makes work possible.

6.11. The value of a state function is independent of the path—only the initial and final values are important.

6.13. (a) The potential energy in a battery consists of the chemicals that can react via a redox reaction; (b) the potential energy in a gallon of gasoline consists of the chemical bonds in the fuel that release energy as the fuel is combusted; (c) the potential energy of the crest of a wave is due to its position above the ground.

6.15. The system is the part of the universe that is being examined. The surroundings are everything else, extending to the entire universe.

6.17. The sign of ΔE depends on the magnitude of q and w.

6.19. (a) exothermic; (b) endothermic; (c) exothermic

6.21. Energy is absorbed from the surroundings. Thus q increases and E increases.

6.23. (a) $-9.25 \times 10^5\ \mathrm{L \cdot atm}$; -9.37×10^7 J

6.25. (a) 80.0 J; (b) 9.2 kJ; (c) -9.40×10^2 J

6.27. (b)

6.29. (a) -127 J; (b) -2.47 kJ

6.31. A change in enthalpy is the sum of the change of internal energy and the product of the system's pressure and change in volume.

6.33. The symbol that refers to a physical change is ΔH_{fus}.

6.35. negative

6.37. (a) negative; (b) positive

6.39. positive

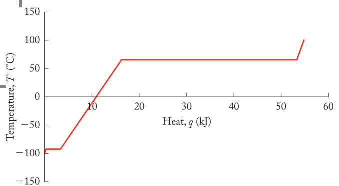
6.41. Specific heat is specified for 1 gram of the substance, while molar heat capacity is specified for 1 mole of the substance.

6.43. no

6.45. Water's high heat capacity compared to that of air means that water carries away more energy from the engine for every Celsius degree rise in temperature, so water is a good choice to cool automobile engines.

6.47. 29.3 kJ

6.49.



6.51. 886.2 g

6.53. gold

6.55. $\Delta T = -47.5$°C

6.57. It is necessary to know the heat capacity of a calorimeter to know how much energy (generated or absorbed by the system) is required to change the temperature of the surroundings (the calorimeter) in order to calculate the heat capacity or final temperature of the system in an experiment.

6.59. The heat capacity of the new liquid is different from that of water. The liquid is part of the calorimeter and therefore part of the surroundings. The calorimeter constant depends on the heat capacity of the surroundings, so the heat capacity must be determined.

6.61. NH_4NO_3 provides the greatest temperature drop.

6.63. 6.12 kJ/°C

6.65. −5127 kJ/mol

6.67. 23.29°C

6.69. (a) $Mg(s) + 2\ H^+(aq) \longrightarrow H_2(g) + Mg^{2+}(aq)$; (b) − 44 kJ

6.71. 0.145 g

6.73. When we apply Hess's law all the heat is accounted for in the reaction—energy is neither created nor destroyed.

6.75. Reverse the direction of the second reaction and then add it to the first reaction to obtain the third reaction (after canceling species common to both sides).

6.77. 54.08 kJ

6.79. If we write out the chemical equations for the ΔH°_f for the reactants and products, these formation reactions will add up to the overall reaction.

6.81. No, allotropes do not have the same standard enthalpy of formation. Because each allotrope has a different bonding arrangement, there will be different amounts of energy contained in the bonding of each allotrope. The most stable is defined as having a standard enthalpy of formation of 0 kJ/mol; any less stable allotrope will have a higher value for its standard enthalpy of formation.

6.83. (a) and (d)

6.85. 52 kJ

6.87. $CO_2(g) + 4\ H_2(g) \rightarrow CH_4(g) + 2\ H_2O(\ell)$; $\Delta H^\circ_{rxn} = -252.9$ kJ
−7198.5 kJ

6.89. −7198.5 kJ

6.91. Reverse the direction of the combustion reaction (change the sign of ΔH_{comb}) and add the reaction describing the formation of $CO(g)$: $\Delta H^\circ_{f,CO} = \Delta H^\circ_{f,CO_2} - \Delta H_{comb,CO}$

6.93. −18 kJ/mol

6.95. The energy per gram a fuel releases on burning

6.97. The fuel value (kJ/g) is obtained by dividing the molar enthalpy of combustion (kJ/mol) by the molar mass (g/mol).

6.99. (a) gasoline; (b) gasoline

6.101. (a) 36.10 kJ/g; (b) 36,100 kJ; (c) 6.95 g

6.103. Diethyl ether has a fuel value of 36.781 kJ/g and a fuel density of 2.624×10^4 kJ/L. Both of these values are lower than those of diesel oil.

6.105. 13 kJ

6.107. 3.54×10^4 mol

6.109. (a) −92.2 kJ; (b) 46.1 kJ

6.111. 58.1 g

6.113. 33.3°C

6.115. (a) $6\ FeO(s) + O_2(g) \rightarrow 2\ Fe_3O_4(s)$; (b) $\Delta H_{rxn} = -636$ kJ

6.117. (a) The reaction is exothermic; (b) bonds must be broken, which requires more energy than for breaking intermolecular forces; (c) 793 kJ

6.119. The balanced chemical equation for the reaction of iron(II) oxide with oxygen to form iron (III) oxide is $4\ FeO(s) + O_2(g) \rightarrow 2\ Fe_2O_3(s)$;

$$\Delta H_{rxn} = -636\ \text{kJ}$$

6.121. (a) −1167.1 kJ; (b) no, less energy would be released if hydrazine was in the liquid state.

6.123. (a) exothermic; (b) − 509.8 kJ; (c) − 955 kJ; (d) the reaction would be less exothermic

6.125. −74.9 kJ/mol

6.127. −1388 kJ

6.129. −1234.7 kJ/mol; ethanol has a greater fuel value

6.131. 39°C

6.133.

Element	[illegible]	[illegible]	[illegible]
Bismuth	[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]	[illegible]
Platinum	[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]	[illegible]
Copper	[illegible]	[illegible]	[illegible]
cobalt/nickel	[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]	[illegible]

Average value in column 4

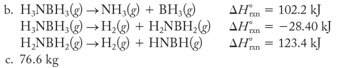
25.3

(a) The units are J/(mol · °C); (c) although silver is the likely element with a mass of 108.6 g/mol, there is more uncertainty about the element with a mass of 58.4 g/mol. This value lies between the accepted molar masses for cobalt and nickel.

6.135. exothermic, $\Delta H^\circ = -1.9$ kJ

6.137. The reaction is endothermic, $\Delta H_{\text{comb}} = 68$ kJ.

6.139. a. For $H_2(g)$ the fuel density is 10.78 kJ/L, and for $H_2(\ell)$ the fuel density is 8492 kJ/L.



b. $H_3NBH_3(g) \rightarrow NH_3(g) + BH_3(g)$ $\Delta H^\circ_{\text{rxn}} = 102.2$ kJ
$H_3NBH_3(g) \rightarrow H_2(g) + H_2NBH_2(g)$ $\Delta H^\circ_{\text{rxn}} = -28.40$ kJ
$H_2NBH_2(g) \rightarrow H_2(g) + HNBH(g)$ $\Delta H^\circ_{\text{rxn}} = 123.4$ kJ
c. 76.6 kg

6.141. yes

6.143. exothermic

Chapter 7

7.1. (a) purple (Na), red (Cr), and orange (Au); (b) blue (Ne); (c) orange (Au); (d) red (Cr); (e) blue (Ne) and green (Cl)

7.3. (a) One electron would be lost from the element shaded blue (Rb) to become the [Kr] core electron configuration; (b) two electrons would be lost from the element shaded green (Sr) to become the [Kr] core electron configuration; (c) three electrons would be lost from the element shaded orange (Y) to become the [Kr] core electron configuration; (d) the element shaded gray (I) would gain one electron to become the [Xe] core electron configuration; (e) the element shaded red (Te) would gain two electrons to become the [Xe] core electron configuration.

7.5. (a) gray (I) < red (Te) < orange (Y) < green (Sr) < blue (Rb); (b) orange (Y^{3+}) < green (Sr^{2+}) < blue (Rb^{+}) < gray (I^{-}) < red (Te^{2-})

7.7. (a) Na; (b) K; (c) Na^{+}

7.9. (a) wave (b); (b) wave (a); (c) wave (b)

7.11. The hydrogen absorption spectrum consists of dark lines at wavelengths specific to hydrogen. The emission spectrum has bright lines on a dark background with the lines appearing at the exact same wavelengths as the dark lines in the absorption spectrum.

7.13. Because each element shows distinctive and unique absorption and emission lines, the bright emission lines observed for the pure elements could be matched to the many dark absorption lines in the spectrum of sunlight. This approach can be used to deduce the Sun’s elemental composition.

7.15. All of these forms of light have perpendicular, oscillating electric and magnetic fields that travel together through space.

7.17. The lead shield protects the parts of the body that might be exposed to the highly energetic X-rays but are not being imaged.

7.19. X-rays and ultraviolet radiation

7.21. (a) Ultraviolet radiation; (b) gamma rays; (c) microwave radiation

7.23. The energy of the UV photon is twice that of the red light photon.

7.25. $6.06 \times 10^{14}\ s^{-1}$ (or Hz)

7.27. (a) 0.13 m; (b) 0.354 m

7.29. (a)

7.31. 1.28 s

7.33. A quantum is the smallest indivisible amount of radiant energy that an atom can absorb or emit. A photon is the smallest individual packet or particle of light energy.

7.35. As the intensity (amplitude) of the light increases, more photons strike the surface as a function of time resulting in more electrons being emitted.

7.37. (b) is quantized, as the elevator can stop only at specified floors. Both the height of the escalator treads (a) and the speed of an automobile (c) are continuously variable and so are not considered quantized.

7.39. 6.52×10^{-19} J; this photon could break the C—C bond.

7.41. potassium; 8.04×10^{5} m/s

7.43. no

7.45. 3.17×10^{18} photons/s

7.47. The single electron interacts only with the proton in the nucleus; there are no other electrons to repel it.

7.49. The difference between *n* levels determines emission energy.

7.51. (a)

7.53. no

7.55. At $n = 7$, the wavelength of the electron's transition (from $n = 7$ to $n = 2$) has moved out of the visible region.

7.57. 18.5 nm; infrared

7.59. (a) decrease; (b) no

7.61. 72.9 nm

7.63. In the de Broglie equation, λ is the wavelength the particle of mass m exhibits as it travels at speed u, where h is Planck's constant. This equation states that (1) any moving particle has wavelike properties because a wavelength can be calculated through the equation, and (2) the wavelength of the particle is inversely related to its momentum (mass multiplied by velocity).

7.65. no

7.67. (a) 10.8 nm; (b) 0.180 nm; (c) 1.3×10^{-27} nm; (d) 3.7×10^{-54} nm

7.69. (c)

7.71. (a) 1.77×10^{3} m/s; (b) 0.0565 nm

7.73. $\Delta x \geq 1.3 \times 10^{-13}$ m

7.75. The Bohr model orbit showed the quantized nature of the electron in the atom as a particle moving around the nucleus in concentric orbits. In quantum theory, an orbital is a region of space where the probability of finding the electron is high. The electron is not viewed as a particle, but as a wave, and it is not confined to a clearly defined orbit; rather, we refer to the probability of the electron being at various locations around the nucleus.

7.77. A larger n means the electron is more likely to be found further from the nucleus so the orbital must also be larger.

7.79. (a) 1; (b) 4; (c) 9; (d) 16; (e) 25

7.81. 8 electrons

7.83. (a) $2s$, two electrons; (b) $3p$, six electrons; (c) $4d$, ten electrons; (d) $1s$, two electrons

7.85. (b)

7.87. Degenerate orbitals have the same energy and are indistinguishable from each other.

7.89. As we start from an argon core of electrons we move to potassium and calcium, which are located in the s block of the periodic table. It is not until Sc, Ti, V, and so on that we begin to fill electrons into the $3d$ shell.

7.91. Electrons may be promoted to many different orbitals with energy higher than the ground state; each of these corresponds to an excited state with a different energy.

7.93. (c) $3s$ < (a) $3d$ < (d) $4p$ < (b) $5p$

7.95. Li: $[He]2s^1$; Li^+: $1s^2$ or [He]; Ca: $[Ar]4s^2$; F^-: $[He]2s^22p^6$ or [Ne]; Na^+: $[He]2s^22p^6$ or [Ne]; Mg^{2+}: $[He]2s^22p^6$ or [Ne]; Al^{3+}: $[He]2s^22p^6$ or [Ne]

7.97. The highest-energy electron in each atom is the first electron to occupy the *s* subshell—each atom's electron configuration ends with ns^1.

7.99. (a) K: $[Ar]4s^1$, one unpaired electron; (b) K^+: [Ar], zero unpaired electrons; (c) S^{2-}: [Ar], zero unpaired electrons; (d) N: $[He]2s^22p^3$, 3 unpaired electrons; (e) Ba: $[Xe]6s^2$, zero unpaired electrons; (f) Ti^{4+}: [Ar], zero unpaired electrons; (g) Al: $[Ne]3s^23p^1$, one unpaired electron

7.101. (a) Ti, 2 unpaired electrons; (b) Cr, 6 unpaired electrons; (c) Cu, 1 unpaired electron; (d) Pd, zero unpaired electrons.

7.103. carbon: $1s^22s^22p^2$

7.105. no

7.107. Al^{3+}, N^{3-}, Mg^{2+}, Cs^+

7.109. (a) and (d)

7.111. (a) B: $1s^22s^22p^1$ or $[He]2s^22p^1$; O: $1s^22s^22p^4$ or $[He]2s^22p^4$; (b) H (+1), B (+3), O (− 2); H^+: $1s^0$; B^{3+}: $1s^22s^0$ or [He]; O^{2-}: $1s^22s^22p^6$ or [Ne]

7.113. (a) $2\ Mg(s) + O_2(g) \rightarrow 2\ MgO(s)$; (b) Mg: $1s^22s^22p^63s^2$ or $[Ne]3s^2$; Mg^{2+}: $1s^22s^22p^6$ or [Ne]; O^{2-}: $1s^22s^22p^6$ or [Ne]; (c) Mg is oxidized and O is reduced

7.115. (c)

7.117. (a) Ionization energy would correspond to removing a $2s$ electron not a $1s$ electron; (b) no

7.119. If electrons do not repel each other as much in Na^+ as they do in Na, they will have a lower energy and be, on average, closer to the nucleus resulting in a smaller size. When electrons are added to an atom (Cl), the electron–electron repulsion increases so the electrons have a higher energy and they will be, on average, farther from the nucleus thereby creating a larger species (Cl^-).

7.121. Rb; the size of the atoms increases down a group because electrons have been added to higher *n* levels.

7.123. (a) Al > P > Cl > Ar; (b) Sn > Ge > Si > C; (c) K > Na >

Li > Li^+; (d) Cl^- > Cl > F > Ne

7.125. (a) As the atomic number increases down a group, electrons are added to higher *n* levels leading to a decrease in ionization energy; (b) as the atomic number increases across a period, the effective nuclear charge increases leading to an increase in ionization energy across a period of elements.

7.127. Fluorine, due to its higher nuclear charge, exerts a higher Z_{eff} on the 2*p* electrons than does boron resulting in higher ionization energy.

7.129. Sr

7.131. (a) I < Br < Cl < F; (b) Na < Mg < Li < Be; (c) N < O < F < Ne (O is actually slightly lower than N but this is an anomaly in the general trend.)

7.133. No, the statement about all atoms with negative EA values existing as anions is false. For example, fluorine atoms are less stable than the fluoride anion and exhibit a negative value for EA, but fluorine exists in nature as F_2, a homonuclear diatomic molecule.

7.135. As we move down a group, electron–electron repulsions decrease as a result of the valence shells being farther from the nucleus. Minimizing the energy penalty of adding an electron results in a greater electron affinity.

7.137. (a) $\lambda = 0.242$ m, $E = 8.22 \times 10^{-25}$ J; (b) no

7.139. 2.3 GHz corresponds to a higher energy, shorter wavelength, and higher frequency than 162 MHz.

7.141. (a) Moving across a period in the periodic table, the energy separation of the 2*s* and 2*p* orbitals would increase. Because energy is inversely proportional to wavelength, the wavelength of this for the $2p \rightarrow 2s$ transition would decrease; (b) moving down a column in the periodic table, the energy separation between the 2*s* and 2*p* orbitals would again increase so the wavelength of this for the $2p \rightarrow 2s$ transition would decrease.

7.143. Both configurations have one unpaired electron so the two configurations would be expected to exhibit the same effect when exposed to a magnetic field.

7.145. (a) true; (b) false; (c) true; (d) true

7.147. (a) No, the second ionization energy for Ga would involve removing an electron from a lower-energy subshell (the 3*d*) than the first ionization energy (the 4*p*); for the other elements, both the first and second ionization energies would be for removing electrons from the 4*p* subshell. This difference results in the second ionization energy for Ga being significantly higher than those of Ge and As, which would not match the trend for first ionization energies. (b) Rb; its higher nuclear charge exerts a greater Z_{eff} on the electron being lost for a second ionization than that of Kr.

7.149. 3.9 nm

7.151. (a) La: [Xe] $6s^25d^1$; Ce: [Xe]$6s^24f^15d^1$; Pr: [Xe]$6s^24f^25d^1$; Nd: [Xe]$6s^24f^35d^1$; Pm: [Xe]$6s^24f^45d^1$; Sm: [Xe]$6s^24f^55d^1$; Eu: [Xe]$6s^24f^65d^1$; Gd: [Xe]$6s^24f^75d^1$; Tb: [Xe]$6s^24f^85d^1$; Dy: [Xe]$6s^24f^95d^1$; Ho: [Xe]$6s^24f^{10}5d^1$; Er: [Xe]$6s^24f^{11}5d^1$; Tm: [Xe]$6s^24f^{12}5d^1$; Yb: [Xe]$6s^24f^{13}5d^1$; Lu: [Xe]$6s^24f^{14}5d^1$; (b) La: same; Ce: same; Pr: [Xe]$6s^24f^3$; Nd: [Xe]$6s^24f^4$; Pm: [Xe]$6s^24f^5$; Sm: [Xe]$6s^24f^6$; Eu: [Xe]$6s^24f^7$; Gd: same; Tb: [Xe]$6s^24f^9$; Dy: [Xe]$6s^24f^{10}$; Ho: [Xe]$6s^24f^{11}$; Er: [Xe]$6s^24f^{12}$; Tm: [Xe]$6s^24f^{13}$; Yb: [Xe]$6s^24f^{14}$; Lu: same; (c) the 5*d* orbital could be higher in energy than the 4*f* orbital; (d) we can for Tb, Dy, Ho, Er, Tm, and Yb.

7.153. (a) Ne, 5.76; Ar, 6.76; (b) the outermost electron in argon is a 3*p* electron, which is mostly shielded by the electrons in the $n = 2$ level (10 electrons) and the $n = 1$ level (2 electrons), whereas the outermost electron in neon is a 2*p* electron, which is shielded only by the electrons in the $n = 1$ level (2 electrons).

7.155. When we think of the electron as a wave we can envision the node between the two lobes as a wave of zero amplitude and the *p* orbital as a standing wave.

7.157. No, it will be in the infrared portion of the electromagnetic spectrum.

Chapter 8

8.1. (a) Be (group 2); (b) C (group 14); (c) O (group 16); (d) Ne (group 18)

8.3. Carbon (blue) has the capacity to make four bonds.

8.5. fluorine (yellow)

8.7. Mg^{2+}

8.9. (b)

8.11. (a) SO_2 exhibits a bent molecular geometry. The central sulfur atom has a lower electronegativity than that of the flanking oxygen atoms so the electron density should be lower at the sulfur and higher at the oxygens.

8.13 The red line represents KF; the blue line represents KCl.

8.15 The arrangement of the atoms in two of the structures is S—O—S, and in the other two structures it is S—S—O. Because the arrangement of atoms differs they are not resonance structures. Also, for each arrangement, the structures do not show a different positioning of electrons on the atoms, just a change in the angle between the bonds. The “bent form” and the “linear form” are not resonance forms of each other if the numbers of lone pairs and bonding pairs of electrons on each atom are the same.

8.17. The structures do not have the correct number of valence electrons. H_2NO_3S: should have 31 valence electrons but only 25 are shown. NO_2Cl: should have 24 valence electrons but only 22 are shown. S_2F_2: should have 26 valence electrons but only 24 are shown. Br_3^-: should have 22 valence electrons but only 18 are shown.

8.19 Bond order and bond length are inversely proportional (blue line). Bond order and bond energy are directly proportional, and this relationship would look like the red line in the diagram.

8.21 The positively charged protons in each atom are attracted to the negatively charged electron in the other atom.

8.23. The sodium cations and the chloride anions are attracted to each other. Particles with the same charge repel each other; sodium cations will repel other sodium cations and chloride anions will repel other chloride anions.

8.25 (a) Ni(*s*): metallic bonding; S_8(*s*): covalent bonding. Both types of bonding result from shared electrons. In metallic bonding those electrons are delocalized to form a “sea” of mobile electrons; in covalent bonding the electrons are shared between the atoms. (b) Ni(*s*): metallic bonding; Na_2S(*s*): ionic bonding. Both types of bonding involve movement of electrons. In metallic bonding electrons are delocalized to form a “sea” of mobile electrons, in ionic bonding electrons are transferred from the cation to the anion. (c) SO_2(*g*): covalent bonding; Na_2S(*s*): ionic bonding.

Both types of bonding rely on atoms reaching a more stable electron arrangement. In covalent bonding electrons are shared to reach the more stable arrangement; in ionic bonding electrons are transferred from cation to anion to reach the more stable arrangement. (d) Ni(*s*): metallic bonding, Na_2SO_4(*s*): ionic bonding between the sodium cation and the sulfate anion, covalent bonding within the sulfate ion. (e) S_8(*s*): covalent bonding; Na_2SO_4(*s*): ionic bonding between the sodium cation and the sulfate anion; covalent bonding within the sulfate ion. (f) Na_2S(*s*): ionic bonding; Na_2SO_4(*s*): ionic bonding between the sodium cation and the sulfate anion; covalent bonding within the sulfate ion.

8.27. yes, for H and He

8.29. yes

8.31. groups 1, 13, 15, and 17

8.33. No, sharing of electrons will result in fewer than 16 electrons in diatomic molecules.

8.35.

8.37. The corrected Lewis symbols are

8.39.

I^- and Ca^{2+} have complete valence-shell octet.

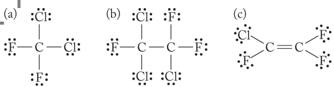
8.41. (a) Ne; (b) the element identity is different but the complement of electrons is identical.

8.43. (a) $[X\cdot]^+$; (b) $[X]^{3+}$

8.45. (a) 8; (b) 8; (c) 8; (d) 10

8.47.

8.49.



8.51.

	 8.53.	 8.55.	If there is an electronegativity difference of 2.0 or greater, the bond between the atoms is ionic; below 2.0 the bond is covalent.
8.57.	The size of the atom is the result of the nucleus pulling on the electrons. The higher the nuclear charge, the stronger the pull on the electrons within a given valence shell. This is why the size of atoms generally decreases across a period. A small atom will form a shorter bond with another atom, and the electrons in the bond will feel a stronger pull from the nucleus of a smaller atom because the bonding electrons will be “closer” to the nucleus. This stronger pull results in a higher electronegativity for smaller atoms.
8.59.	A polar covalent bond is one in which the electrons are shared, but not equally, by the atoms.
8.61.	Like the panes of glass in a greenhouse, the greenhouse gases in the atmosphere are transparent to visible light. Once the visible light warms the surface of Earth and is reemitted as infrared (lower energy) light, the greenhouse gases absorb the infrared light; this prevents some of the warmth from escaping the atmosphere in the same way that the panes of glass do not allow the energy from inside the greenhouse to escape.
8.63.	An infrared-active stretch must change the electric field of the molecule. Stretching the nonpolar N–N bond will not alter the dipole moment whereas stretching the N–O bond will. Only the N–O bond stretch contributes to the absorption of infrared radiation by N_2O.
8.65	The polar bonds and the atoms with the greater electronegativity (underlined) are: C—Se, C—O, N—H, and C—H.
8.67.	CsI
8.69.	the I—Cl bond
8.71.	the O—H bond

8.73.

PF_3

8.75.

Resonance occurs when two or more valid Lewis structures may be drawn for a molecular species. The true structure of the species is a hybrid of the structures drawn.

8.77.

A molecule or ion shows resonance when there is more than one correct Lewis structure; that is, when the electrons in the correct Lewis structure may be distributed in more than one way. Often, when the central atom has both a single and a double bond, resonance is possible.

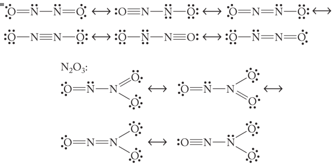
8.79.

Either N–O bond in the NO_2 structure could be double-bonded, and the formal charges for each structure are identical, so there is more than one correct Lewis structure, and NO_2 will exhibit resonance.

The resonance forms of CO_2 show that one is dominant (the one in which all formal charges are zero), and so the other forms contribute little to the true structure of CO_2.

8.81.

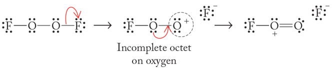
8.83.



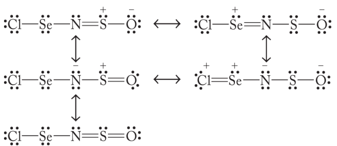
8.85.

a.

b. The presence of an O□O double bond shortens the bond length.



8.87.



8.89. The best possible structure for a molecule judging by formal charges is the structure in which the formal charges are minimized and the negative formal charges are on the most electronegative atoms in the structure.

8.91. No. The electronegativity of oxygen (3.5) is higher than that of sulfur (2.5) so the negative formal charge must be on the O atom in the structure that contributes to the bonding.

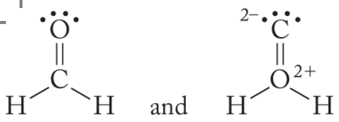
8.93.

The formal charges are zero for all the atoms in HCN, whereas in HNC the carbon atom, with a lower electronegativity than N, has a − 1 formal charge.

8.95.

The preferred structure is the one with the C triple-bonded to N.

8.97. (a)



The Lewis structure with carbon as the central atom is more likely as it minimizes formal charges; (b) no

8.99.

Because oxygen is more electronegative than nitrogen, none of these structures is likely to be stable because the formal charge on O is positive.

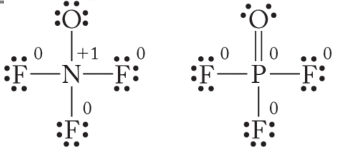
8.101. yes

8.103. In order for the atom to accommodate more than 8 electrons in covalently bonded molecules, it would require the use of orbitals beyond *s* and *p*. The *d* orbitals are not available to the small elements in the second period.

8.105. (a), (b), and (c)

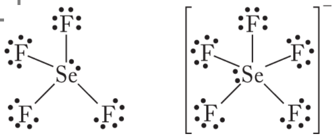
8.107. (a) 6; (b) 6; (c) 12; (d) 10

8.109.



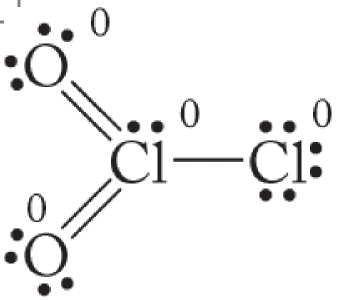
In POF_3 there is a double bond and no formal charges; in NOF_3 there are only single bonds and formal charges are present on N and O.

8.111.



In both structures Se has more than eight valence electrons.

8.113.

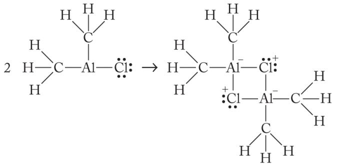


The central chlorine atom has 12 electrons.

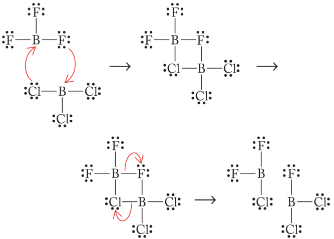
8.115. (c), (d), and (e)

8.117. (d)

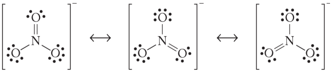
8.119. The formation of a dimer completes the octet on Al.



8.121.



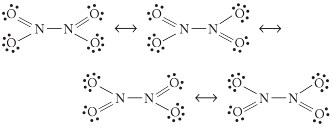
8.123. Each bond in the nitrate ion is 1.33 bonds because of resonance.



Each bond in the nitrite ion is 1.5 bonds because of resonance.

No, the nitrogen–oxygen bond lengths in NO_3^- and NO_2^- are not the same, they are different.

8.125. The nitrogen–oxygen bond in N_2O_4 has a bond order of 1.5 due to four equivalent resonance forms:



The nitrogen–oxygen bond in N_2O has a bond order of 1.5 due to resonance between three resonance forms (where the last resonance structure shown does not significantly contribute to the structure of the molecule because of the buildup of too much formal charge):

Therefore N_2O_4 and N_2O are expected to have nearly equal bond lengths.

8.127. (a) $NO^+ < NO_2^- < NO_3^-$; (b) $NO_3^- < NO_2^- < NO^+$

8.129. no

8.131. We must account for all the bonds that break and all the bonds that form in the reaction. In order to do so, we must have a balanced chemical reaction.

8.133. If the compounds are in the solid or liquid phase, interactions between molecules may slightly change the bond energy for a given bond.

8.135. (a) 862 kJ; (b) 98 kJ; (c) 93 kJ

8.137. 10.8 kJ/mol

8.139. 2.8 kJ less

8.141. −667 kJ

8.143. 5.2 kJ/mol

8.145.

a.

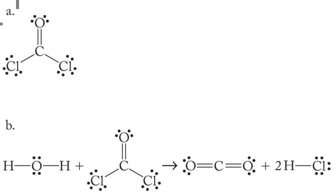
b. The two carbon oxygen bonds in this molecule would have the same length.

8.147. A potassium ion has a charge of +1. The potassium ion would have lost the single valence electron that would be present in the neutral potassium atom.

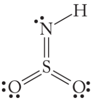
8.149.

The preferred structure would be the one with the carbon atom in the center.

8.151.

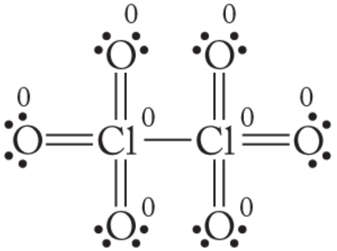


8.153. (a) Each arrangement has a structure where all atoms have a zero formal charge:

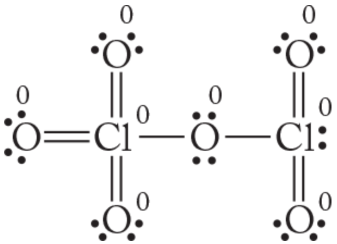


(b) In both structures the S–N bond is a double bond. (c) Formal charges cannot be used to predict the preferred arrangement because both arrangements have all zero formal charges. (d) 143 pm for the sulfur–oxygen bond in each structure.

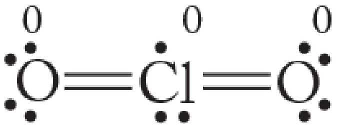
8.155. For Cl_2O_6 with a Cl—Cl bond:



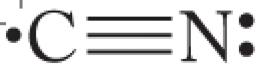
For Cl_2O_6 with Cl—O—Cl bonds:



For ClO_2:

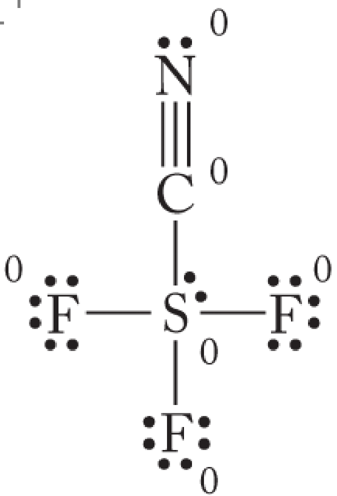


8.157. (a)

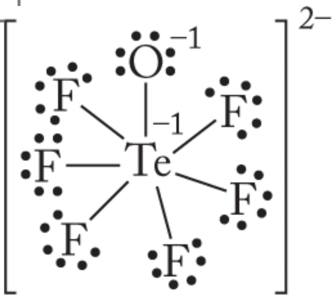


The more likely structure for cyanogen is the one with the C—C bond. (b) It would be expected that oxalic acid would retain the C—C bond from the cyanogen from which it is formed in the reaction of cyanogen with water. This is consistent with the structure for cyanogen predicted from formal charges of the two possible structures.

8.159.



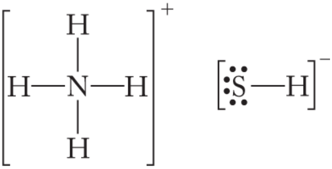
8.161.



8.163. (a) 2; (b) 4; (c) 1; (d) 5; (e) 8

8.165. (a) Assuming A and X have different electronegativities, we would be able to distinguish X—A—A from A—X—A. Bond lengths would only be useful if we were able to look for a characteristic A—A bond that would be found in X—A—A but not in A—X—A. (b) Electrostatic potential mapping cannot distinguish resonance forms. If the resonance forms for A—X—A shown are all equally weighted (none is more preferred than another), we would expect the average X—A bond to be a double bond as in A□X□A. If one resonance form contributes more to the bonding in a molecule, we would see that resonance form reflected in the bond distances being shortened or lengthened.

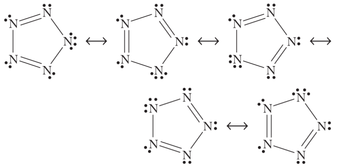
8.167.



There cannot be a nitrogen–sulfur covalent bond because the nitrogen atom in $NH_4{}^+$ has a complete octet through its bonding with hydrogen and because it cannot expand its octet as it is a second period element.

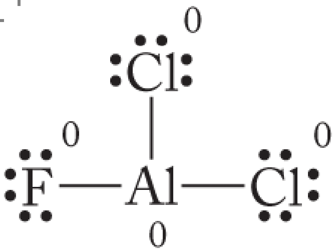
8.169.

a.



b. Bond order is 1.4 (or 7/5). There are seven bonds between any two nitrogen atoms spread over five structures. The bond distance is ~140 pm.

8.171.

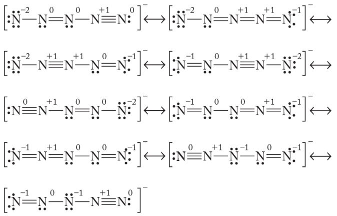


8.173.

(b) and (c)

8.175.

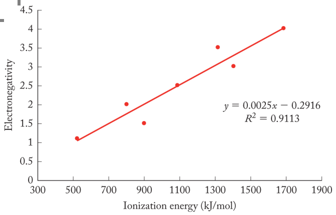
(a) and (b)



The structures that contribute the most are the ones with the lowest formal charges (the last four of the structures shown). (c) N_3^- has the Lewis structures:

From these resonance structures we see that each bond is predicted to be of double-bond character in N_3^-. Therefore in N_5^- there are two longer N–N bonds than in N_3^-. N_3^- has the higher average bond order.

8.177.



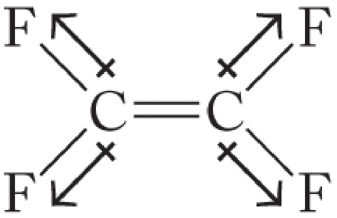
Using the equation for the best-fit line where x = the ionization energy of neon gives a value of y (electronegativity) of neon: $y = 4.9$

8.179.

(a) Isoelectronic means that the two species have the same number of electrons.
(b)

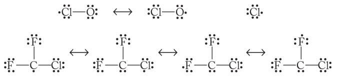
(c) The central nitrogen atom in all resonance structures always carries a +1 formal charge. (d) The second and third resonance forms shown are unacceptable because they have greater than the minimal formal charges on the atoms. (e) Structures can be drawn with the fluorine as the central atom in the molecule, but this would place a +3 formal charge on the fluorine atom (the most electronegative element) so these structures are very unlikely:

8.181.



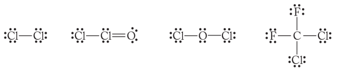
This molecule is nonpolar overall because the individual bond dipoles are equal in magnitude and, as vectors, they cancel each other out.

8.183. a.



In order of increasing reactivity: $CF_2Cl\cdot < ClO\cdot < Cl\cdot$.

b. The products are



Chapter 9

9.1. (b)

9.3. (a) trigonal planar, trigonal planar; (b) tetrahedral, trigonal pyramidal; (c) trigonal bipyramidal, T-shaped

9.5. All three molecules have polar bonds. BF_3 has no dipole moment.

9.7. (a) trigonal planar and tetrahedral; (b) trigonal planar: *sp*^{2}; tetrahedral: *sp*^{3}; (c) One hybridized orbital is required for each electron domain around a central atom. A trigonal planar structure has three electron domains and therefore requires three hybridized orbitals. A tetrahedral structure has four electron domains and therefore requires four hybridized orbitals.

9.9. N_2F_2 and NCCN are planar; there are no delocalized π electrons in any of these molecules.

9.11. more

9.13. 72° and 90°

9.15. Because the electrons take up most of the space in the atom and because the nucleus is located in the center of the electron cloud, the electron clouds repel each other before the nuclei get close to each other.

9.17. Because the lone pair is attracted by only one nucleus, it is less confined than bonding pairs and occupies more space around the nucleus of the central N atom.

9.19. The seesaw geometry has only two lone pair–bond pair interactions at 90° (compared to a trigonal bipyramidal–derived trigonal pyramidal, which would have three), so it has lower energy.

9.21. (b) < (c) < (a)

9.23. trigonal bipyramidal and seesaw

9.25. (a)

9.27. Pentagonal pyramid and distorted octahedral

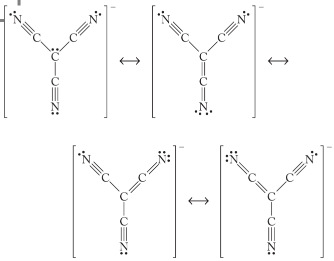
9.29. (a) tetrahedral; (b) trigonal pyramidal; (c) bent; (d) tetrahedral

9.31. (a) 109.5°; (b) < 109.5°; (c) ~120°; (d) 90°, 180°

9.33. (a) tetrahedral; (b) tetrahedral; (c) trigonal planar; (d) linear

9.35. O_3, SO_2, and S_2O are bent (120°), whereas N_2O and CO_2 are linear.

9.37.



The last three structures are more important contributors than the first structure because the negative formal charge resides on a nitrogen atom instead of a carbon atom.

9.39. Silicon and sulfur may exceed an octet allowing them to form a double bond with the central nitrogen making the nitrogen trigonal planar in $N(SiH_3)_3$ and $N(SCF_3)_3$. Carbon cannot exceed an octet so the carbon atoms can only form single bonds in $N(CH_3)_3$ resulting in a trigonal pyramidal geometry.

9.41.

Bond order = 1.5
ClO$_2$
SN = 4
Electron-pair geometry = tetrahedral
One lone pair + one unpaired electron
Molecular geometry = bent (118°)
Bond order = 1.5

9.45. Moving down the periodic table from S to Se to Te, the lone-pair electrons reside in sequentially larger orbitals. With those electrons spread over a larger volume, the remaining bonds in the seesaw structure would be pushed closer together.

9.47. Bond types are defined on the basis of the electronegativity differences of the atoms involved. Bonds are classified as nonpolar covalent if the atoms involved have the same electronegativity. Bonds are classified as polar covalent if the electronegativity difference of the atoms is between 0 and 2.0. Bonds are classified as ionic if the electronegativity difference between the atoms is greater than or equal to 2.0.

9.49. yes

9.51. (a) All five molecules contain polar bonds; (b) $CHCl_3$, H_2S, and SO_2 are polar; (c) CCl_4 and CO_2 are nonpolar

9.53. All three of the molecules are polar.

9.55. (a) Yes. (b) The most polar bond in each molecule is the C–N bond. (c) BrXeCN would have a larger value of μ. There is a smaller electronegativity difference in the Br–Xe bond than in the Cl–Xe bond resulting in less of a counterbalance to the electronegativity difference in the C–N bond.

9.57. (a) i; (b) i; (c) ii

9.59. (a) tetrahedral; (b) nonpolar

9.61. It is energetically unfavorable to hybridize orbitals unless a chemical bond is also formed.

9.63. A sigma bond is formed from the overlap of two atomic or hybridized atomic orbitals along a bonding axis. A pi bond is formed from unhybridized *p* or *d* orbitals above and below a bonding axis.

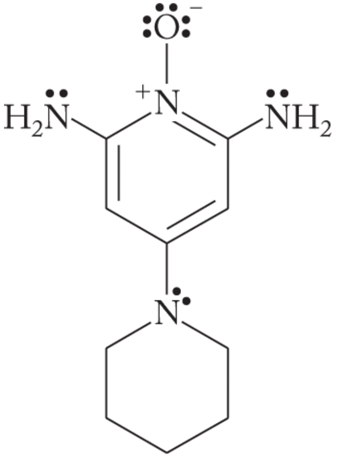
9.67. Both Lewis structures have three resonance forms: one with two N=N double bonds and two with an N≡N triple bond and an N—N single bond. For both molecules the central nitrogen atoms are *sp* hybridized.

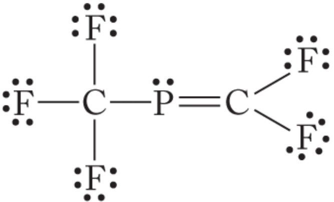
9.69. SF_2 (sp^3), SF_4 (sp^4), and SF_6 (sp).

9.71. The N—O bond is a single bond. There is also an N—C single bond and an N=C double bond.



The molecular geometry around the phosphorus atom is bent and its hybridization is sp^2.

9.73.



9.75. All types of structure convey the correct atom stoichiometry within the molecule, though the condensed structure does not show connectivity. Lewis, Kekulé, and carbon-skeleton structures are all capable of displaying resonance structures, and functional groups may be identified in each. A certain degree of chemical knowledge is required to correctly interpret a carbon-skeleton structure because the identity or presence of C and H atoms is to be assumed.

9.77. Yes, in resonance structures the electron distribution is blurred across all of the resonance forms. Resonance forms are Lewis structures that show alternative (yet still valid) electron distributions in a molecule.

9.79. (b) and (c)

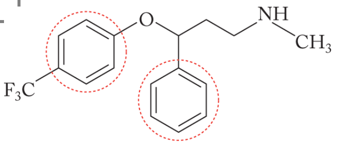
9.81. $CH_3(CH_2)_2CH$□$CH—CH$□$CH(CH_2)_9OH$

9.83. (a) Progesterone has 20 carbon atoms, testosterone has 19 carbon atoms; (b) progesterone has four sp^2 carbon atoms, testosterone has three sp^2 carbon atoms; (c) both molecules contain alkane, alkene, and ketone functional groups.

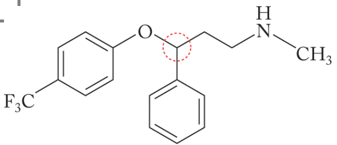
9.85. Progesterone has six chiral carbons, and testosterone has six chiral carbons.

9.87. $CH_3(CH_2)_7CH$□$CH(CH_2)_7C(O)OH$

9.89.



9.91.



9.93. (a) Starting from the top of the ring and progressing clockwise: S is tetrahedral, N is bent, all three carbons in the six-membered ring are trigonal planar, and O is bent. (b) C–O bond: sp^2 C orbital with sp^3 O orbital; C–N bond: sp^2 C orbital with sp^3 N orbital; (c) the extra electron is in an sp^3 hybrid orbital; (d) no delocalized electrons.

9.95. (a) and (c) are chiral; none of the molecules have delocalized electrons.

9.97. A bonding molecular orbital has its highest region of electron density between the atom centers. An antibonding molecular orbital has its highest region of electron density outside of the space between the atom centers.

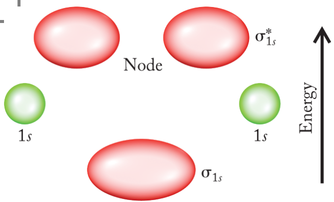
9.99. No; the overlap of 1*s* and 2*s* orbitals is not as efficient as 1*s*–1*s* or 2*s*–2*s* overlaps—there is better overlap for orbitals of the same size and energy.

9.101. If a molecule or ion has an even number of valence electrons distributed over an odd number of orbitals or if the highest occupied molecular orbital is a π orbital, paramagnetic species could result.

9.103. In the sea-of-electrons model, application of an electrical potential across a metal causes its mobile valence electrons to move toward the positive potential. In band theory there is no energy gap between the valence and the conduction band so electrons are free to move into the empty band.

9.105. Doping a metalloid generates a semiconductor with a smaller bandgap than that of the starting material. The n-type semiconductors have “extra” electrons higher in energy than the valence band of the undoped material. The p-type semiconductors have “extra” holes lower in energy than the conduction band of the undoped material. In both types of doped semiconductor, the effect is similar; the band gap is lowered and the electrons flow with a smaller energy barrier.

9.107.



9.109. (a) N_2^+: $(\sigma_{2s})^2 (\sigma^*_{2s})^2 (\pi_{2p})^4 (\sigma_{2p})^1$; O_2^+: $(\sigma_{2s})^2 (\sigma^*_{2s})^2 (\sigma_{2p})^2 (\pi_{2p})^4 (\pi^*_{2p})^1$; C_2^+: $(\sigma_{2s})^2 (\sigma^*_{2s})^2 (\pi_{2p})^3$; Br_2^{2-}: $(\sigma_{4s})^2 (\sigma^*_{4s})^2 (\sigma_{4p})^2 (\pi_{4p})^4 (\pi^*_{4p})^4 (\sigma^*_{4p})^2$; (b) N_2^+: BO $= 2.5$;

O_2^+: BO = 2.5; C_2^+: BO = 1.5; Br_2^{2-}: BO = 0; (c) all species with nonzero bond order (N_2^+, O_2^+, C_2^+) are expected to exist.

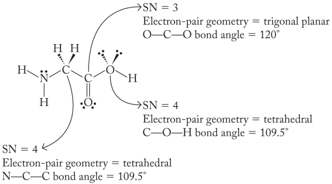
; (b) bond order = 2

9.123.

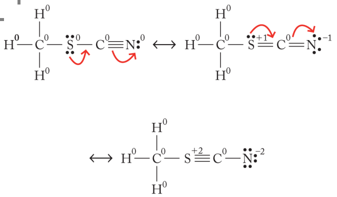


SN = 3
Electron-pair geometry = trigonal planar
O—C—O bond angle = 120°
SN = 4
Electron-pair geometry = tetrahedral
C—O—H bond angle = 109.5°
SN = 4
Electron-pair geometry = tetrahedral
N—C—C bond angle = 109.5°

9.125.

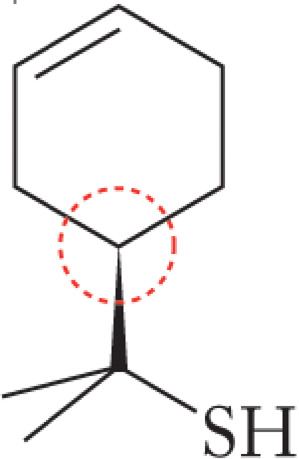
The first structure shown provides the best description of the bonding in BNO (as it minimizes formal charges). In all of the resonance forms the B atom does not have a complete octet. The molecular geometry is bent with a 120° angle.

9.127.



The first structure would be the most stable as it minimizes formal charges. The carbon attached to the three hydrogens and the sulfur is tetrahedral and the carbon bonded to the sulfur and the nitrogen is linear.

9.129.



9.131.

O2 2−

Superoxide, O_2^-: $(\sigma_{2s})^2\ (\sigma^*_{2s})^2\ (\sigma_{2p})^2\ (\pi_{2p})^4\ (\pi^*_{2p})^3$, BO = 1.5; peroxide, O_2^{2-}: $(\sigma_{2s})^2\ (\sigma^*_{2s})^2\ (\sigma_{2p})^2\ (\pi_{2p})^4\ (\pi^*_{2p})^4$, BO = 1. The Lewis structures predict a BO = 1 for both compounds:

The predicted bond order for peroxide is the same in the molecular orbital diagram and the Lewis structure, but the bond order for superoxide is different: 1.5 from the molecular orbital diagram and 1 from the Lewis structure.

9.139. Valence bond theory without hybrid orbitals would provide a better description of the bonding in H_2S, H_2Se, and H_2Te because unhybridized *p* orbitals are 90° from each other. VSEPR and valence bond theory with hybrid orbitals would predict an angle of 109.5° for these molecules.

Chapter 10

10.1. The figure represents Xe in the solid state. The attractions between Xe atoms are the result of dispersion forces. As temperature increases, the solid will melt into a liquid (the particles would still be close together but will not have a rigid, ordered arrangement) and eventually vaporize into a gas (the particles would be far apart).

10.3. All three would be vanishingly soluble in water but (b) would be the least soluble. As the hydrocarbon chain gets longer, the dispersion interactions between the molecules within its pure liquid form will get stronger; also, the longer the chain, the more its dissolution would disrupt the hydrogen bonding in water.

10.5. The slope of the trend line in each graph is proportional to the size of ΔH_{vap}, so the graph with the larger slope has a larger enthalpy of vaporization. A large value of ΔH_{vap} corresponds to strong intermolecular forces, as seen in the graph for the liquid on the left.

10.7. (a) The freezing point increases. (b) No; as pressure is increased, the liquid phase is converted into solid at a given temperature. This means that the solid is more dense than the liquid and so the solid will not float in its liquid phase.

10.9. dispersion forces

10.11. Because real gases have nonzero volume, and when cooled they have less kinetic energy to overcome their intermolecular forces.

10.13. (a) CCl_4; (b) C_3H_8

10.15. PCl_5 is a solid at room temperature, whereas PCl_3 is a liquid. Despite being nonpolar, PCl_5 has a higher molar mass and a larger surface area, so the dispersion forces for PCl_5 outweigh the weaker dispersion forces and dipole–dipole interactions for PCl_3.

10.17. Because of the full positive or negative charge on the ion, the ion–dipole interaction is stronger than the dipole–dipole interaction.

10.19. The charge buildup on H (partially positive) and the electronegative element (partially negative) means that the X–H bond is polar. It is still a dipole–dipole interaction except that its strength is noticeably higher than in other dipole–dipole interactions.

10.21. The greater dispersion forces of CH_2Cl_2 add to the dipole–dipole interactions to give stronger intermolecular forces between the CH_2Cl_2 molecules than those between the CH_2F_2 molecules.

10.23. Dimethylsulfide has stronger intermolecular forces. Sulfur is larger and more polarizable than oxygen, which leads to stronger dispersion forces.

10.25. (a) Ethanol has a higher boiling point because it is capable of hydrogen bonding, whereas ethanethiol is not; (b) 1.968 times faster

10.27. (b)

10.29. (a) and (d)

10.31. When the average kinetic energy of the liquid molecules increases, more of the molecules can escape the liquid phase and enter the gas phase. More molecules in the gas phase increase the vapor pressure.

10.33. intensive

10.35. (a) < (b) < (c)

10.37. (a) 41.0 kJ/mol; (b) 4.32 torr

10.39. 27.3 kJ/mol

10.41. (a) solid, liquid, and gas; (b) liquid and gas

10.43. (a) solid phase; (b) gas phase

10.45. Yes. From the phase diagram for water we see that above the triple point, the solid phase must change to the liquid phase to enter the gas phase. Below the triple point, changing the temperature at a given pressure will sublime solid water into the gas phase.

10.47. approximately 55°C to 60°C

10.49. Ethylene glycol has stronger intermolecular forces. We can tell this from the higher boiling point of ethylene glycol and explain it based on a second O–H bond that can hydrogen-bond to nearby molecules in the liquid phase.

10.51. Reduce the temperature from 25°C to 0.01°C then reduce the pressure from 1 atm to 0.006 atm.

10.53. Water would be in the liquid phase initially and would vaporize to the gas phase when the pressure was lowered.

10.55. (a) Yes, as pressure increases the melting point of ice decreases. (b) It would take approximately 100 atm of pressure to reduce the melting point by 0.5°C.

10.57. A needle floats on water but not on methanol because of the high surface tension of water. This is because water can hydrogen-bond through two O–H bonds with other water molecules whereas methanol has only one O–H bond through which to form hydrogen bonds.

10.59. The expansion of the water in the pipes on freezing may create sufficient pressure on the walls of the pipes to cause them to burst.

10.61. The cohesive forces in mercury are stronger than the adhesive forces of the mercury to the glass. In water the adhesive forces of the water to the glass are strong enough that the water can climb upward on the glass.

10.63. Molecules in the bulk liquid are “pulled” by all the other liquid molecules surrounding them and they are therefore “suspended” in the bulk liquid. Molecules on the surface of a liquid, however, are pulled only by the molecules under and beside them creating a tight film of molecules on the surface.

10.65. As the temperature increases, the surface tension decreases because the intermolecular forces acting on the molecular “film” on the surface of the liquid are weaker. Likewise, the viscosity decreases as the temperature increases because molecules have more energy to readily break the intermolecular forces to enable them to slide past each other more freely.

10.67. Water is able to form more hydrogen bonds to the glass surface (composed of Si—O—H bonds) than ethanol so water rises higher in the capillary tube.

10.69. Liquid B is expected to have higher surface tension and higher viscosity because its higher boiling point is indicative of stronger intermolecular forces.

10.71. Miscible solutes and solvents dissolve completely in each other; an insoluble solute does not dissolve at all.

10.73. 1,1-Dichloroethane is polar and therefore soluble in water. 1,2-Dichloroethane is nonpolar and insoluble in water.

10.75. Hydrophilic substances dissolve in water. Hydrophobic substances do not dissolve, or are immiscible, in water.

10.77. (a) $CHCl_3$; (b) CH_3OH; (c) NaF; (d) BaF_2

10.79. (a), (b), (c), and (d)

10.81. (b)

10.83. Both of these compounds can dissociate when added to water. Dissociation will result in ion–dipole interactions with water, which are even stronger than the hydrogen-bonding interactions that would be present in the nonionic form of the drugs.

10.85. (b) and (c) are ethers, whereas (a) and (d) are alcohols. The expected ordering of boiling points is (b) < (c) < (a) < (d).

10.87. At lower temperature, the solubility of a gas increases because fewer gas molecules dissolved in a solvent have sufficient (kinetic) energy to overcome the intermolecular forces between the solvent molecules and escape the surface of the liquid.

10.89. No, the Henry’s law constant for air is not simply the sum of k_H for N_2 and O_2.

$$\begin{aligned}
C_{\mathrm{air}} &= k_{\mathrm{H,air}}P_{\mathrm{air}} = C_{\mathrm{O_2}} + C_{\mathrm{N_2}}\\
k_{\mathrm{H,air}}P_{\mathrm{air}} &= k_{\mathrm{H,O_2}}P_{\mathrm{O_2}} + k_{\mathrm{H,N_2}}P_{\mathrm{N_2}}\\
&= k_{\mathrm{H,O_2}}(0.22P_{\mathrm{air}}) + k_{\mathrm{H,N_2}}(0.78P_{\mathrm{air}})\\
&= 0.22k_{\mathrm{H,O_2}}P_{\mathrm{air}} + 0.78k_{\mathrm{H,N_2}}P_{\mathrm{air}}\\
&= (0.22k_{\mathrm{H,O_2}} + 0.78k_{\mathrm{H,N_2}})P_{\mathrm{air}}\\
k_{\mathrm{H,air}} &= 0.22k_{\mathrm{H,O_2}} + 0.78k_{\mathrm{H,N_2}}
\end{aligned}$$

10.91. SO_3 and CO_2 (because they are nonpolar).

10.93. 3.7×10^{-2} mol/(L · atm)

10.95. (a) $2.7 \times 10^{-3} M$; (b) $2.3 \times 10^{-2} M$

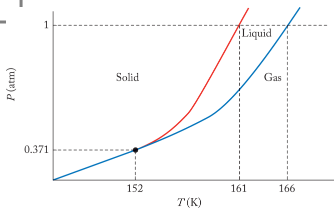
10.97. 2.18 g

10.99. Alcohols exhibit stronger intermolecular forces (hydrogen bonds) than do ethers (dipole–dipole).

10.101. Increase; the equilibrium line between the solid and vapor phases of water increases upward and to the right of the phase diagram. As the pressure increases, the temperature at which sublimation occurs will also increase until the ice reaches the triple point (0.0060 atm and 0.010°C).

10.103. yes

10.105.



10.107. Inside a narrow capillary tube, the mass of water that rises to a particular height in the column equals the mass of water that can rise in a wider-diameter tube, but the level in the test tube is lower because the volume (mass) is spread out across a wider area. It is the same mass that feels the force of gravity being balanced by the adhesive and cohesive forces.

10.109. As the temperature of the pond water increases, the oxygen becomes less soluble and the fish do not have enough oxygen to survive.

10.111. (a)

Chapter 11

11.1. (a)

11.3. (a) (I) = NaCl, (II) = $MgCl_2$, (III) = $C_6H_{12}O_6$, (IV) = K_3PO_4; (b) (i) (III), (ii) (IV), (iii) (III), (iv) (IV)

11.5. (a) If the substances were electrolytes we would expect to observe deviations from linearity at higher concentrations due to ion-pair formation. Because both substances exhibit a linear relationship between temperature change in the freezing point of the solution and molality, they are nonelectrolytes. (b) The freezing-point-depression constant (K_f) would correspond to the slope of the line: because the slope is the same for both solutions, we can conclude that the K_f value is the same for both solutions.

11.7. (a) In diagram (i) water will pass through the membrane from the pure water side to the protein solution side, and in diagram (ii) water will pass from the 0.2 M KCl solution side to the protein solution side. (b) In diagram (i) Na^+ ions will flow from the 0.5 *M* NaCl (protein solution) side to the pure water side of the membrane, and in diagram (ii) Na^+ ions will flow from the 0.5 *M* NaCl (protein solution) side to the aqueous 0.2 *M* KCl side of the membrane. (c) In diagram (i) K^+ ions will flow from the 0.1 *M* KCl (protein solution) side to the pure water side of the membrane, and in diagram (ii) K^+ ions will flow from the 0.2 *M* KCl (aqueous solution) side to the 0.1 *M* KCl (protein solution) side of the membrane.

11.9. (a) The sample is a mixture. (b) (i) The mixture contains three substances; (ii) the first (lowest boiling) material has a volume of 20 mL, the second (middle boiling) material has a volume of 50 mL, and the third (highest boiling) material has a volume of 30 mL; (iii) the first material boils at 20°C, the second at 70°C, and the third at 130°C.

11.11. (c)

11.13. The ion–ion bond in $CaSO_4$ is stronger than the ion–ion bond in NaCl because of the higher charges on the cation and anion. For $CaSO_4$ this is greater than the ion–dipole interactions that would occur when Ca^{2+} and $SO_4{}^{2-}$ dissolve, so $CaSO_4$ is not very soluble in water. NaCl has a lower ion–ion bond strength and its ion–dipole interactions with water are strong, so it dissolves in water.

11.15. $CsBr < KBr < SrBr_2$

11.17. MgO will have a higher melting point than LiF.

11.19. The enthalpy of solution ($\Delta H_{solution}$) is the overall change in enthalpy when an ionic solute is dissolved in a polar solvent. This is the sum of the ion–ion interactions between ions, dipole–dipole interaction between solvent molecules, and ion–dipole interactions between the solute and the solvent. The enthalpy of hydration ($\Delta H_{hydration}$) is the energy associated only with the formation of solvated ions. This is the sum of the dipole–dipole interaction between solvent molecules and the ion–dipole interactions between the solute and the solvent. The lattice energy (*U*) is the change in energy when free ions in the gas phase combine to form 1 mole of a solid ionic compound.

11.21. A large negative lattice enthalpy (*U*) means that $\Delta H_{solution}$ is more likely to be positive (because $\Delta H_{solution} = \Delta H_{hydration} - U$). Therefore, it will be less favorable to separate the ions.

11.23. Melting point decreases as the atomic number of X increases.

11.25. (a)

11.27. −723 kJ/mol

11.29. −6.90 × 10^2 kJ/mol

11.31. A nonvolatile solute is a compound that dissolves into a solvent and does not, under conditions to maintain the solution, enter appreciably into the gas phase.

11.33. When the average kinetic energy of the liquid molecules increases, more of the molecules can escape the liquid phase and enter the gas phase. More molecules in the gas phase increases the vapor pressure.

11.35. The vapor pressure of pure ethanol is greater that the vapor pressure of the sugar solution of ethanol. The rate of evaporation will be higher for the pure ethanol. On the other hand the rate of condensation in the beaker containing the sugar solution is higher than the rate of evaporation, so eventually the beaker containing the sugar solution will overflow.

11.37. Mole fraction of water in solution: $X = 0.70$; vapor pressure of solution at 25°C: $P_{\text{solution}} = 17$ torr

11.39.

$$\begin{aligned}
P_{\text{soln}} &= X_{\text{solvent}} \cdot P^\circ_{\text{solvent}} \\
X_{\text{solvent}} + X_{\text{solute}} &= 1 \\
X_{\text{solvent}} &= 1 - X_{\text{solute}} \\
P_{\text{soln}} &= (1 - X_{\text{solute}}) \cdot P^\circ_{\text{solvent}} \\
P_{\text{soln}} &= P^\circ_{\text{solvent}} - P^\circ_{\text{solvent}} \cdot (X_{\text{solute}}) \\
P^\circ_{\text{solvent}} \cdot (X_{\text{solute}}) &= P^\circ_{\text{solvent}} - P_{\text{soln}} \\
X_{\text{solute}} &= \frac{(P^\circ_{\text{solvent}} - P_{\text{soln}})}{P^\circ_{\text{solvent}}}
\end{aligned}$$

11.41. C_5H_{12}

11.43. Both components of the solution are of similar size and both are nonpolar. It is reasonable that the magnitude of the intermolecular forces would be similar and that the solution would behave ideally.

11.45. 18 torr

11.47. (a) The vapor phase would be 54% styrene and 46% ethylbenzene for an ethylbenzene-to-styrene ratio of 27:23; (b) (ii)

11.49. The van ’t Hoff factor is an experimentally determined value and cannot be used to determine the molality (and thus the formula mass) for an ionic solute.

11.51. As the solute of the sap evaporates, the remaining solution becomes more concentrated. This will lower the vapor pressure and raise the boiling point.

11.53. Whereas a molecular compound will not dissociate, an ionic compound may dissociate in the solvent. This dissociation yields two or more particles in solution from one dissolved solute particle. This results in greater changes in the melting and boiling points than for those of a molecular solute that does not dissociate.

11.55. The theoretical value of i for CH_3OH is 1 because methanol is molecular and does not dissociate in a solvent such as water. NaBr has a theoretical value of $i = 2$ because it dissociates into two particles on dissolution (Na^+ and Br^-). K_2SO_4 has a theoretical value of $i = 3$ because it dissociates into three particles on dissolution ($2\ K^+$ and $SO_4{}^{2-}$).

11.57. A semipermeable membrane is a boundary between two solutions through which some molecules may pass but others cannot. Usually small molecules may pass through but large molecules are excluded.

11.59. Solvent flows across a semipermeable membrane from the more dilute solution side to the more concentrated solution side to balance the concentration of solutes on both sides of the membrane.

11.61. Reverse osmosis transfers solvent across a semipermeable membrane from a region of higher solute concentration to a region of lower solute concentration. Because reverse osmosis goes against the natural flow of solvent across the membrane, the key component needed is a pump to apply pressure to the more concentrated side of the membrane. Other components needed include a containment system, piping to introduce and remove the solutions, and a tough semipermeable membrane that can withstand the high pressures needed.

11.63. Because NaCl(aq) exists in solution as $Na^+(aq)$ and $Cl^-(aq)$, we need twice as many moles of dextrose to achieve the same molar concentration.

11.65. (a) 0.21 m; (b) 0.572 m; (c) 0.440 m

11.67. (a) 74.9 g; (b) 31.7 g; (c) 104.6 g

11.69. $6.56 \times 10^{-5} m$ NH_3; $8.7 \times 10^{-6} m$ $NO_2{}^-$; $2.19 \times 10^{-2} m$ $NO_3{}^-$

11.71. 3.80°C

11.73. $2.52 \times 10^{-2} m$

11.75. −1.89°C

11.77. (a) < (b) < (c)

11.79. (a) from side A to side B; (b) from side B to side A; (c) from side A to side B

11.81. (a) 57.5 atm; (b) 0.682 atm; (c) 52.9 atm; (d) 46 atm

11.83. (a) $2.76 \times 10^{-2} M$; (b) $1.11 \times 10^{-3} M$; (c) $1.00 \times 10^{-2} M$

11.85. 1.8 mL

11.87. 1.41 atm

11.89. A cation exchanger can replace dissolved cations with H^+ and an anion exchanger can replace dissolved anions with OH^-.

11.91. (a) 1. $Ag^+(aq) + Cl^-(aq) \rightarrow AgCl(s)$; 2. NR; 3. $Mg^{2+}(aq) + 2\,OH^-(aq) \rightarrow Mg(OH)_2(s)$; (b) reactions 1 and 3

11.93. (a) osmotic pressure increases; (b) freezing point decreases; (c) boiling point increases

11.95. concentrations between 0.014 and 0.022 *M* (or 850–1300 g of hemoglobin/L)

11.97. Molar mass = 164 g/mol; the molecular formula of eugenol is $C_{10}H_{12}O_2$

11.99. Step 1: Sodium metal, Na(*s*), absorbs energy and is sublimated, Na(*g*). Step 2: Energy is added to $Cl_2(g)$ causing the Cl–Cl bond to be broken producing Cl(*g*). Step 3: Energy is added to Na(*g*) causing the loss of an electron and the formation of gas-phase sodium cations, $Na^+(g)$. Step 4: Energy is released as the gas-phase chlorine atom, Cl(*g*), gains an electron to form the gas-phase ion, $Cl^-(g)$. Step 5: Energy is released as the gas-phase ions, Na^+(g) and Cl^-(g), react to form the ionic solid NaCl(*s*).

11.101. yes

11.103. For 0.0935 *m* NH_4Cl, $i = 1.85$; for 0.0378 *m* $(NH_4)_2SO_4$, $i = 2.46$

11.105. 2.3 atm

11.107. 1.26×10^2 g/mol

11.109. Cations:

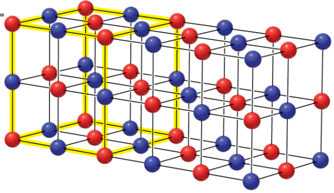
$[Na^+4_{\text{saline}} = [Na^+]_{\text{Ringer's}} + [K^+]_{\text{Ringer's}} + [Ca^{2+}]_{\text{Ringer's}}$; anions: $[C^-]_{\text{saline}} = [Cl^-]_{\text{Ringer's}} +$

[C3H5O3$^-$]Ringer's

Chapter 12

12.1. (b) and (d) are crystalline, (a) and (c) are amorphous

12.3.



The chemical formula is A_4B_4 or AB.

12.5. A_4B_2C

12.7. Li_2S

12.9. empirical formula: NiTi; density: 5.78 g/cm^3

12.11. MgB_2

12.13. (c)

12.15. (a) Hydrogen bonds. (b) Each strand contains amide functional groups. Amides can be formed by a condensation reaction between an amine and a carboxylic acid.

12.17. Cubic closest-packed structures have an *abcabc* . . . pattern, and hexagonal closest-packed structures have an *abab* . . . pattern.

12.19. body-centered cubic

12.21. These structural forms are not allotropes because iron is not molecular.

12.23. 104.2 pm

12.25. 5.3 pm

12.27. (c)

12.29. 1.05 g/cm^3

12.31. 4.50 g/cm^3

12.33. In a substitutional alloy some of the atoms of one lattice are replaced with atoms of another element. One example of a substitutional alloy is bronze, in which up to 30% of the Cu atoms in a copper lattice have been replaced with tin atoms. The tin atoms in this alloy are randomly distributed throughout the lattice occupying any lattice position normally occupied by a copper atom. An interstitial alloy contains solutes in the spaces (or “holes”) between atoms when the solvent lattice forms. One example of an interstitial alloy is austenite, an alloy of carbon in the octahedral holes of the iron fcc lattice.

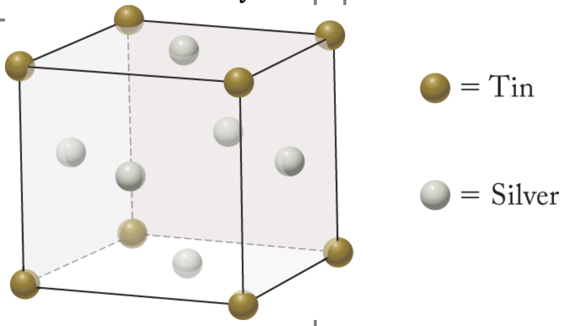
12.35. The edge length will be smaller.

12.37. The significant increase in mass when hafnium is substituted for magnesium will result in an alloy of greater density than that of pure magnesium.

12.39. Yes, both unit cells contain the same ratio of Ni to Ti so both are valid.

12.41. (a) 90 pm; (b) substitutional alloy

12.43. 1. substitutional alloy



2.

12.45. V_2C

12.47. (a) MoW; (b) yes, the heavier tungsten atom is occupying the body center; (c) 14.1 g/cm^3

12.49. (a) a substitutional alloy with a bcc lattice; (b) $CuZn_3$

12.51. Yes, the alloy would be more dense. Tin has a greater molar mass than copper so substituting tin into the unit cell would result in a greater mass.

12.53. K^+ is large and so does not fit well into the octahedral holes of the fcc lattice of the Cl^- ions.

12.55. The radius of Cl^- is 181 pm and the radius of Cs^+ is 170 pm so their radii are very similar. Figure P12.55 shows the Cs^+ occupying the center of the cubic cell, so CsCl could be viewed as a body-centered cubic structure when taking into account the ions’ slight difference in size. The CsCl structure could also be viewed as a simple cubic lattice of Cl^- ions with a Cs^+ in the cubic holes.

12.57. The rock salt structure would not provide the correct ratio of ions for $CaCl_2$.

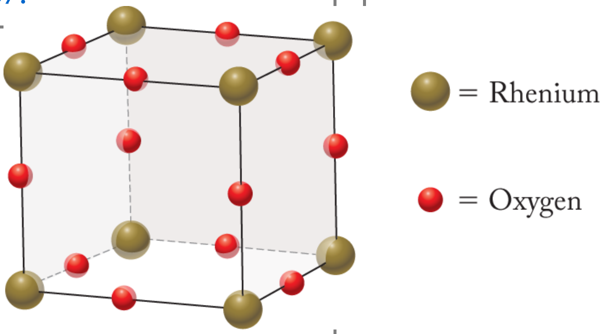
12.59. less than

12.61. MgFe$_2$O$_4$

12.63. (a) octahedral; (b) half

12.65. (a) The rock salt structure is an fcc lattice of anions with cations in the octahedral holes. The cesium chloride structure is a simple cubic lattice of anions with cations in the cubic holes. (b) Both structures have the same ratio of Mg^{2+} to Se^{2-} ions (1:1).

12.67.



5.25 g/cm^3

12.69. 4.1 pm

12.71. The hybridization of the phosphorus atom in black phosphorus is sp^3 with bond angles of 102° to give a puckered ring. In graphene, the carbon atoms are sp^2 hybridized with bond angles of 120° which gives graphene a flat geometry.

12.73. (a) 1.71 g/cm^3; (b) 498.6 pm

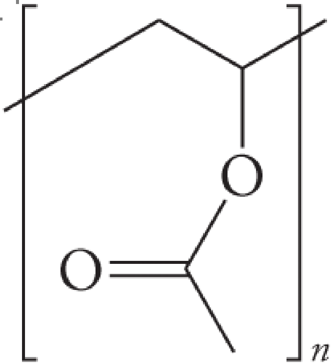
12.75. (a) 3.81 g/cm^3; (b) because of the increased distance between P atoms (238 pm compared to 200 pm if the P atoms are touching along the cell edge), either B or Si could fit into a cubic hole; (c) as both B and Si have fewer valence electrons than P does, these structures would be equivalent to p-type semiconductors.

12.77. Monomers must have appropriate functional groups to react with one another in a polymerization. Provided they have appropriate functional groups, different monomers can react to form a polymer.

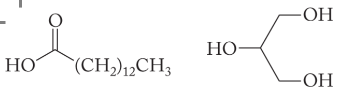
12.79. Polyethylene and $C_{24}H_{50}$ are both composed primarily of long chains of –CH$_2$– groups (with –CH$_3$ groups at the ends of the chains). The difference between the structures is that polyethylene would contain chains of varying lengths and molecular weights, whereas all of the chains in $C_{24}H_{50}$ have the same length and molecular weight.

12.81. 35.1 monomer units

12.83.



12.85.



12.87. a. Polymer I monomers:

$H_2N(CH_2)_8NH_2$ and $HO\overset{O}{\overset{\|}{C}}(CH_2)_8\overset{O}{\overset{\|}{C}}OH$

Polymer II monomers:

$H_2N(CH_2)_6NH_2$ and $HO\overset{O}{\overset{\|}{C}}(CH_2)_{10}\overset{O}{\overset{\|}{C}}OH$

b. Because of the longer chain length between C═O bonds in polymer II, we might expect that this polymer would be more flexible along that portion of the polymer chain.

12.89. (a) HCl; (b) the CO_3 or –OCOO– linkage found in the Lexan structure is what qualifies it as a polycarbonate.

12.91. XYZ_3

12.93. (a) bcc; (b) two phase changes, hcp → bcc → hex (3).

12.95. (a) 2.3×10^5 unit cells/particle; (b) 9.1×10^5 Ag atoms; (c) 8.4×10^{12} Ag particles

12.97. (a) 7.53 g/cm^3; (b) 3.42 g/cm^3; (c) 3.36 g/cm^3

12.99. (a) The sizes of the neutral atoms are Li, 152 pm; and Cl, 99 pm (compared to Li^+, 76 pm; and Cl^-, 181 pm). The cubic unit cell for the neutral atoms would therefore have a shorter edge length of 502 pm (514 pm for the ionic version). Because the masses within the unit cell would be the same, this version of the compound would have a higher density.

(b) 2.23 g/cm^3

12.101.

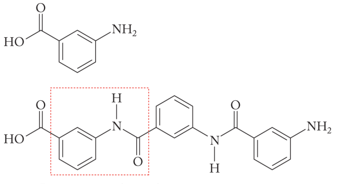
The maximum size of the atomic radius to fit into the tetrahedral hole in P_4 would be 45.1 pm. Hydrogen (37 pm) or helium (32 pm) would be able to fit.

12.103.

A bcc Cu lattice with four corner atoms replaced by Al is consistent with the formula.

12.105.

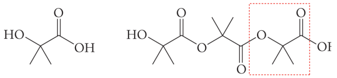
a.



Repeating unit depicted in Problem 12.105(a)

---

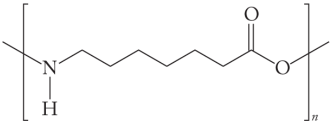
b.



Repeating unit depicte in Problem 12.105(b

12.107.

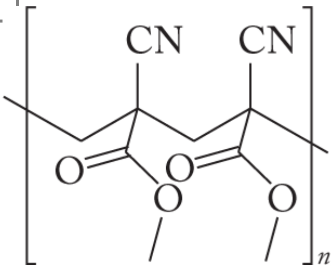
This polymer has one monomeric unit with seven carbon atoms; nylon-6 has a single monomeric unit as well, but it consists of six carbon atoms.



12.109.

Cross-linking increases the strength, hardness, melting (softening) point, and chemical resistance of a polymer.

12.111.



Chapter 13

13.1. $[N_2O]$: green line; $[O_2]$: red line

13.3. (b)

13.5. (d)

13.7. (c)

13.9. (a) 3*; (b) arrow a (red); (c) arrow b (black); (d) arrow c (blue)

13.11. Reaction 2 has the larger slope and therefore the larger activation energy. The rate of reaction 2 will be more sensitive to changes in temperature.

13.13. As the concentration of NO increases in the atmosphere, more NO_2 is generated. This process is not immediate and it results in a decrease in the amount of NO in the atmosphere as it proceeds. The maximum concentration of NO_2 will occur several hours after the maximum concentration of NO is reached as a result of this delay.

13.15. O atoms are more reactive as a result of the incomplete octet and unpaired electrons on each atom.

13.17. nitrogen, N (light blue)

13.19. The rate of a reaction is the overall change in the concentration of reactants and products, whereas the rate constant for a reaction is the proportionality between the rate of the reaction and the concentration of each reactant raised to the order of each reactant.

13.21. Tracking the partial pressure of CH_3CHO, CH_4, or CO. The collected rate data would be the same for all alternatives. A fourth possibility, as there are different numbers of moles of gas on the reactant and product sides of the equation, would be to track changes in the total pressure as the reaction proceeds.

13.23. In solution, ionic compounds can dissociate and mix with one another. As solids, ions from the two reactants are still bound to one another so it is very unlikely that a reaction will occur on any significant scale.

13.25. The rate of formation of B and consumption of A are equal but are opposite in sign.

13.27. decrease

13.29.

$$\text{(a) } \frac{\Delta[N_2]}{\Delta t} = \frac{\Delta[O_2]}{\Delta t}; \text{ (b) } \frac{\Delta[N_2]}{\Delta t} = -\frac{1}{2}\frac{\Delta[NO]}{\Delta t}$$

13.31. $5.8 \times 10^{-6} M/s$

13.33.

$$\text{(a) rate} = \frac{\Delta[CO_2]}{\Delta t} = -\frac{2}{3}\frac{\Delta[CO]}{\Delta t};$$

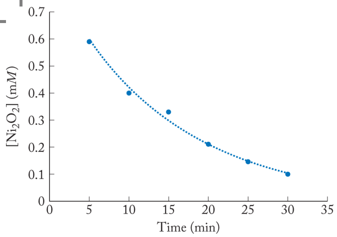
$$\text{(b) rate} = \frac{\Delta[COS]}{\Delta t} = -\frac{\Delta[SO_2]}{\Delta t};$$

$$\text{(c) rate} = \frac{\Delta[CO]}{\Delta t} = 3\frac{\Delta[SO_2]}{\Delta t}$$

13.35. (a) $1.2 \times 10^{7} M/s$; (b) $2.9 \times 10^{4} M/s$

13.37. between 0 and 100 μs: $1.4 \times 10^{-5} M/\mu s$; between 200 and 300 μs: $5.5 \times 10^{-6} M/\mu s$

13.39.



Instantaneous rate changes: at 10 minutes = 3.8 mM/min; at 15 minutes = 2.7 mM/min; at 25 minutes = 1.3 mM/min.

13.41. The concentration of reactants decreases over time so the likelihood of collisions between reactants decreases and the rate of reaction will decrease.

13.43. zero order

13.45. If the $[B]_0 = 50[A]_0$ then even if all of A reacts, the amount and concentration of B will appear unchanged due to the large excess of B. Because [B] is essentially constant in the reaction, it will appear to be part of the rate constant, k, and the rate law will appear to be rate $= k[A]$.

13.47. (a) first order in [A], first order in [B], second order overall; (b) second order in [A], first order in [B], third order overall; (c) first order in [A], second order in [B], third order overall; (d) first order in [A], -1 order in [B], zero order overall

13.49. (a) rate $= k[O][NO_2]$; k units $= M^{-1}\,s^{-1}$; (b) rate $= k[NO]^2[Cl_2]$; k units $= M^{-2}\,s^{-1}$; (c) rate $= k[CHCl_3][Cl_2]^{1/2}$; k units $= M^{-1/2}\,s^{-1}$; (d) rate $= k[O_3]^2[O]^{-1}$; k units $= s^{-1}$

13.51. (a) rate $= k[BrO]$; (b) rate $= k[BrO]^2$; (c) rate $= k[BrO]$; (d) rate = $k[\text{BrO}]^0 = k$

13.53. No; the same behavior would be observed if the reaction were second order in one reactant and zero order in the other.

13.55. (a) rate = $k[\text{NO}_2][\text{O}_3]$; (b) $4.9 \times 10^{-11} M/\text{s}$; (c) $4.9 \times 10^{-11} M/\text{s}$; (d) the rate doubles

13.57. (c)

13.59. rate = $3.4 \times 10^{-5}\ \text{s}^{-1}\ [\text{N}_2\text{O}_5]$

13.61. rate = $k[\text{ClO}_2][\text{OH}^-]$; $k = 14\ M^{-1}\ \text{s}^{-1}$

13.63. rate = $k[\text{NO}]^2[\text{H}_2]$; $k = 6.34\ M^{-2}\ \text{s}^{-1}$

13.65. (a) rate = $k[\text{Ni}_2\text{O}_2]$ (a plot of $\ln[\text{Ni}_2\text{O}_2]$ vs. time is a straight line indicating a first-order reaction); (b) $k = 0.0701\ \text{min}^{-1}$; (c) $t_{½} = 9.89$ min

13.67. (a) $0.0740\ \text{min}^{-1}$; (b) 0.11 (or 11%)

13.69. (a) $k = 4.99 \times 10^{-3}\ \text{min}^{-1}$ (or $8.31 \times 10^{-5}\ \text{s}^{-1}$); (b) 0.616 M

13.71. (a) rate = $k[\text{N}_2\text{O}]$; (b) 4

13.73. (a) rate = $k[^{32}\text{P}]$ and $0.0485\ \text{day}^{-1}$; (b) 14.3 days

13.75. $k = 5.40 \times 10^{-12}\ \text{cm}^3\ \text{molecules}^{-1}\ \text{s}^{-1}$; $t_{1/2} = 0.712$ s

13.77. reverse

13.79. An increase in temperature increases the frequency and the kinetic energy at which the reactants collide. This speeds up the reaction. The order of the reaction is unaffected.

13.81. the reaction with the larger activation energy (150 kJ/mol)

13.83. Lowering the temperature slows the undesired reaction that leads to loss of the aromas.

13.85. E_a 14.5 kJ/mol; $A = 1.74 \times 10^9$

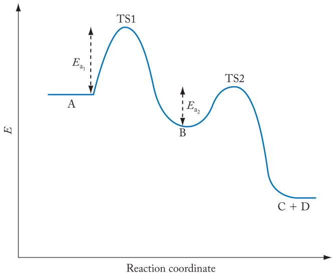
13.87. (a) $E_\text{a} = 314$ kJ/mol; (b) $A = 5.03 \times 10^{10}$; (c) $k = 1.06 \times 10^{-44} M^{-1/2}\ \text{s}^{-1}$

13.89. E_a 39.1 kJ/mol; $A = 1.27 \times 10^{12}$

13.91. Yes, though it doesn’t have to be one step. If a catalyst or intermediate is involved, the reaction could proceed in two or more steps.

13.93. No. If a reactant is zero order, its involvement in the mechanism (collision with other reactants or intermediates) must occur after the rate-determining step.

13.95.

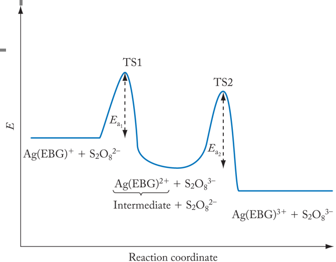


13.97. (a) rate $= k[SO_2Cl_2]$; unimolecular; (b) rate $= k[NO_2][CO]$; bimolecular; (c) rate $= k[NO_2]^2$; bimolecular

13.99. $N_2O_5(g) + O(g) \rightarrow 2\ NO_2(g) + O_2(g)$

13.101. the second step

13.103. (a) The second step is rate determining; (b)



13.105. (b) or (c)

13.107. Yes. Because the rate of the reaction is faster (affecting the rate) and the activation energy is lowered (affecting the value of k), a catalyst affects both the rate of the reaction and the value of the rate constant.

13.109. yes

13.111. no

13.113. NO is the catalyst.

13.115. the reaction of O_3 with Cl

13.117. When the concentration of a reactant (O_2 for the combustion reaction) increases, the rate of the reaction increases.

13.119. The bodily reactions that use O_2 are slower at colder temperatures.

13.121. Yes, we could use other times, not just $t = 0$, as long as the rate of the reverse reaction is still much slower than that of the forward reaction; reactant concentrations would still be used.

13.123. An elementary step with a molecularity of zero would have no molecules colliding.

13.125. 5.2 M/s

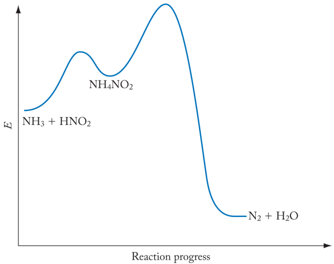
13.127. (a) rate $= k[NH_3][HNO_2]^2$; the units of k are $M^{-2}\,s^{-1}$. (b) step 1: $NH_3(g) + HNO_2(aq) \rightarrow NH_4^+(aq) + NO_2^-(aq)$; for this step $k_1[NH_3][HNO_2] = k2_1[NH_4^+][NO_2^-]$; rearranging:

$$[NH_3][HNO_2] = \frac{k_{-1}}{k_1}[NH_4^+][NO_2^-];$$

plugging into the rate law from part (a): rate $= k[NH_4^+][NO_2^-][HNO_2]$.

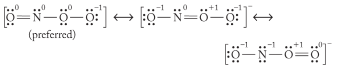
(c) − 482.4 kJ.

(d)



13.129. a. rate $= k[NO][ONOO^-]$; $k = 1.30 \times 10^{-3} M^{-1}\,s^{-1}$

b.



c. − 55 kJ

Chapter 14

14.1.

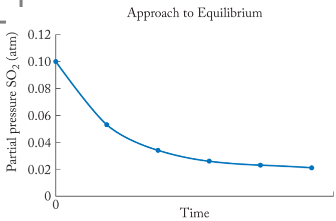
(a) $K_c = \dfrac{[A_3B]^2}{[A_2]^3[B_2]}$; (b) $K_c = 0.87$

14.3. This reaction is not at equilibrium because Q (0.038) ZK. Because $Q < K$, the reaction would shift to the right (product side).

14.5. No, at 20 μs the concentrations of A and B are still changing.

14.7. (a)

14.9.



Because

$$K_c = \frac{1}{P_{SO_2}}$$

, the equilibrium pressure of SO_2 will be 0.02 atm.

14.11.

A graph describing the progress of a reaction to equilibrium will reach a point where the concentrations of the reactants and products do not change over time. Kinetics evaluates the change in concentration of a reactant over time.

14.13.

No. The equilibrium may favor either the products or the reactants depending on the thermodynamic energy difference. The rate at which the reversible reaction occurs does not change the energy of the products or the reactants.

A system is at equilibrium when the rate of the forward reaction equals the rate of the reverse reaction.

14.15.

14.17.

As the reaction approaches equilibrium the reverse reaction (higher rate constant) occurs more rapidly than the forward reaction so more A is formed than B.

14.19.

$2.7 \times 10^{-3} M/s$

14.21.

14.23.

An equilibrium constant expression is defined as the ratio of the concentrations or partial pressures of products to reactants (each term raised to a power equal to the coefficient of that substance in the balanced equation) at equilibrium. The equilibrium constant is the numerical value of the equilibrium constant expression at a particular temperature.

14.25.

When $\Delta n = 0$ (when the number of moles of gaseous products is equal to the number of moles of gaseous reactants).

14.27.

$$\text{(a) } K_c = \frac{[H_2O]^2[Cl_2]^2}{[HCl]^4[O_2]},\ K_p = \frac{{P_{H_2O}}^2{P_{Cl_2}}^2}{{P_{HCl}}^4 P_{O_2}};$$

$$\text{(b) } K_c = \frac{[CH_4][H_2S]^2}{[CS_2][H_2]^4};\ K_p = \frac{P_{CH_4}{P_{H_2S}}^2}{P_{CS_2}{P_{H_2}}^4}$$

14.29.

$$K_p = \frac{P_{SO_2}}{P_S P_{O_2}},\ K_c = \frac{[SO_2]}{[S][O_2]}$$

; $K_p = K_c\,(RT)\,\Delta n$ with $\Delta n = 1 - 2 = -1$ for this reaction.

14.31. 0.068

14.33. 0.50

14.35. 27

14.37. $K_p \neq K_c$ for any of the reactions.

14.39.

$$K_{c,\text{forward}} = \frac{RT}{K_{p,\text{reverse}}}$$

14.41. 0.10

14.43. 0.65

14.45. When scaling the coefficients of a reaction up or down, the new value of the equilibrium constant is the first K raised to the power of the scaling constant. In this case: $K_2 = {K_1}^{1/2}$.

14.47. $K_2 = {K_1}^{1/2}$

14.49. 1.7×10^{-2}

14.51. (a) 0.049; (b) 420; (c) 20

14.53. 1.1×10^{-18}

14.55. The reaction quotient, Q, is for a reaction mixture not necessarily at equilibrium. Only if the system is at equilibrium will Q be equal to K.

14.57. No, $Q < K$ so the reaction proceeds to the right (toward products) to reach equilibrium.

14.59. $Q > K$ so the reaction will proceed to the left (toward reactants).

14.61. The reaction is not at equilibrium. It will proceed to the left (toward reactants).

14.63.

	$K_c = \frac{1}{[O_2]}$
14.65.	$K_c = \frac{1}{[Fe(OH)_2]^4[O_2]}$
14.67. step 1:	$\frac{[CO_3{}^{2-}]}{[CO_2][OH^-]^2}$
	; step 2: $\frac{[OH^-]^2}{[Ca(OH)_2][CO_3{}^{2-}]}$
overall reaction:	; $K_c = \frac{1}{[CO_2][Ca(OH)_2]}$

14.69. No. The relative concentrations of the reactants and products will adjust until they achieve the value of *K*. This value is affected only by temperature.

14.71. As the concentration of O_2 increases, the reaction shifts to the right and the CO on the hemoglobin is displaced.

14.73. According to Le Châtelier's principle, an increase in the partial pressure (or concentration) of O_2 above the water shifts the equilibrium to the right so that more oxygen becomes dissolved in the water. This is consistent with Henry's law.

14.75. (b) and (d)

14.77. (a) Increasing the concentration of the reactant O_3 shifts the equilibrium to the right, increasing the concentration of the product O_2; (b) increasing the concentration of the product O_2 shifts the equilibrium to the left, increasing the concentration of the reactant O_3; (c) decreasing the volume of the reaction to 1/10 its original volume shifts the equilibrium to the left, increasing the concentration of the reactant O_3.

14.79. The equilibrium shifts to the left.

14.81. (b)

14.83. When *K* is small, the amount of reactants that are transformed into products may be so small that at equilibrium the concentrations of the reactants are approximately equal to the initial concentrations. This means we can make an approximation in the *K* expression to make our calculations easier.

14.85. (a) $P_{PCl5} = 0.024$ atm, $P_{PCl3} = 1.036$ atm, $P_{PCl2} = 0.536$ atm; (b) the partial pressure of PCl_3 decreases and the partial pressure of PCl_5 increases.

14.87. $[H_2O] = [Cl_2O] = 3.76 \times 10^{-3} M$, $[HOCl] = 1.13 \times 10^{-3} M$

14.89. 6.9×10^{5}:1

14.91. $P_{CO} = 2.4$ atm; $P_{CO2} = 3.8$ atm

14.93. (a) $P_{NO} = 0.272$ atm, $P_{NO2} = 7.98 \times 10^{-3}$ atm; (b) $P_{total} = 0.416$ atm

14.95. $P_{O2} = 0.17$ atm, $P_{N2} = 0.75$ atm, $P_{NO} = 0.080$ atm

14.97. 5.75 *M*

14.99. $P_{CO} = P_{Cl2} = 0.258$ atm, $P_{COCl2} = 0.00680$ atm

14.101. $[CO] = [H_2O] = 0.031\ M$, $[CO_2] = [H_2] = 0.069\ M$

14.103. The reaction is endothermic; at 1500 K, $K_p = 5.5 \times 10^{-11}$; at 2500 K, $K_p = 4.0 \times 10^{-3}$; and at 3000 K, $K_p = 0.40$. This reaction does not favor products even at very high temperatures so it is not a viable source of CO and is not a remedy to decrease CO_2 as a contributor to global warming. Also, the process produces poisonous CO gas.

14.105. $9 \times 10^{-22} M$

14.107. (a) $P_{SO2} = 9.2 \times 10^{-74}$ (b) 2.63×10^{-47} molecules, so essentially all the SO_2 has been removed from the reaction mixture.

14.109. (a) $K_p = P_{CO2}$ for both reactions; (b) $5\ CaCO_3(s) + 2\ MgCO_3(s) \rightarrow 5\ CaO(s) + 2\ MgO(s) + 7\ CO_2(g)$, $K_p = [CO]^7$; (c) In an open container the gaseous CO_2 can leave the reaction vessel and the reaction can continue to form more products until the reactants run out. In a closed container the CO_2 builds up and an equilibrium could be established limiting the production of the products; (d) No, the value of K_p depends only on the temperature.

Chapter 15

15.1. red line

15.3. the right (smallest) bar

15.5. (a) basic; (b) the amine group (R_2NH)

15.7. Piperidine is the stronger base. The electronegative O atom in morpholine pulls electron density away from the N atom rendering this the less basic molecule. By comparison, piperidine with a $–CH_2–$ group instead of an O atom nearby is a stronger base.

15.9. The electron-withdrawing Cl atoms pull electron density away from the O–H bond leading to greater ionization.

15.11. Water acts as the Brønsted–Lowry acid and LiOH acts as the Brønsted–Lowry base.

15.13. Water acts as the Brønsted–Lowry acid and methylamine acts as the Brønsted–Lowry base.

15.15. (a) HCl is the acid and NaOH is the base; (b) HCl is the acid and $MgCO_3$ is the base; (c) H_2SO_4 is the acid and NH_3 is the base.

15.17. Sulfur is more electronegative than selenium. The higher electronegativity on the sulfur atom stabilizes the anion HSO_4^- more than the anion $HSeO_4^-$.

15.19. The $–CH_3$ group on CH_3NH_2 is electron-donating compared to –H and results in a greater electron density on the N in CH_3NH_2.

15.21. 0.65 *M*

15.23. 0.0410 *M*

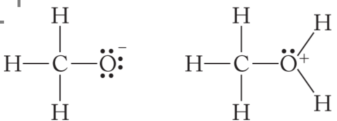
15.25. HF conjugate base: F^-; $HBrO_2$ conjugate base: BrO_2^-; H_2SO_4 conjugate base: HSO_4^-; $HClO_4$ conjugate base: ClO_4^-

15.27. Conjugate acid: H_3PO_4; conjugate base: HPO_4^{2-}

15.29. Because the pH function is a $-\log$ function, as $[H_3O^+]$ increases the value of $-\log[H_3O^+]$ decreases.

15.31. $[H_3O^+]$ must be greater than 1 *M*. One example is 2.5 *M* HCl, which has a pH of -0.40.

15.33.



15.35. (a) pH = 3.62, pOH = 10.38, acidic; (b) pH = 7.26, pOH =

6.74, basic; (c) pH = 12.41, pOH = 1.59, basic; (d) pH = 0, pOH = 14, basic

15.37. (a) $7.7 \times 10^{-4} M$; (b) 0.012 *M*; (c) $1.9 \times 10^{-2} M$; (d) $4.4 \times 10^{-4} M$

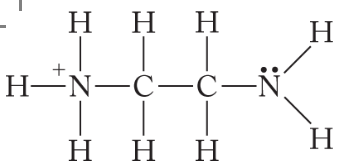
15.39. (a) pH = 0.810, pOH = 13.190; (b) pH = 2.301, pOH = 11.699; (c) pH = 1.903, pOH = 12.097; (d) pH = 1.204, pOH = 12.796

15.41. 7.003

15.43. (a) $HCl > HNO_2 > CH_3COOH > HClO$; (b) $HClO < CH_3COOH < HNO_2 < HCl$

15.45. As a strong acid, HCl completely dissociates in aqueous solution; because HF is a weak acid, it only partially dissociates. The 1.0 *M* HCl solution contains significantly more ions to carry electrical current than does the HF solution.

15.47.



15.49. (a) water; (b) water

15.51. 8.95×10^{-4}

15.53. 1.34%

15.55. 2.3 times

15.57. (a) weaker; (b) 10.86; (c) 1.0×10^{-4}

15.59. (a) 9.73; (b) 9.30

15.61. 9.50

15.63. With each successive ionization it becomes more difficult to remove H^+ from a species that is more negatively charged.

15.65. Ge is less electronegative than C, so even less electron density is pulled away from the acidic proton in H_2GeO_3 than in H_2CO_3 resulting in a lower percent ionization and K_a for H_2GeO_3.

15.67. −0.304

15.69. 2.80

15.71. 10.27

15.73. ammonium nitrate

15.75. The citric acid in the lemon juice neutralizes the volatile trimethylamine to make a nonvolatile dissolved salt.

15.77. 3.77

15.79. 7.35

15.81. (a) $HClO_4$ and CH_3COOH; (b) $Ca(OH)_2$; (c) $HClO_4$ and CH_3COOH; (d) $Ca(OH)_2$ and CH_3NH_2

15.83. Yes, all Arrhenius bases are Brønsted–Lowry bases. No, not all Brønsted–Lowry bases are Arrhenius bases. For example, NH_3 is a Brønsted–Lowry base but not an Arrhenius base.

15.85. In burning S-containing fuels:

$$S_8(s) + 8\,O_2(g) \rightarrow 8\,SO_2(g) \xrightarrow{+4\,O_2(g)} 8\,SO_3(g)$$

In the presence of water these produce a weak acid, H_2SO_3, and a strong acid, H_2SO_4:

$SO_2(g) + H_2O(\ell \rightarrow H_2SO_3(aq)$

$SO_3(g) + H_2O(\ell \rightarrow H_2SO_4(aq)$

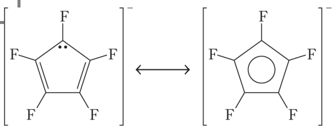
These acids dissolve $CaCO_3$:

$2\,H^+(aq) + CaCO_3(s) \rightarrow H_2CO_3(aq) + Ca^{2+}$

15.87. 1.8×10^9 L

15.89. (a) In water, amines show basic character. They pick up a proton from water to form ammonium cations and OH^-. Therefore dissolving Prozac in water gives a slightly basic solution. (b) The secondary amine (N atom) on Prozac is more likely to react with HCl than is the O atom. (c) The HCl salt of Prozac is more soluble because it is charged, and water molecules form ion–dipole forces around the molecule that are stronger than the dipole–induced dipole forces between the neutral molecule and water.

15.91. (a)

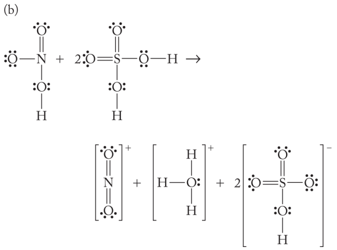


$4n + 2 = 6$ π electrons so this ring is aromatic. (b) C_5F_5H is very acidic because the presence of five very electronegative F atoms on the carbon ring stabilizes the anion formed when the proton is lost.

15.93.

$$\overset{+1}{H}\overset{+5}{N}\overset{-2}{O_3} + 2\,\overset{+1}{H_2}\overset{+6}{S}\overset{-2}{O_4} \rightarrow \overset{+5}{N}\overset{-2}{O_2}{}^+ + \overset{+1}{H_3}\overset{-2}{O}{}^+ + 2\,\overset{+1}{H}\overset{+6}{S}\overset{-2}{O_4}{}^-$$

No oxidation numbers change over the course of this reaction so it is not a redox reaction.



acid = H_2SO_4, conjugate base = HSO_4^-, base = HNO_3 (the –OH group), conjugate acid = H_3O^+

15.95. increase

Chapter 16

16.1. The blue titration curve represents the titration of a 1 *M* solution of strong acid; the red curve represents the titration of a 1 *M* solution of weak acid.

16.3. the indicator with a pK_a of 9.0

16.5. The red titration curve represents the titration of Na_2CO_3; the blue titration curve represents the titration of $NaHCO_3$.

16.7. NH_4Cl is dissolved in the yellow solution, $NaC_2H_3O_2$ is dissolved in the blue solution, and $NH_4C_2H_3O_2$ is dissolved in the light green solution.

16.9. (a) buffer; (b) some of the weak acid, HCOOH, will be converted to conjugate base form, $HCOO^-$.

16.11. A buffer is formed that can resist changes in pH as a result of adding acid or base to the solution. A weak acid can only moderate pH changes when base is added.

16.13. iodoacetic acid–sodium iodoacetate

16.15. The quantity of an external acid or base that can be added to a buffer while maintaining a pH that is ±1 unit from the pK_a of the acid component

16.17. The pH will not change.

16.19. 0.54

16.21. 2.46

16.23. 0.178:1

16.25. 46.3 g of bromoacetic acid and 107 g of sodium bromoacetate

16.27. 2.27 g of dimethylammonium chloride and 21.3 g of dimethylamine

16.29. 9.25

16.31. 53.7 mL

16.33. (a) 3.50; (b) 3.42

16.35. Yes; strong acid–strong base neutralizations generate water and a neutral salt, which would have a pH of 7.

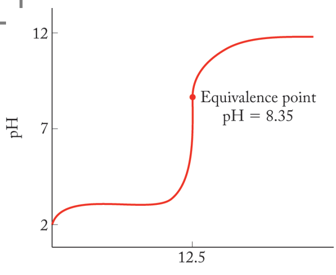
16.37. The end point is a highly visible, colored to colorless transition that occurs at pK_a of 8.8, near the first equivalence point of pH = 8.5.

16.39. 4.44

16.41. After 10.0 mL of OH^- has been added, the pH = 4.75; after 15.0 mL of OH^- has been added, the pH = 5.23; after 20.0 mL of OH^- has been added, the pH = 8.78; after 25.0 mL of OH^- has been added, the pH = 12.10; after 35.0 mL of OH^- has been added, the pH = 12.50.

16.43. (a) 2.945 *M*; (b) no effect

16.45.



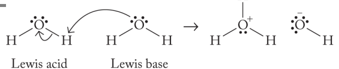
16.47. (a) less than 7; (b) greater than 7; (c) equal to 7

16.49. two equivalence points; phenolphthalein and alizarin yellow R

16.51. No; some Lewis bases donate an electron pair but do not accept a proton while doing so.

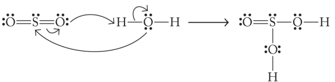
16.53. Yes; Brønsted–Lowry acids donate a proton, meaning that they can also accept an electron pair.

16.55.

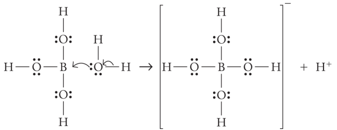


16.57. The sulfur atom in SO_2 and the hydrogen atom in H_2O are acting as Lewis acids while the oxygen atoms in SO_2 and H_2O

are acting as Lewis bases.



16.59. $B(OH)_3$ is the Lewis acid and H_2O is the Lewis base.



16.61. water.

16.63. Ag^+ forms a soluble complex with NH_3 removing Ag^+ from solution and shifting the equilibrium for the dissolution of AgCl to the right.

16.65. $1.25 \times 10^{-10} M$

16.67. $2.48 \times 10^{-13} M$

16.69. (b) and (d)

16.71. The solution will become more acidic.

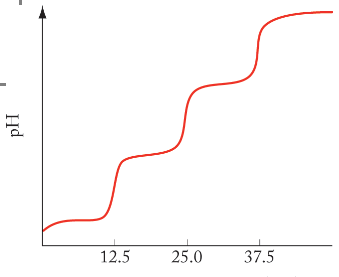
16.73. In basic solution: $Cr(OH)_3(s) + OH^-(aq) \rightleftharpoons Cr(OH)_4{}^-(aq)$; in acidic solution: $Cr(OH)_3(s) + 3\,H^+(aq) \rightleftharpoons Cr^{3+}(aq) + 3\,H_2O(\ell)$

16.75. $Al(OH)_3$ reacts with OH^- in solution to form soluble $Al(OH)_4{}^-$. The other ions do not form this type of soluble complex ion.

16.77. 2.80

16.79. 1.80

16.81.



16.83. Molar solubility is the quantity (moles) of substance that dissolves in a liter of solution. The solubility product is the equilibrium constant for the dissociation of a substance.

16.85. Mg^{2+}

16.87. endothermic

16.89. Acidic substances react with the OH^- released on dissolution of hydroxyapatite. The equilibrium is shifted to the right dissolving more hydroxyapatite.

16.91. 1.08×10^{-10}

16.93. $[Cu^+] = [Cl^-] = 1.01 \times 10^{-3} M$

16.95. 10.151

16.97. (d)

16.99. no

16.101. yes

16.103. (a) $SO_4{}^{2-}$; (b) $1.34 \times 10^{-4} M$

16.105. (a) Because HF is weak, the $[F^-]$ is lower than that of water and so HF reacts with H_2O to form F^- as the major anionic species; (b) $K_{overall} = 1.8 \times 10^{-4}$; (c) pH = 2.01; $[HF_2{}^-]_{eq} = 3.64 \times 10^{-4} M$

16.107. 6.61×10^{-16}

Chapter 17

17.1. The gas in the balloon on the right is under greater pressure and has a greater entropy.

17.3. No. This is a low probability because each gas would then be confined to a smaller volume and would have more order, so this change would involve a decrease in entropy. The tank is an isolated system as long as no heat is transferred through the cylinder wall.

17.5. Entropy would decrease as the system goes from 3 moles of gaseous reactants to 2 moles of gaseous products.

17.7. Entropy would increase as the system goes from 3 moles of gaseous reactants to 7 moles of gaseous products.

17.9. at low temperature

17.11. (a) and (c) are spontaneous because both have a negative value for ΔG_{rxn}. The balanced equations are (a) $2\ C_6H_6(\ell) + 15\ O_2(g) \rightarrow 12\ CO_2(g) + 6\ H_2O(\ell)$ and (c) $2\ H_2(g) + O_2(g) \rightarrow 2\ H_2O(\ell)$.

17.13. There are more microstates available in (b) than in (a).

17.15. They are equal in magnitude but the sign is reversed.

17.17. ΔS_{sys} is positive and ΔS_{surr} is negative.

17.19. (a) and (b)

17.21. ΔS_{sys} is negative and ΔS_{univ} is negative.

17.23. ΔS_{surr} must be less than +66.0 J/K.

17.25. (a) decreases; (b) increases; (c) approximately the same

17.27. (a) $S_8(g)$; (b) $S_2(g)$; (c) $O_3(g)$; $O_2(g)$

17.29. fullerenes

17.31. (a) $CH_4(g) < CF_4(g) < CCl_4(g)$; (b) $CH_2O(g) < CH_3CHO\ (g) < CH_3CH_2CHO(g)$; (c) $HF(g) < H_2O(g) < NH_3(g)$

17.33. positive

17.35. Solids have a lower entropy (are a more ordered phase) than that of particles dissolved in aqueous solution. As a result of the precipitation reaction, fewer particles are present in any phase of the reaction. Both of these factors lead to the ΔS_{rxn} values being less than zero.

17.37. (a) 24.9 J/K; (b) − 146.4 J/K; (c) − 73.2 J/K; (d) − 175.8 J/K

17.39. 5.4 J/(K · mol)

17.41. (c)

17.43. In general, exothermic reactions have a corresponding increase in entropy. Both an increase in entropy and decrease in enthalpy lead to a spontaneous reaction, though now we realize that it is possible for an exothermic reaction to be spontaneous at low temperatures if disfavored by entropy.

17.45. ΔS is positive, ΔH is positive, and ΔG is negative.

17.47. (b) and (d)

17.49. For NaBr, − 18 kJ/mol; for NaI, − 30. kJ/mol

17.51. +91.4 kJ

17.53. +56.5 kJ

17.55. −90.3 kJ

17.57. No; if ΔS_{rxn} were positive then the exothermic reaction would be spontaneous at all temperatures.

17.59. high temperature

17.61. 981.3 K

17.63. $\Delta H^\circ = 51.5$ kJ; $\Delta S^\circ = 123.1$ J/K or 0.1231 kJ/K; 418 K or 145°C

17.65. (a) low temperatures; (b) low temperatures; (c) all temperatures

17.67. positive

17.69. Yes. In a circumstance where the product concentrations are zero, the value of the reaction quotient, Q, will be zero. The equilibrium constant must be larger than zero, so in this circumstance $Q < K$ and this reaction will shift toward the products until it reaches the point where $Q = K$.

17.71. (c)

17.73. 27.1 kJ/mol

17.75. exothermic

17.77. exothermic

17.79. 1.3×10^{-31}

17.81. −115 kJ/mol

17.83. Some of the products of one reaction must be reactants of the second reaction and the overall value of ΔG when the reactions are summed must be negative.

17.85. The bond arrangements are only slightly different between the two structures.

17.87. (a) +50.8 kJ and − 394.4 kJ; (b) $CH_4(g) + O_2(g) \rightarrow 2\ H_2(g) + CO_2(g)$, $\Delta G°_{rxn} = -343.6$ kJ; − spontaneous

17.89. 3.81×10^{-3}

17.91. −73 kJ/mol

17.93. 24

17.95. 4.47×10^{3}

17.97. 83.5 J/(K · mol)

17.99. (a) −90.7 J/(K · mol); (b) a large negative value of ΔH will cause ΔG to be negative (despite the expected negative ΔS) and thus the reaction is spontaneous.

17.101. (c) and (d)

17.103. −1308.4 kJ

17.105. below 386.0 K

17.107. above 896 K

17.109. (a) Cu_2O: copper(I) oxide; CuO: copper(II) oxide; (b) never spontaneous; (c) Cu_2O is more complex than CuO because it has more bonds.

17.111. (a) Trouton's rule predicts that $\Delta S°_{vap}$ for liquids is relatively constant because the change in entropy from liquid to gas should be similar for similar molecules; (b) helium exhibits a lower $\Delta S°_{vap}$ because its intermolecular forces are weak causing more randomness than usual in the liquid phase. Methanol and water deviate because these liquids form hydrogen bonds causing more order in the liquid state.

17.113. (a) ΔH is negative and ΔS is positive. (b) No; the reverse reaction with a positive ΔH and a negative ΔS would never be spontaneous.

Chapter 18

18.1. With careful layering, the electrode in each half-cell is immersed in a solution of its cations. Ions can migrate across the interface between the two solutions, which allows the cell reaction to proceed without a porous bridge.

18.3. Ag is the cathode; Pt in the standard hydrogen electrode (SHE) is the anode; electrons flow from the SHE to Ag.

18.5. blue line

18.7. (a) $2\ H^+(aq) + 2\ e^- \rightarrow H_2(g)$, $E^\circ_{\text{cathode}} = -0.000$ V; $2\ H_2O(\ell) \rightarrow O_2(g) + 4\ H^+(aq) + 4\ e^-$, $E^\circ_{\text{anode}} = 1.229$ V; (b) sulfuric acid increases the conductivity of the solution.

18.9. (a) cathode; (b) chromium forms a protective surface layer of Cr_2O_3, which prevents the metal beneath it from being oxidized

18.11. (b)

18.13. (a) The separator allows the transport of ionic charge carriers that are needed to complete the circuit during the passage of current through an electrochemical cell; (b) the wire would allow electrons to pass, but not ions, and because electrons cannot travel through the solution, the wire would not complete the circuit.

18.15. $Cr_2O_7^{2-}(aq) + 14\ H^+(aq) + 6\ Fe^{2+}(aq) \rightarrow 2\ Cr^{3+}(aq) + 7\ H_2O(\ell) + 6\ Fe^{3+}(aq)$

18.17. (a) cathode: $Ni^{2+}(aq) + 2\ e^- \rightarrow Ni(s)$; anode: $Cd(s) \rightarrow Cd^{2+}(aq) + 2\ e^-$; (b) $Ni^{2+}(aq) + Cd(s) \rightarrow Ni(s) + Cd^{2+}(aq)$; (c) $Cd(s)\ |\ Cd^{2+}(aq)\ ||\ Ni^{2+}(aq)\ |\ Ni(s)$

18.19. (a) cathode: $O_2(g) + 4\ H^+ + 4\ e^- \rightarrow 2\ H_2O(\ell)$; anode: $4\ Li(s) \rightarrow 4\ Li^+(aq) + 4\ e^-$; $H^+(aq)/O_2(g)\ |\ H_2O(\ell)\ ||\ Li^+(aq)\ |\ Li(s)$; (b) cathode: $O_2(g) + 2\ H_2O(\ell) + 4\ e^- \rightarrow 4\ OH^-(aq)$; anode: $4\ Li(s) \rightarrow 4\ Li^+(aq) + 4\ e^-$; $H_2O(\ell)/O_2(g)\ |\ OH^-(aq)\ ||\ Li^+(aq)\ |\ Li(s)$

18.21. (a) For M = Ag or Au: $4\ M(s) + 2\ H_2O(\ell) + O_2(g) \rightarrow 4\ M^+(aq) + 4\ OH^-(aq)$; (b) 4 moles of electrons are transferred

18.23. Cl_2 ($\Delta E^\circ_{\text{red}} = 1.3583$ V) is a better oxidizing agent than O_2 ($\Delta E^\circ_{\text{red}} = 1.229$ V). The higher the reduction potential, the more powerful the oxidizing agent.

18.25. no.

18.27. $O_2(g) + 2\ H_2O(\ell) + 2\ Zn(s) + 4\ OH^-(aq) \rightarrow 2$

$Zn(OH)_4{}^{2-}(aq)$

18.29. (a) less than 1.10 V; (b) Zn

18.31. (a) $NiO(OH)(s) + TiZr_2H(s) \rightarrow TiZr_2(s) + Ni(OH)_2(s)$; (b) 1.32 V

18.33. The negative sign is an indication that the work done by the voltaic cell on its surroundings corresponds to free energy that is lost by the cell.

18.35. −48.3 kJ

18.37. −290 kJ

18.39. −196 kJ

18.41. The platinum electrode transfers electrons to the half-cell; it is inert and not involved in the reaction.

18.43. it requires passing hydrogen gas, which is combustible, across the elctrode surface

18.45. (a) 2.37 V; (b) Mg; (c) $H_2(g)$

18.47. Voltage of a battery is governed by the Nernst equation:

$$E_{\text{cell}} = E^{\circ}_{\text{cell}} - \frac{RT}{nF} \ln Q$$

The logarithmic relationship between E_{cell} and Q means that large changes in the concentrations of products and reactants as the battery discharges produce only small changes E_{cell} (battery voltage).

18.49. (a) 0.130 V; (b) 2.47×10^4

18.51. $E_{\text{rxn}} = 1.55$ V; decrease

18.53. At constant pH the reaction will have a positive E_{cell} (and be spontaneous) until the $[Pb^{2+}]$ reaches $1.5 \times 10^{-6} M$.

18.55. (c) and (f)

18.57. $Al–O_2$

18.59. $Li–MnO_2$

18.61. Teflon is a polymeric material composed of poly(tetrafluoroethylene). Because no metals or ionizable atoms are present in Teflon (the C–F bond is extremely stable), no redox activity is expected. Teflon is also water repellent, which keeps the metal structure drier than it would be with asbestos mats.

18.63. The material must have a more negative standard reduction protential than aluminum. Magnesium or an aluminum–magnesium alloy could serve as a sacrificial anode for aluminum.

18.65. In a voltaic cell the electrons are produced at the anode so a negative (−) charge builds up there; in an electrolytic cell electrons are forced onto the cathode so that it builds up negative (−) charge.

18.67. Br_2

18.69. The student's best choices are Na_2SO_4, H_2SO_4, and Na_2CO_3. Electrolysis of NaBr and NaI solutions may form Br_2 and I_2 at the anodes.

18.71. 27.0 minutes

18.73. (a) 5.78×10^{-3} L; (b) no, because some Cl_2 and Br_2 would be produced

18.75. −0.270 V

18.77. Hybrid vehicles are less expensive, have greater driving ranges between refueling stops, and burn gasoline, which is cheaper and more widely available than hydrogen. However, cars powered by fuel cells and electric motors emit fewer pollutants and convert the chemical energy in their hydrogen fuel to mechanical work more efficiently.

18.79. Electric engines are more efficient, converting more of the energy into motion instead of losing it as heat.

18.81.
$-4\ \ +1\ \ +1\ \ +2\ 0$
(a) $CH_4(g) + H_2O(g) \rightarrow CO(g) + 3\ H_2(g)$;
$+2\ \ +1\ 0\ \ +4$
$CO(g) + H_2O(g) \rightarrow H_2(g) + CO_2(g)$. (b) For the reaction of CH_4 with H_2O, $\Delta G^\circ_{rxn} = 142.2$ kJ/mol; for the reaction of CO with H_2O, $\Delta G^\circ_{rxn} = -28.6$ kJ/mol; and for the overall reaction, $\Delta G^\circ_{overall} = \Delta G^\circ_{rxn1} + \Delta G^\circ_{rxn2} = 113.6$ kJ.

18.83. oxidation of Cr^{3+}

18.85. 0.617 V

18.87. 8.56×10^{19}

18.89. (a) cathode; (b) no, because Mg^{2+} has a lower (less negative) reduction potential than Na^+; (c) no; (d) H_2, Cl_2 and O_2

18.91. (a) −0.87 V; (b) Mo_3S_4: Mo = +2.67; $MgMoS_4$: Mo = +2; (c) Mg^{2+} is added to the electrolyte to better carry the charge in the cell. This cation is produced at the anode and consumed at the cathode.

18.93. 0.067 V

18.95. (a) $Fe(s) + 3\ OH^-(aq) \rightarrow Fe(OH)_3(s) + 3\ e^-$; $O_2(g) + 2\ H_2O(\ell) + 4\ e^- \rightarrow 4\ OH^-(aq)$; (b) 1.176 V; (c) −1484.4 kJ;

1.28 V

18.97. (a) 0.21 V; (b) 1.2×10^7; (c) $[OCl^-] = 1.0 \times 10^{-7} M$ or 0.0051 mg/L

Chapter 19

19.1. (a) purple (lithium); (b) red (radium); (c) red (radium)

19.3. (c)

19.5. (d)

19.7. (c), (d), and (e)

19.9. positive

19.11. The *mass defect* is the difference between the mass of the nucleus of an isotope and the sum of the masses of the individual nuclear particles that make up that isotope. The *binding energy* is the energy released when individual nucleons combine to form the nucleus of an isotope.

19.13. For all nuclides up to iron, the binding energy per nucleon for the reactants is less than that of the products, therefore the products are more stable and energy is released.

19.15. 3.47×10^{-13} J

19.17. 1.09×10^{-12} J

19.19. greater than 1

19.21. Alpha decay increases the neutron-to-proton ratio, which produces less stable isotopes that become more stable through β decay, which decreases the neutron-to-proton ratio.

19.23. Both of these processes are β decay.

19.25. Increasing neutron:proton ratio: $^{25}Al < ^{24}Na < ^{11}B < ^{14}C$; ^{24}Na has the most neutrons.

19.27. (a) ^{64}Ni for ^{64}Cu, ^{89}Y for ^{89}Zr; (b) $^{64}{}_{28}Ni + ^{1}{}_{1}p \rightarrow ^{64}{}_{29}Cu + ^{1}{}_{0}n$; $^{89}{}_{39}Y + ^{1}{}_{1}p \rightarrow ^{89}{}_{40}Zr + ^{1}{}_{0}n$; (c) not necessarily, as long as the decay occurs slowly enough to ensure the desired isotope is present

19.29. (a) electron capture or positron emission; (b) electron capture or positron emission; (c) β decay

19.31. ^{56}Co has 27 protons and 29 neutrons and is neutron-poor; it may undergo electron capture or positron emission. ^{44}Ti has 22 protons and 22 neutrons and is neutron-poor; it may undergo electron capture or positron emission.

19.33. (a) ^{32}Cl, ^{33}Cl, and ^{34}Cl will emit positrons; (b) ^{38}Cl and ^{39}Cl will emit β particles; (c) ^{36}Cl will emit either positrons or β particles.

19.35. The rate of a radioactive decay is dependent only on the amount of the reactant.

19.37. the ability of radioactive particles to ionize atoms

19.39. 0.181 day^{-1}

19.41. 1.1 years

19.43. After 8.762 half-lives (50,000 years), the ratio of ^{14}C present to that originally in an artifact is $N_t/N_0 = 0.50^{8.726} = 0.00236$, or 0.236%. This is too low of a level to detect.

19.45. After 0.00023 half-lives (300,000 years), the ratio of ^{40}K present to that in the original sample is $N_t/N_0 = 0.50^{0.00023} = 0.9998$, or 99.98%. This value represents a decrease of 0.02%, which is the smallest change in ^{40}K activity that can be determined accurately.

19.47. 35%

19.49. The oldest ring would have a 15% lower ^{14}C/^{12}C ratio.

19.51. 36.600 years

19.53. The level of radioactivity is the amount of radioactive particles present in a given instant of time. The dose is the accumulation of exposure over a length of time.

19.55. When radon-222 decays to polonium-218 while in the lungs, it emits an α particle; the ^{218}Po, a reactive solid that is chemically similar to oxygen, lodges in the lung tissue where it continues to emit α radiation. Alpha radiation is one of the most damaging kinds of radiation when in contact with biological tissues. The result of exposure to high levels of radon is an increased risk for lung cancer.

19.57. 5 μSv = 5 μGy; 250 μJ

19.59.

(a) $^{90}_{38}\text{Sr} \rightarrow {}^{0}_{-1}\beta + {}^{90}_{39}\text{Y}$

(c) strontium-90 is more concentrated in milk than in many other foods because it is chemically similar to calcium and milk is rich in calcium.

19.61. (a) 0.115 decays/s; (b) 7.0 × 10^4 atoms

19.63. (a) The half-life should be long enough to effect treatment of the cancerous cells but not so long as to cause damage to healthy tissues; (b) because α radiation does not penetrate far beyond a tumor, the α decay mode is best; (c) products should be nonradioactive, if possible, or have short half-lives and be able to be flushed from the body by normal cellular and biological processes.

19.65. No. Imaging should use isotopes with short half-lives so as to produce a measurable signal and not cause too much damage to cells. Imaging isotopes should produce radiation that can be detected outside of the body (β particles or γ rays). Radionuclides used for cancer treatments can have longer half-lives and produce radiation (such as α particles) that severely damage nearby cells.

19.67. (a) positron emission or electron capture; (b) positron emission or electron capture; (c) positron emission or electron capture

19.69. 74.3 days

19.71. 51%

19.73. 1.6 min

19.75.

(a) $^{10}_{5}\text{B} + {}^{1}_{0}\text{n} \rightarrow {}^{7}_{3}\text{Li} + {}^{4}_{2}\alpha$; (b) 4.42×10^{-13} J; (c) α

(c) α particles have high relative biological effectiveness and they do not penetrate into healthy tissue if the radionuclide is placed inside a tumor.

19.77. Control rods made of boron or cadmium are used to absorb excess neutrons to control the rate of energy release.

19.79. The neutron-to-proton ratio for heavy nuclei is high, and when the nuclide undergoes fission to form smaller nuclides it must emit neutrons because the fission products require a lower neutron-to-proton ratio for stability.

19.81. (a) $^{138}{}_{52}\text{Te}$; (b) $^{133}{}_{51}\text{Sb}$; (c) $^{143}{}_{55}\text{Cs}$

19.83. (a) no; (b) none of the reactions produce neutrons; (c) 1.50×10^{-10} J

Today's Sun has fewer neutrons than the primordial Sun. The

19.85. primordial Sun formed α particles via the fusion of protons and neutrons:

$$2\,^1_1\text{p} + 2\,^1_0\text{n} \rightarrow 2\,^2_1\text{H} \rightarrow ^4_2\text{He}$$

Today's Sun forms α particles via the fusion of two protons:

$$2\,^1_1\text{p} \rightarrow ^2_1\text{H} + \,^0_{+1}\beta$$

$$2\,^2_1\text{H} + 2\,^1_1\text{p} \rightarrow 2\,^3_2\text{He} \rightarrow ^4_2\text{He} + 2\,^1_1\text{p}$$

19.87. (a) 4.37×10^{-12} J; (b) 6.80×10^{-12} J; (c) 2.69×10^{-12} J; (d) 1.60×10^{-12} J

19.89. (a) 7.67×10^{-13} J; (b) -3.96×10^{-13} J

19.91. (a) The annihilation when antihydrogen reacts with hydrogen would release a large amount of energy to power the starship *Enterprise*; hydrogen is an abundant fuel in the universe and therefore could easily be procured to react with any antihydrogen produced in the warp engine. (b) If any of the antimatter fuel came into contact with conventional matter (such as the ship, the crew, or the warp engine), the two would annihilate each other releasing a large quantity of energy in the form of an explosion.

19.93. The energy released in the fusion reaction is $\Delta E = 9.91 \times 10^{-13}$ J/nucleon. The energy released in the fission reaction is $\Delta E = 1.4 \times 10^{-13}$ J/nucleon. On a per-nucleon basis, the fusion reaction generates more energy.

19.95. (a) Geiger counter; (b) 2880 years; (c) ^{241}Am is an α emitter, and α particles do not travel more than a few inches in air and cannot penetrate the first layer of skin.

19.97. (a) $^{249}_{98}\text{Cf} + ^{48}_{20}\text{Ca} \rightarrow ^{294}_{118}\text{Og} + 3\,^1_0\text{n}$; (b) $^{290}_{116}\text{Lv}$; (c) $^{286}_{114}\text{Fl}$; (d) $^{282}_{112}\text{Cn}$; (e) because ^{294}Og is a member of the noble gas family, it should have chemical and physical properties similar to those of radon.

19.99. ^{210}Pb

19.101. (a) $^{64}_{28}\text{Ni} + ^{124}_{50}\text{Sn} \rightarrow ^{188}_{78}\text{Pt}$; (b) $^{196}_{78}\text{Pt}$

19.103. 3.35:1

19.105. (a) $^{40}_{19}\text{K} \rightarrow ^{40}_{18}\text{Ar} + \,^0_{+1}\beta$;

	(b) because the half-life of ^{40}K is so much longer than that of ^{14}C.

Chapter 20

20.1.	 NH₂ N H Adenine O NH NH₂ Guanine O NH O N H Thymine NH₂ N O N H Cytosine
20.3.	(a) palmitic acid; (b) stearic acid
20.5.	Tyrosine, glycine, glycine, phenylalanine, and methionine
20.7.	Trans fats exhibit a type of stereoisomerism around the C□C bond where similar groups on the two carbon atoms are situated on opposite sides of the double bond. Structures (a) and (c) contain trans fats.
20.9.	Sucrose; the difference in the structures is that in sucralose three –OH groups on sucrose have been replaced by Cl atoms. Being derived from sucrose implies that the sugar is natural, but the presence of Cl atoms on sugars is not natural.
20.11.	No. The molecular formulas are different (C_6H_{14} for hexane and C_6H_{12} for cyclohexane).
20.13.	No; the terms *enantiomer* and *optically active* can be used to describe the same chiral molecule, but that molecule would not be *achiral*.
20.15.	Constitutional isomers have the same molecular formula but different bonds to the atoms, possibly even different functional groups. Stereoisomers have the same bonds to each atom but different arrangements of those bonds.
20.17.	Glycine has no chiral carbon centers.
20.19.	sp^3
20.21.	20.23.	(b), (c), (d), and (e)
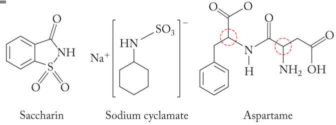
20.25.	With the C□C bond at the end of the carbon chain, a potential rotation about the C□C bond doesn't produce a different stereoisomer. (Another way to look at it: if one of the carbon atoms that are part of the double bond has the same two

groups attached—like 2 H atoms in these examples—there will not be cis and trans isomers.)

20.27. (a) trans, *E*; (b) cis, *Z*

20.29. (a)

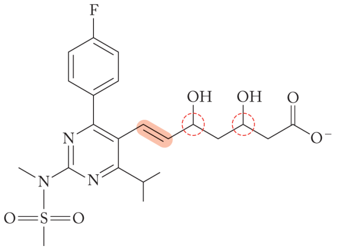
20.31.



Saccharin Sodium cyclamate Aspartame

Neither saccharin nor sodium cyclamate contains a chiral center.

20.33. (a) Yes, there are 2 chiral centers (circled below); (b) yes, in addition to the 2 chiral centers there is a trans double bond (highlighted below).



20.35. decreases

20.37. Both amino acids have acidic, polar side chains, with a C=O bond approximately the same distance from the amine and acid functional groups.

20.39. d- and l- refer to how the four groups on a chiral carbon are oriented.

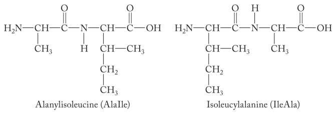
20.41. (a) and (c)

20.43. Most amino acids are zwitterionic at pH < 7.4 because the amino group will be protonated and the carboxylic acid group will be deprotonated, giving $H_2N–CH(R)–COO^{-}$.
+

20.45. hydrogen bonding

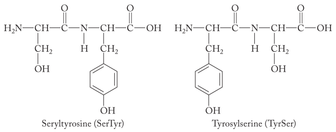
20.47. Lysine contains two amino groups, one of which is on a long carbon tail. This can react with the carboxylic acid on the carbon tail of glutamic acid to form a salt bridge.

20.49. a.



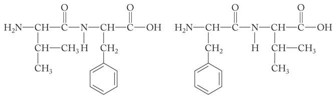
Alanylisoleucine (AlaIle)
Isoleucylalanine (IleAla)

b.



Seryltyrosine (SerTyr)
Tyrosylserine (TyrSer)

c.



Valylphenylalanine (ValPhe)
Phenylalanylvaline (PheVal)

20.51. (a) alanine + glycine; (b) leucine + leucine; (c) tyrosine + phenylalanine

20.53. NH_3

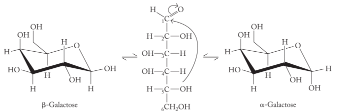
20.55. Starch has α-glycosidic bonds, but cellulose has β-glycosidic bonds. Starch coils into granules, but cellulose forms linear molecules.

20.57. No, they are slightly different because the linear structure has one CjO double bond instead of two ChO single bonds in each of the cyclic structures.

20.59. The bonding in glucose and fructose is nearly the same.

20.61. To calculate the free-energy change for a two-step process, we sum the individual ΔG values for each reaction.

20.63. The position of the hydroxyl group on carbon 1 differs between the α and β forms of galactose. The relative positions of the hydroxyl groups on carbons 2, 3, and 4 are the same on both isomers.



β-Galactose
α-Galactose

20.65. (c)

20.67. (b)

20.69. −16.4 kJ

20.71. Saturated fatty acids have all carbon–carbon single bonds in their structures but unsaturated fatty acids have carbon–carbon double bonds.

20.73. Fatty acids have a high fuel value, and eating sticks of butter affords Arctic explorers more energy per gram of food compared to that of carbohydrates or protein.

20.75. If the two fatty acids linked to the glycerol at C-1 and C-3 are different then, yes, the triglyceride has a chiral center.

20.77. 0.50 kg of α-linolenic acid would consume more hydrogen than would 1.0 kg of oleic acid; (b) no; the hydrogenation product of both species is stearic acid.

20.79.

H
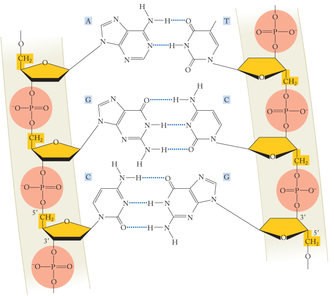
OH
OH

20.87. a. A-G-C

b.



(a) 12; (b) alkene, aldehyde; (c) cis/trans isomerism

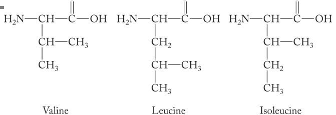
20.89.

20.91. (a) sucrose; (b) esters; (c) $C_{15}H_{31}COOH$

20.93. (a) There is an extra $–CH_2–$ group in homocysteine's sulfur-containing side chain; (b) yes

20.95. yes

20.97.



20.99. glutamic acid, cysteine, and glycine

20.101. Yes, because there is no difference in the number of C—C, C—H, C=O, C—O, or N—H bonds between the two compounds, we expect on the basis of average bond energies that the fuel values of leucine and isoleucine should be identical. Isoleucine might have a lower fuel value because the $–CH_3$ group is close to the $–COOH$ and $–NH_2$ groups, and this difference in shape contributes to the slightly different fuel values.

20.103. 16

20.105. Alanine, aspartic acid, cysteine, glutamic acid, glutamine, glycine, isoleucine, leucine, methionine, phenylalanine, proline, serine, threonine, tryptophan, tyrosine, and valine all have a p*I* value below 7.4 and would be primarily in the zwitterionic form at pH 7.4. Arginine, asparagine, histidine, and lysine have p*I* values above 7.4 and will not reach the zwitterionic form until higher pH values.

20.107. Both molecules have a N atom with a bent shape that has a lone pair of electrons oriented away from the ring it is bound in and an additional N atom located on a flexible chain of carbon atoms.

Chapter 21

21.1. (d)

21.3. group 16 (lavender)

21.5. −6.7 kJ

21.7. trigonal planar

21.9. phosphate

21.11. Without an essential element, biological processes that rely on that element would shut down or deteriorate. If a nonessential element is missing, there would not be severe deleterious effects.

21.13. The main criterion that distinguishes major, trace, and ultratrace essential elements from one another is their concentration in the body. Ultratrace elements are present at < 1 μg/g, trace elements are between 1 and 1000 μg/g, and major elements are present at > 1 mg/g.

21.15. (a) 1.6 ppm; (b) 525 ppm; (c) 0.43 ppm

21.17. (a) oxygen; (b) oxygen; (c) carbon

21.19. The valence electrons for the neutral atoms from groups 1 and 2 reside in *s* sublevels (thus *s*-block elements); the valence electrons for neutral atoms in groups 13–18 reside in *s* and *p* sublevels with the higher-energy electrons being in the *p* sublevel (thus *p*-block elements).

21.21. Li_2O is an ionic compound whereas the bonding in CO is covalent.

21.23. electrical conductivity

21.25. Ca^{2+} is larger than Mg^{2+} and may not fit into the active site of a biomolecule as easily as Be^{2+}, which is smaller than Mg^{2+}.

21.27. K^+

21.29. $Al^{3+} < Mg^{2+} < Li^+ < Cl^-$

21.31. $K < Mg < S < F$

21.33. The two processes are the reverse of one another.

21.35. ion channels, ion pumps, and through diffusion when part of a complex ion

21.37. The hydrophobic interior of the cell membrane makes it difficult to transport charged ions through the cell membrane.

21.39. K^+

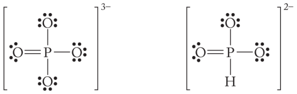
21.41. $CaCO_3$ is more insoluble (less soluble) than $CaSO_4$, which makes calcium carbonate a better structural material. Also, the partial pressure of CO_2 in the atmosphere is higher than that of SO_3.

21.43. 0.56 atm

21.45. 0.072 V

21.47. (a) 0.059 V; (b) 0.34 mol

21.49. a.



Phosphate
oxidation state on P = +5

Phosphite
oxidation state on P = +3

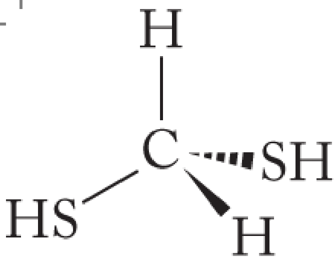
b. Fewer weeds would grow when phosphite fertilizer is used so less herbicide would be needed.

21.51. $^{137}Cs^+$ may substitute for K^+ in cells; as a β emitter with a relatively long half-life, it would lead to an increase in cancer risk.

21.53. ΔS is probably positive (more disorder when solid is dissolved) and ΔH is probably negative (would require breaking bonds).

21.55. The superoxide anion contains an unpaired electron and an incomplete octet on one of the oxygen atoms. This radical will react to complete the octet and pair the electron, which would cause it to be reduced in the process.

21.57. a.



Methanedithiol would have the highest vapor pressure.

b. Vapor pressure would decrease. The presence of oxygen means the resulting molecules would be capable of hydrogen-bonding interactions, which are significantly stronger than the dipole–dipole interactions involving sulfur atoms. The stronger interactions would lead to higher boiling points and lower vapor pressure.

21.59. 3.06

21.61. $K = [OH^-]/[F^-] = 8.48$; the equilibrium lies slightly to the right under standard conditions.

21.63. (a) More soluble; (b) 8.5×10^{-8} mol/L; (c) 1.5×10^{-7} mol/L

21.65. (a) $2.7 \times 10^{-7} M$; (b) no, the solubility corresponds to 56 ppb; (c) $PbCO_3$ will be more soluble in acidic solutions as the CO_3^{2-} ion can be protonated to HCO_3^-, which would shift the solubility equilibrium forward.

21.67. H_2O is the most polar and H_2Te is the least polar.

21.69. We must consider the decay mode to ensure that α emitters are not used inside the body. The γ radiation produced by imaging radionuclides has relatively low energy and can easily escape the body minimizing damage to tissues and organs.

21.71. Because β particles have low charge and relatively small mass, they penetrate tissues better than α particles do. When β particles exit the body, they are imaged on a detector screen to create the image of the organ.

21.73. ^{111}In is proton-rich (or neutron-poor), so electron capture, which changes a proton into a neutron, helps the nucleus become more stable. ^{213}Bi is proton-poor (or neutron-rich), so β decay, which changes a neutron to a proton, helps the nucleus become more stable.

21.75. dispersion forces and dipole–induced dipole interactions

21.77. 41 h

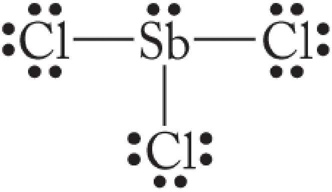
21.79. (a) $Bi^{3+}(aq) + 7\ H_2O(\ell) \rightleftharpoons Bi(H_2O)_5(OH)^{2+}(aq) + H_3O^+(aq)$; (b) pH = 2.5; (c) more acidic than vinegar

21.81. $Al(OH)_3(s) + 3\ H^+(aq) \rightarrow 3\ H_2O(\ell) + Al^{3+}(aq)$

21.83. (a) $Al(OH)_3$; (b) yes; (c) 2.5 g of $Mg(OH)_2$, 2.2 g of $Al(OH)_3$

21.85. a. group 15

b.



c. Lewis base

Chapter 22

22.1. (a) chromium (green) and cobalt (yellow); (b) vanadium (black) and zinc (blue); (c) zinc (blue)

22.3. (d)

22.5. All of the compounds have some ligands that are in cis arrangements and some in trans arrangements.

22.7. flask (a) (orange): $[Co(NH_3)_6]^{3+}$; flask (b) (blue): $[Co(H_2O)_6]^{3+}$; flask (c) (slight yellow/colorless): $[Co(CN)_6]^{3-}$

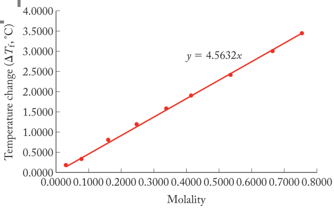
22.9. Max absorption is in the yellow to green portion of the visible light spectrum so the solution should be purple.

22.11. (a) blue: $CoI_4{}^{2-}$; (c) black: $CoCl_4{}^{2-}$

22.13. water molecules

22.15. Iron in the anion is in the Fe^{2+} oxidation state (for an overall charge of − 4 for each complex anion). The iron atoms not in the complex anion are in the Fe^{3+} oxidation state.

22.17.



In the equation of the line, the slope is equal to the van ’t Hoff factor times the freezing-point-depression constant. For an aqueous solution, the freezing-point-depression constant for water is 1.86°C/molal, which would mean the value of the van ’t Hoff factor would be 2.45 for $K_3[Fe(CN)_6]$ indicating there is significant ion-pair formation occurring (an ideal solution of $K_3[Fe(CN)_6]$ would have a van ’t Hoff factor approaching 4).

22.19. $[Pt(NH_3)_6]Cl_4$; $[Pt(NH_3)_5Cl]Cl_3$; $[Pt(NH_3)_4Cl_2]Cl_2$; $[Pt(NH_3)_3Cl_3]Cl$; $[Pt(NH_3)_2Cl_4]$

22.21. $[Pt(NH_3)_6]Cl_4$: hexaammineplatinum(IV) chloride; $[Pt(NH_3)_5Cl]Cl_3$: pentaamminechloroplatinum(IV) chloride; $[Pt(NH_3)_4Cl_2]Cl_2$: tetraamminedichloroplatinum(IV) chloride; $[Pt(NH_3)_3Cl_3]Cl$: triamminetrichloroplatinum(IV) chloride; $[Pt(NH_3)_2Cl_4]$: diamminetetrachloroplatinum(IV)

22.23. (a) hexaamminechromium(III); (b) hexaaquacobalt(III); (c) pentacyanonickelate(II)

22.25. (a) potassium tetrabromocobaltate(II); (b) ammonium aquatrihydroxozincate(II); (c) pentaamminechloroiron(I) dimer

22.27. (a) bis(ethylenediamine)zinc(II) sulfate; (b) pentaammineaquanickel(II) chloride; (c) potassium hexacyanoferrate(II)

22.29. A sequestering agent is a multidentate ligand that separates metal ions from other substances so that they can no longer react. Properties that make a sequestering agent effective include strong bonds formed between the metal and the ligand and large formation constants.

22.31. As pH increases the chelating ability increases because OH^- removes the H atoms on the carboxylic acid groups, providing an additional site for binding to the metal cation.

22.33. The energy difference between *d* orbitals lies within the visible range of the spectrum. For most transition metals, transitions occur between *d* orbitals, and thus these complexes appear colored.

22.35. The repulsions due to the ligands in a square planar crystal field are higher for the d_{xy} orbital than for the d_{xz} and d_{yz} orbitals. The d_{xy} orbital's energy is higher because this orbital lies in the plane of the ligands.

22.37. The yellow solution contains (b) $Cr(NH_3)_6^{3+}$ and the violet solution contains (a) $Cr(H_2O)_6^{3+}$.

22.39. colorless

22.41. $NiCl_4^{2-}$

22.43. Ligand field strength determines whether a complex is high or low spin. Stronger ligand fields induce low-spin arrangements.

22.45. Fe^{2+} has four unpaired electrons; Cu^{2+} has one unpaired electron; Co^{2+} has three unpaired electrons; Mn^{3+} has four unpaired electrons

22.47. For the Fe^{2+} (d^6) to have no unpaired electron in an octahedral crystal field, it would have to be low spin. The change from 298 to 80 K must have caused the compound to transition from high spin to low spin.

22.49. (a) Mn^{4+} in MnO_2, two Mn^{3+} and one Mn^{2+} in Mn_3O_4; (b) both low-spin and high-spin configurations are possible in Mn_3O_4 (d^4 and d^5) but not in MnO_2 (d^3).

22.51. paramagnetic

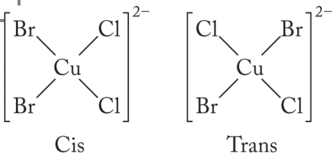
22.53. For an octahedral geometry, *cis*- means that two ligands are side by side and have a 90° bond angle between them. Ligands that are *trans*- to each other have 180° bond angles between them.

22.55. at least two different ligands

yes

22.57.

22.59.



Neither of these isomers is chiral.

22.61. (a) Enzymes catalyze biochemical reactions; (b) no

22.63. Enzymes lower the activation energy.

22.65. much greater than 1

22.67. positive

22.69. 1.59×10^8 times faster

22.71. zero order

22.73. Toxic metals that are sensitive imaging agents may be used at extremely low concentrations such that we could essentially ignore any toxicity. The complex ion could also exhibit different toxicity from that of the metal ion alone. The metal ion might also be taken up preferentially by, for example, cancer cells, thus targeting any damage to unhealthy cells.

22.75. γ radiation

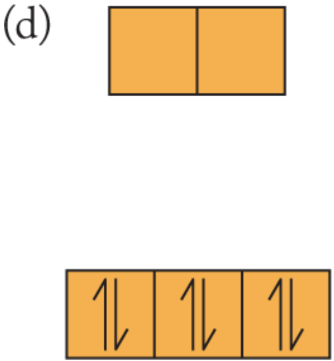
22.77. by binding to the nitrogen atoms in DNA to stop the division of cells

22.79. paramagnetic

22.81. $K = 1130$

22.83. $[\text{penicillamine}]_{eq} = 4.43 \times 10^{-4} M$ and $[\text{cysteine}]_{eq} = 5.6 \times 10^{-4} M$

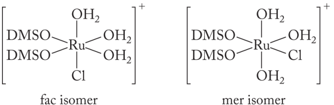
22.85. (a) The ammonia and azide ligands are each cis to one another in one molecule and trans to one another in the other molecule; (b) *cis*-diamminediazidodihydroxyplatinum(IV) and *trans*-diamminediazidodihydroxyplatinum(IV); (c) yes;



22.87. (a) yes; (b) diamagnetic

22.89. a. The yellow complex has larger splitting energy. We can conclude that it contains Co^{3+} due to its having no unpaired electrons.

b.



22.91. Ag^{2+} would be d^9—with an odd number of electrons it will always have one unpaired electron and be paramagnetic. Ag^+ would most likely be $5s^0 4d^{10}$ (instead of $5s^1 4d^9$). With a completely filled *d* shell there would be no unpaired electrons so the ion would be diamagnetic. Ag^{3+} would be d^8. The silver ions in AgO are square planar, which results in the d_{xz}, d_{yz}, d_{z2}, and d_{xy} orbitals being filled and the much higher in energy $d_{x2–y2}$ orbital being empty resulting in all electrons being paired and the ion being diamagnetic.

22.93. a.

Index

Note: Material in figures or tables is indicated by *italic* page numbers. Footnotes are indicated by n after the page number.

A

absolute entropy, 859–61, 862–64, 886

absolute temperature

average kinetic energy of gas molecules and, 244, 245, 247–48

Kelvin scale of, 32, 33–34

pressure of gas and, 226–28

volume of gas and, 223–25

absolute zero (0 K), 33

determined from Charles's law, 225

zero entropy of crystal at, 859–60, 886

absorbance (*A*), 162–63

absorbed dose, 963

acceptor band, 492

accuracy, 27, 28–30

acetaldehyde, in photochemical smog, 651

acetamide, *632*

acetate, at hydrothermal vents, 1030

acetic acid

condensation reaction with ammonia, *632*

converted to methane by bacteria, 304

dimer of, *514*

endothermic reaction with sodium bicarbonate, 853, 854

titration with sodium hydroxide, 818–19

vinegar as solution of, 173–74, 589, 853

as weak acid, 169, 759–60, 771

as weak electrolyte, 164–65

acetone

boiling point, 513

dipole moment, 513

hydrogen bonding with water, 516

acetyl-coenzyme A, 1020, 1025, 1112

acetylene (ethyne), 72

hybrid orbitals in, 467

Lewis structure of, 403

mass spectrum of, 128

torch using, 288

acid rain

chemical weathering caused by, 167–68, 183

on early Earth, 91

nonmetal oxides producing acid in, 168, *169*

sulfur trioxide and, 91, 103, *168*, 783, 1061–62

sulfur-containing fuels and, 103, 783

acid–base equilibria

autoionization of water and, 767–68, 781–82, 786

in blood, 756–57, 792–93

of complex ions, 830–34

conjugate acid–base pairs and, 764–67, 789–90, 806–9

ocean acidification and, 804–6, 841–42

See also K_a; K_b; *pH*

acid–base reactions, 152, 165–71

according to Lewis model, 829

antacid tablets and, 153, 174–75, 1056–57

precipitate formed in, 176, 179

See also acid–base titrations; neutralization reactions

acid–base titrations, 171–75, 818–27

of amino acids, 1004–6

indicators for, 173, 816–17, 818

midpoint of, 821, 823

with multiple equivalence points, 824–27

principal steps of, 818

of strong acid with strong base, 171–72, 818–20 of weak acid with strong base, 173–74, 818–19, 820–22

of weak or strong base with strong acid, 174–75, 823

acidic salts, 788–90, 791–92

acids

Arrhenius concept of, 756

Brønsted–Lowry concept of, 165, 756–57, 764, 765, 789, 827–29, 832–34

carboxylic, *73*, 169, 628–34

formulas of, 69–70, *70*

gastric, 153, 770, 771–72, 1056–57

hydrated metal ions as, 830, 832–34, 838, 1085

ionization reactions of, 758–60

Lewis concept of, 827–30, 1085

naming of, 69–70, *70*

oxoacids, 69–70, *70*, 760–62, 783–87, 832

polyprotic, 169, 783–87

See also amino acids; strong acids; weak acids

acrolein, 445, 472

actinides, 60, 368, 373

activated complex, 676, 681

activation energy (E_a), 674–80

calculation of, 676–78

of catalyzed reaction, 736

of enzyme-catalyzed reaction, 692

for ozone decomposition, 688–89

active site

of biomolecular structure, 446, 473

of enzyme, 692, 1014–15

activity series, 191–93

actual yield, 116–19

addition polymers, 622, *634*

addition reactions, 622

adenine, 1025–29, 1111

adenosine diphosphate (ADP), 882–84, 1054, 1061

adenosine triphosphate (ATP), 882–84

calcium ions and, 1054

conversion between ADP and, 1061

cytochromes and, 1111

in formation of peptide bond, 1006

gastric acid and, 1056

in glucose metabolism, 1014

magnesium ions and, 1054

Na^+–K^+ pumps and, 1052

phosphate ions and, 1061

adenosine-59-phosphosulfate, 1062

adhesive forces, 527–28

adipic acid, *631*, 632

adsorption, by heterogeneous catalyst, 689

aerosol cans, 227–28

air, 214, 215

composition of, *214*

density of, 215

See also atmosphere of Earth

air bags, automobile, 232, 234

airplanes

oxygen generators on, 233–34

oxygen partial pressure outside of, 241

alanine

as chiral compound, 997

titration curve for, 1004

as zwitterion at physiological pH, 1003–4

alcohols, 72, *73*

in ester formation, 628

hydrogen bonding in, 519, 520–21, 528

in polyester formation, 628–30

polymers of, 626–28

viscosity of, 528

water solubility of, 529–30

See also ethanol; methanol

aldehydes, *73*

Lewis structures of, 402

See also acetaldehyde; formaldehyde

alkali metals (group 1), 60, 1049, 1050

bcc unit cells of, *606*, 607

colors in Bunsen burner flames, *366*

hydroxides of, 763, 778–79

alkaline batteries, 909–10

alkaline earth metals (group 2), 60, 1049, 1050

hydroxides of, 763, 778, 779

alkalinity titration, 824–27

alkanes, 71, 313–15

boiling points, *314*, 510–11

isomers of, 991–93

melting points, *314*

nomenclature of, 313

prefixes for naming, *313*

standard molar entropies of, 862

valence bond theory of, 467

alkenes, 71–72

isomers of, 993–95

polymers of, 622–25

valence bond theory of, 467

alkyl hydroperoxides, 1066

alkynes, 72

valence bond theory of, 467

allotropes, 410

of carbon, 620–21

alloys, 604, 612–16

definition of, 612

electrochemical properties, 935–36

interstitial, 614–16

substitutional, 613–14, 615–16

alpha (α) decay, 954

in uranium-238 decay series, 954, 955

alpha (α) particles

biological effects of, 963, *964*, 965

in BNCT for brain tumors, 1072

from breathing radon, 965

early experiments with, 51–53, 959

in Geiger counter, 956

in nuclear fusion, 972–75

from radium, 975

symbols and mass of, *949*

α helix, *1009*, 1011, 1012, 1013

altitude

atmospheric pressure and, 217, 535, 536

partial pressure of oxygen and, 241, 242, 535, 536

alumina, 319–20

aluminum

in $AlGaAs_2$ semiconductors, 492–93

alloys with magnesium, 927

electron configuration of, 366

in human body, 1072

bent (angular) geometry of, 454, 459

boiling point of, 520, 521

boiling-point-elevation constant, *572*, 572–73

corrosion promoted by, 925–27

density changes with temperature, 524, 528–29

distillation of, 281–82

electrolysis of, 905–6

entropy changes in changes of state, 858, 860–61, 861n

freezing-point-depression constant, *572*, 574–75

group 16 dihydrides compared to, 1062–63, *1063*

hard, 587–88

heat capacity of, 290, 291, 293, 294–95, 296

heating curve of, 289–90

heating of, 289–93

hydrated complex ions and, 830, 832–34, 838, 1085, 1093–94, 1098–99, 1104, 1120–21

hydrated ions and, 512, 554–55, 559–61

hydrogen bonding in, 513–15, 521, 526–27, 560 hydrogen bonds with acetone, 516

in hydrolysis reactions, 168, 1060

intermolecular interactions of, 511–12, 526–28

ionizing radiation and, 962, 962n

as Lewis base, 1094

on Mars, 150

melting point of, 524

melting/freezing behavior, 524, 525–26

molecular motion in phases of, 854, *855*

normal boiling point of, 520

origin of life and, 150

partition coefficient between octanol and, 537

phase diagrams for, 523–26, 569–70

phase equilibria of, 869–70

as polar molecule, 459, 511–12

purification of, 10, 281–82, 588

from reaction between hydrogen and oxygen, 8, 272–73, 279

remarkable properties of, 526–29

solubilities in, 531–34

solubility of gases in, 534–37

sp^3 hybrid orbitals in, 464–65

spontaneous phase changes of, 854, 869–70 states of, 14–15

supercritical, 525

swimming pool pH and, 816–17

temporary dipole induced by, *513*

viscosity of, 528

See also aqueous solutions; drinking water; freshwater; ice; seawater

water pollution

cell membranes and, 533

with MTBE, 669

water softening, 587–88

water vapor

from combustion of hydrocarbons, 105–7

of early atmosphere, 88, 90, 150

entropy of, 860–61

gaseous product collected over water and, 242–43

partial pressure of, *242*

reaction with sulfur trioxide, 90, 98–99, 168, 783

See also steam–methane reforming reaction

water–gas shift reaction

achievement of equilibrium in, 711–12

equilibrium constant for, 712–13

equilibrium partial pressure calculation, 739–40

K_p equals K_c for, 718

reaction quotient for, 724–26

removing carbon dioxide to shift equilibrium, 729–30

watt (W), 921

wave functions (c), 354–55

wave mechanics, 354

wave number (1/λ), 346

wavelength (λ), 339–40

de Broglie, 350–52

energy of a quantum and, 342

wave–particle duality, 344–45, 352–53, 354

waves

characteristics of, 339

electromagnetic, 339–40

wax, *314*, 315

weak acids, 169

amides functioning as, 632

buffers based on, 809–10

calculating pH of, 779–80

common examples of, 758–59, *759*

conjugate bases of, 766

definition of, 169

degree of ionization of, 772–75

diprotic, 785–86

ionization reactions in water, 758–59

K_a values of, 773–75, 779–80

oxoacid strength and, 785–86

pH of solution of, 779–80

pH of solution of diprotic acid, 785–86

pH of solution with conjugate base and, 807–8

salt solutions with property of, 791–92

weak bases, 169, 763–64

amines as, 170

ammonia as, 169–70, 763–64, 776, 780–81, 808–9

buffers based on, 810

common examples of, *763*

conjugate acids of, 766

degree of ionization of, 776–78

pH of solution of, 780–81

pH of solution of conjugate acid and, 808–9

salt solutions with property of, 788, 789–91

weak electrolytes, 164–65, 170

weak-link principle, 24–26

weather balloons, 220, 228–29, 230–31

weighted average, 56–57

weighting factor, 56

welding, nitric oxide produced in, 418

Werner, Alfred, 1085–86

wet gas, 242

wetlands, soil color in, 193–94, 195–96

Wilson, Robert W., 35

wind power, 933–34

Wöhler, Friedrich, 65, 89, 991

Wollaston, William Hyde, 337

work

definition of, 273

electrical, 911–12, 920–21

energy and, 8, 273, 852

internal energy and, 283–85

maximum energy available for, 865, 869, 886

pressure–volume (*P*–*V*) work, 284–86, 869

work function (ϕ), 343, 344–45

X

xanthine oxidase, 1111, 1112

xenon, banned for athletes, 1071

xenon difluoride, 488

xenon-129, in magnetic resonance imaging, 1071

X-rays

biological effects of, 962, 964

discovery of, 51, 51n

Y

yellowcake, 969

yield

actual, 116–19

percent, 117–19

theoretical, 114, 115–16

yttrium, 1114

Z

Z isomers, 994

See also cis–trans isomers

zeolites, 588

zero-order reactions, 672–73

half-life of, 673

reaction mechanisms and, 686

summary of how to distinguish, 673–74

Zevalin, 1070

Zewail, Ahmed H., 680n

zinc

band theory and, 491

in brass, 612

in carbonic anhydrase, 1109–10

conductivity of, 491

electron configuration of cation of, 372

redox reaction between copper and, 900–903

in sacrificial anodes, 927

in superoxide dismutase, 1112

zinc hydroxide, 834

zinc sulfide

crystal structure of, 618

in fluorescent paint, 975, 976

zinc–air battery, 910–11

zinc/copper voltaic cell, 901–3

cell diagram of, 903–4

ion concentrations and, 918

standard cell potential of, 908–9, 911, 912

standard free-energy change of, 912

work done by, 911–12

zircon, in dating geological samples, 960

zwitterions, 1003–6
